ETIOLOGIC FACTORS: Sustained systolic pressures greater than 140 mm Hg and diastolic pressures higher than 90 mm Hg define hypertension (see Chapter 16). Mild to moderate hypertension causes typical hypertensive nephrosclerosis, thus belying the previous term, *benign nephrosclerosis.* In fact, hypertensive nephrosclerosis is identified in about 15% of patients with "benign hypertension." Changes like those in hypertensive nephrosclerosis may occur in older individuals who have never had hypertension and are attributed to aging itself.

PATHOLOGY: The kidneys are smaller than normal (atrophic) and are usually affected bilaterally. Renal cortical surfaces are finely granular (Fig. 22-59), but coarser scars are occasionally present. On cut section, the cortex is thinned. Many glomeruli appear normal; others show varying degrees of ischemic change. Initially, glomerular capillaries are broader because of thickening, wrinkling and collapse of GBMs. Cells of the glomerular tuft are progressively lost, and collagen and matrix material are deposited within the Bowman space. Eventually, glomerular tufts are obliterated by a dense, eosinophilic globular scar, all inside the Bowman capsule. Tubular atrophy, due to glomerular obsolescence, is associated with interstitial fibrosis and chronic inflammation. Globally, sclerotic glomeruli and surrounding atrophic tubules are often clustered in focal subcapsular zones, with adjacent areas of preserved glomeruli and tubules (Fig. 22-60), which accounts for the granular surfaces of nephrosclerotic kidneys.

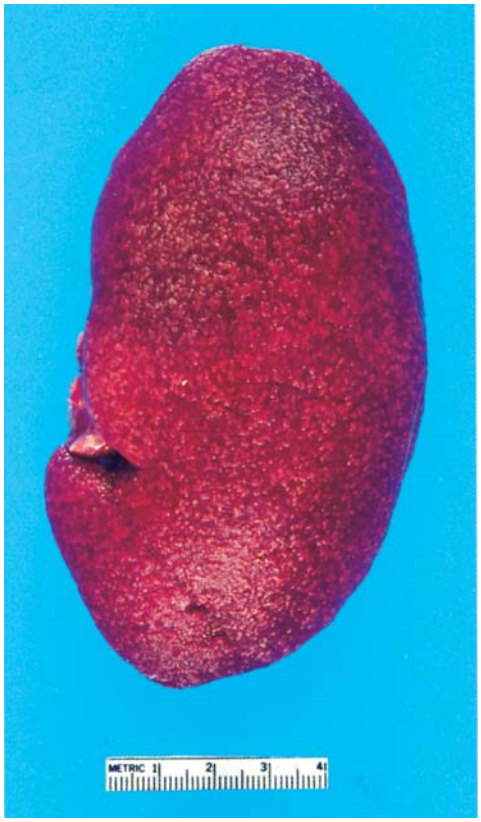

FIGURE 22-59. Hypertensive nephrosclerosis. The kidney is reduced in size, and the cortical surface exhibits fine granularity.

The pattern of change in renal blood vessels depends on vessel size. Intimas of arteries as small as arcuate arteries have fibrotic thickening, replication of the elastica-like lamina and partial replacement of the muscularis with fibrous tissue. Interlobular arteries and arterioles may develop medial hyperplasia. Arterioles show concentric hyaline thickening of the wall, often with smooth muscle cell loss or displacement to the periphery. This arteriolar change is called **hyaline arteriolosclerosis**.

CLINICAL FEATURES: Although hypertensive nephrosclerosis does not usually impair renal function, some people with hypertension develop progressive renal failure, which may lead to ESRD. Since hypertension is so common, the relatively small percentage of hypertensive patients who develop renal insufficiency amounts to 1/3 of patients with ESRD. ***Hypertensive nephrosclerosis is most prevalent and aggressive in blacks, among whom hypertension is the leading cause of ESRD.***

Malignant Hypertensive Nephropathy Causes Rapid Loss of Renal Function

ETIOLOGIC FACTORS: No specific blood pressure defines malignant hypertension, but diastolic pressures greater than 130 mm Hg, retinal vascular changes, papilledema and renal functional impairment are usual criteria. There are prior histories of benign hypertension in 1/2 of patients, and many others have a background of chronic renal injury caused by many different diseases. Occasionally, malignant hypertension arises de novo in apparently healthy people, particularly young black men. The pathogenesis of the vascular injury in malignant hypertension is not entirely clear. One hypothesis proposes that very high blood pressure, combined with microvascular vasoconstriction, causes endothelial injury as blood slams into narrowed small vessels. At such sites, plasma constituents leak into injured arteriolar walls (causing fibrinoid necrosis), into arterial intimas (inducing edematous intimal thickening) and into the subendothelial zone of glomerular capillaries (consolidating glomeruli). At these sites of vascular injury, thrombosis can result in focal renal cortical necrosis (infarcts).

PATHOLOGY: Renal sizes in malignant hypertensive nephropathy vary from small to enlarged, depending on the duration of preexisting benign hypertension. The cut surface is mottled red and yellow,

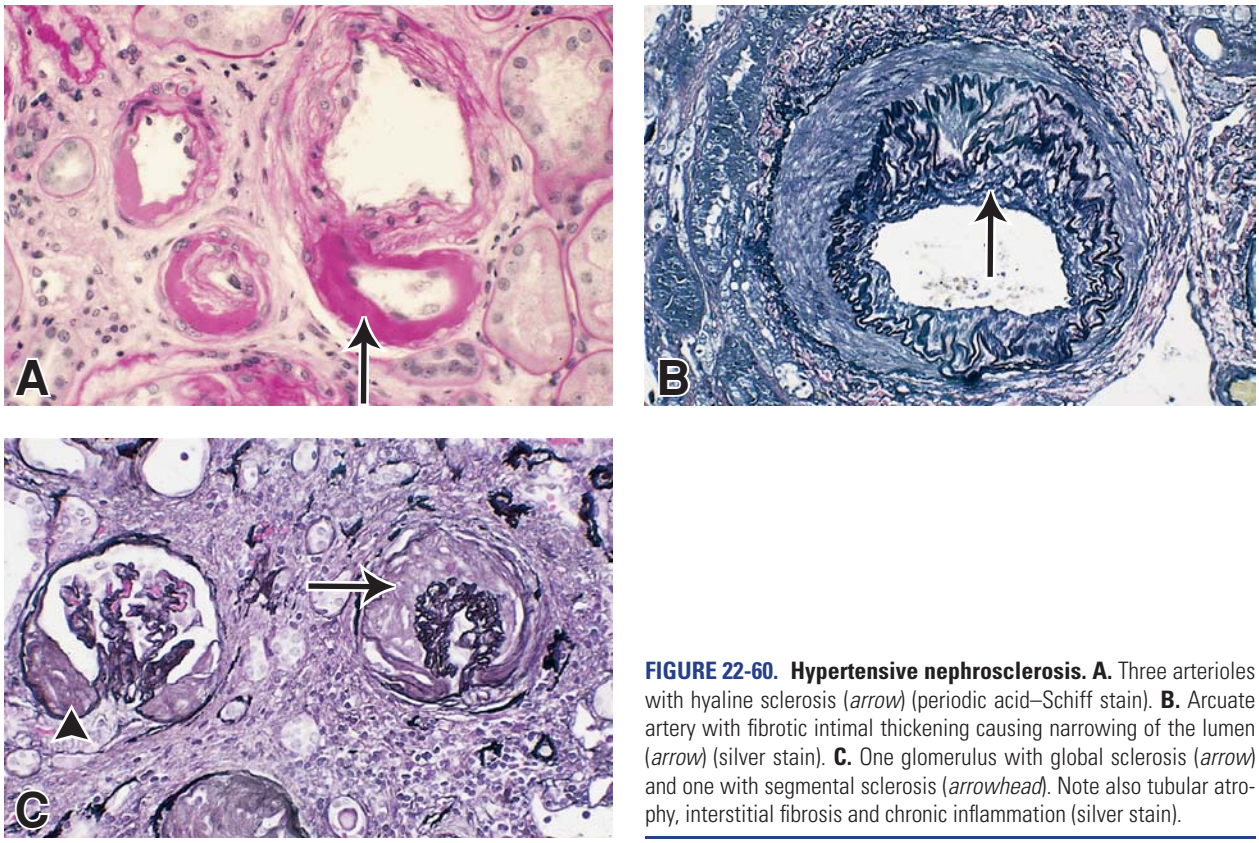

FIGURE 22-60. Hypertensive nephrosclerosis. A. Three arterioles with hyaline sclerosis (*arrow*) (periodic acid–Schiff stain). **B.** Arcuate artery with fibrotic intimal thickening causing narrowing of the lumen (*arrow*) (silver stain). **C.** One glomerulus with global sclerosis (*arrow*) and one with segmental sclerosis (*arrowhead*). Note also tubular atrophy, interstitial fibrosis and chronic inflammation (silver stain).

with occasional small cortical infarcts. Malignant hypertensive nephropathy is often superimposed on hypertensive nephrosclerosis, with edematous (myxoid, mucoid) intimal expansion in arteries and fibrinoid necrosis of arterioles. Glomerular changes vary from capillary congestion to consolidation to necrosis (Fig. 22-61). Severe cases show thrombosis and focal ischemic cortical necrosis (infarction). By electron microscopy, electron-lucent material expands glomerular subendothelial zones. There may be focal insudation of plasma proteins into injured vessel walls. These changes are identical to those seen in other forms of thrombotic microangiopathy (see below).

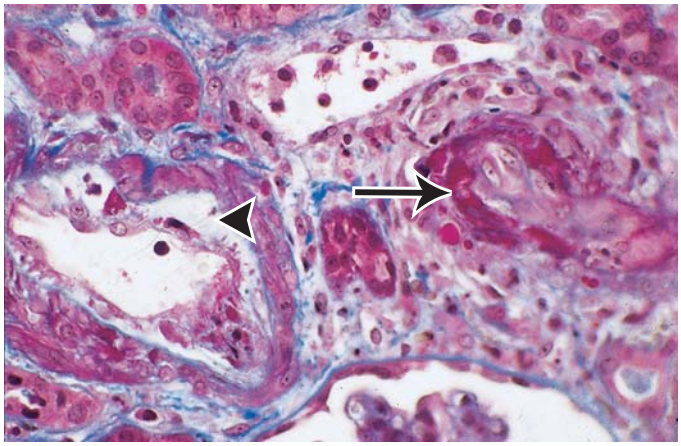

FIGURE 22-61. Malignant hypertensive nephropathy. Red fibrinoid necrosis (*arrow*) in the wall of the arteriole on the right and clear edematous expansion (*arrowhead*) in the intima of the interlobular artery on the left from a patient with malignant hypertension (Masson trichrome stain).

CLINICAL FEATURES: Malignant hypertension is more common in men than in women, typically around the age of 40. Patients suffer headache, dizziness and visual disturbances and may develop overt encephalopathy. Hematuria and proteinuria are frequent. Progressive renal deterioration develops if the condition persists. Aggressive antihypertensive therapy often controls the disease.

Renovascular Hypertension Follows Narrowing of a Major Renal Artery

PATHOPHYSIOLOGY: Stenosis or total occlusion of a main renal artery produces hypertension that is potentially curable if the arterial lumen is restored. Harry Goldblatt carried out the initial studies of this syndrome in dogs in 1934. Since then, a kidney deprived of vascular supply has been known as a **Goldblatt kidney**. In patients with renal artery stenosis, hypertension reflects increased production of renin, angiotensin II and aldosterone. Renal vein renin from an ischemic kidney is elevated, but it is normal in the contralateral kidney. Most (95%) cases are caused by atherosclerosis, which explains why this disorder is twice as common in men as in women, and mainly at older ages (average age, 55). Fibromuscular dysplasia and vasculitis are less common causes overall but are the most frequent causes in children.

PATHOLOGY: Regardless of the cause of renal artery stenosis, renal parenchymal changes are the same. The size of the involved kidney is reduced. Glomeruli appear normal but are closer to each other than normal, because intervening tubules show marked ischemic atrophy without extensive interstitial fibrosis. Many glomeruli lose their attachments to the proximal tubule. Juxtaglomerular apparati are prominent, hyperplastic and more granular than usual, due to greater renin production.

When atherosclerotic plaques cause the vascular stenosis, they impinge on the aortic ostium or narrow the renal artery lumen, more often on the left than on the right. Occasionally, an abdominal aortic aneurysm affects the origin of the renal arteries. Takayasu arteritis and giant cell arteritis cause renal artery stenosis by inflammatory and sclerotic thickening of the artery wall with resultant narrowing of the lumen.

In **fibromuscular dysplasia,** the renal artery becomes fibrous and shows stenosis due to muscular hyperplasia. There are several patterns of renal artery involvement: intimal fibroplasia, medial fibroplasia, perimedial fibroplasia and periarterial fibroplasia. As the names imply, these disorders affect different layers of the artery, from the intima to the adventitia. Medial fibroplasia is the most common and accounts for 2/3 of cases. This process creates areas of medial thickening alternating with areas of atrophy, producing a "string of beads" pattern in angiograms.

CLINICAL FEATURES: Renovascular hypertension is characterized by mild to moderate blood pressure elevations. A bruit may be heard over the renal artery. Diagnosis requires imaging studies, such as angiography. In more than 1/2 of patients, surgical revascularization, angioplasty or nephrectomy cures the hypertension. If the renovascular hypertension is long-standing, the uninvolved kidney may develop hypertensive nephrosclerosis.

Renal Atheroembolism May Complicate Aortic Atherosclerosis

In patients with severe aortic atherosclerosis, atheromatous debris may embolize into the renal arteries and vascular tree as far as glomerular capillaries and cause acute renal failure. This may occur spontaneously or be initiated by trauma, such as angiographic procedures. **Cholesterol clefts** are seen in vessel lumens (Fig. 22-62). Early lesions are surrounded by atheromatous material or thrombus. They may later elicit a foreign body reaction and may stimulate fibrosis in the adjacent vessel wall.

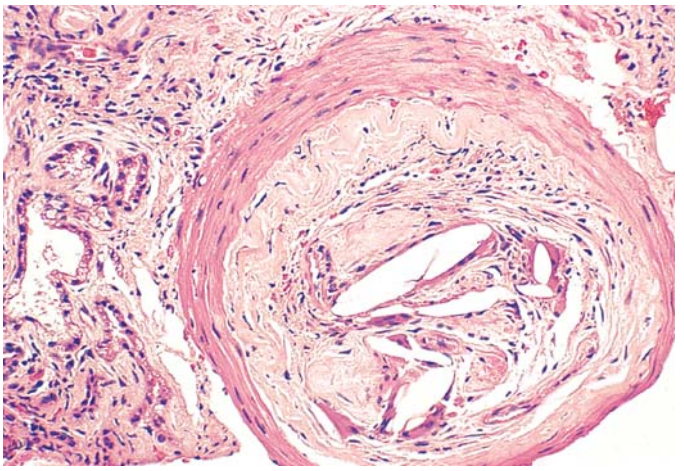

FIGURE 22-62. Atheroembolus. An atheroembolus obstructs an arcuate artery. Note the cholesterol clefts.

Thrombotic Microangiopathies Cause Microangiopathic Hemolytic Anemia and Renal Failure

PATHOPHYSIOLOGY: Thrombotic microangiopathy has a variety of causes and at least two distinct pathogenic pathways. One pathogenic pathway that causes typical and atypical **hemolytic–uremic syndrome (HUS)** produces endothelial damage that allows plasma constituents to enter the intima of arteries, walls of arterioles and subendothelial zone of glomerular capillaries, narrowing vessel lumens and causing ischemia. The injured endothelial surfaces promote thrombosis, which worsens ischemia and may cause focal ischemic necrosis. **Typical HUS** follows diarrhea due to toxin-producing bacteria, most often *E. coli* (usually the O157:H7 strain), in contaminated food. The toxin injures glomerular endothelial cells, initiating the sequence described above. **Atypical HUS** is unrelated to diarrhea and is caused by different mechanisms, including genetic abnormalities in complement regulatory proteins (mostly factor H but also factor I and membrane cofactor protein), autoantibodies to complement regulatory proteins (anti–factor H) or both.

Thrombotic thrombocytopenic purpura (TTP) is caused by a genetic or acquired deficiency of a protease that cleaves multimers of von Willebrand factor on the surface of endothelial cells (see Chapter 26). The large uncleaved multimers promote platelet aggregation and microvascular thrombosis. Passage of blood through vessels injured by HUS or TTP leads to a nonimmune (Coombs-negative) hemolytic anemia, with misshapen and disrupted erythrocytes (schistocytes) and thrombocytopenia. This syndrome is **microangiopathic hemolytic anemia (MAHA)**. Thus, because both HUS and TTP present with MAHA, they can be very difficult to distinguish clinically. Thrombotic microangiopathies that resemble HUS and TTP can also be due to drugs, autoimmune diseases and malignant hypertension (Table 22-10).

PATHOLOGY: The renal pathology of HUS is like that of malignant hypertensive nephropathy (see above), which is a form of thrombotic microangiopathy. The basic renal lesions are:

- Arteriolar fibrinoid necrosis
- Arterial edematous intimal expansion
- Glomerular consolidation, necrosis or congestion
- Vascular platelet-rich thrombosis

Electron microscopy of glomeruli shows electron-lucent expansion of the subendothelial zone (Figs. 22-63, 22-64), due to insudation of plasma proteins under injured endothelial cells. By fluorescence microscopy, fibrin and insudated plasma proteins are seen in injured vessel walls.

TABLE 22-10
CATEGORIES OF THROMBOTIC MICROANGIOPATHY

Thrombotic thrombocytopenic purpura
Autoantibodies against ADAMTS13
Inherited deficiency in ADAMTS13
Typical hemolytic–uremic syndrome
E. coli
Shigella spp.
Pseudomonas spp.
Atypical hemolytic–uremic syndrome
Genetic mutation (e.g., factor H, factor I, membrane cofactor protein)
Autoantibodies to complement regulatory proteins (e.g., anti–factor H)
Drug-induced thrombotic microangiopathies
Mitomycin
Cisplatin
Cyclosporin
Tacrolimus
Anti-VEGF therapy
Autoimmune diseases
Systemic sclerosis (scleroderma)
Systemic lupus erythematosus
Antiphospholipid antibody syndrome
Malignant hypertension
Pregnancy and postpartum factors

VEGF = vascular endothelial growth factor.

TTP may have vascular lesions that resemble HUS, but TTP is characterized by more numerous platelet-rich thrombi in glomerular capillaries as well as in capillaries, arterioles and small arteries in many tissues of the body.

CLINICAL FEATURES: Their clinical presentations and causes allow discrimination among the different categories of thrombotic microangiopathy. The MAHAs all have in common microangiopathic hemolytic anemia, thrombocytopenia, hypertension and renal failure, but to different degrees. In a patient with thrombotic microangiopathy, an accompanying diseases process (e.g., bloody diarrhea, SLE, systemic sclerosis) or treatment (e.g., mitomycin, cisplatin, vascular endothelial growth factor [VEGF] inhibitor) may point to the cause of the MAHA.

Hemolytic–Uremic Syndrome

Typical postdiarrheal HUS features MAHA and acute renal failure, with little or no significant vascular disease outside the kidneys. ***Typical HUS is among the most common causes of acute renal failure in children.*** It is less common in adults. HUS occurs as isolated cases or in epidemics caused by food contaminated with enterohemorrhagic *E. coli.* Patients present with hemorrhagic diarrhea and rapidly progressive renal failure. Even when dialysis is required, normal renal function usually returns within several weeks. However, impaired renal function may eventually reemerge after 15–25 years in in more than 1/2 of patients. Atypical HUS is more frequent in adults and is not preceded by diarrhea. Its prognosis is

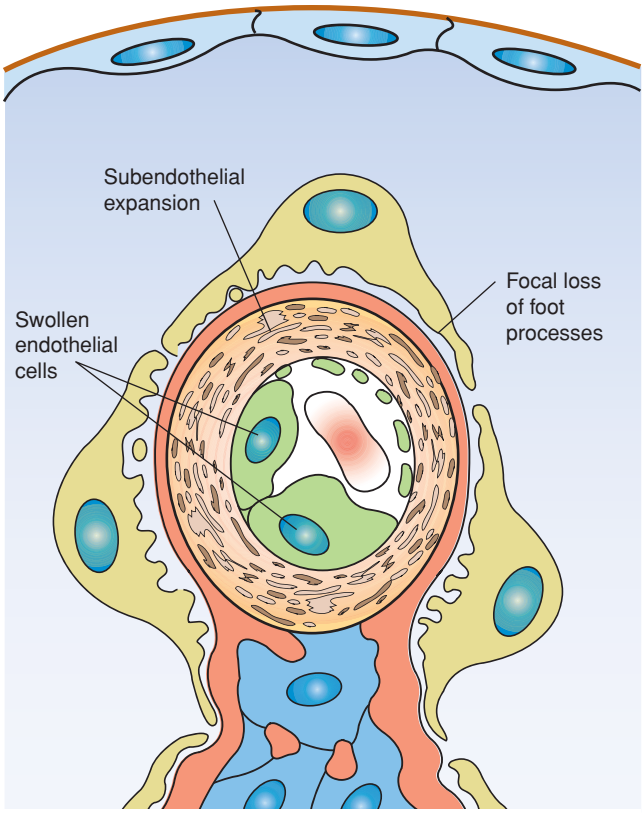

FIGURE 22-63. Hemolytic–uremic syndrome. A wide band of subendothelial expansion due to insudation of plasma proteins causes narrowing of the capillary lumen. Endothelial cell swelling also contributes to narrowing of the lumen.

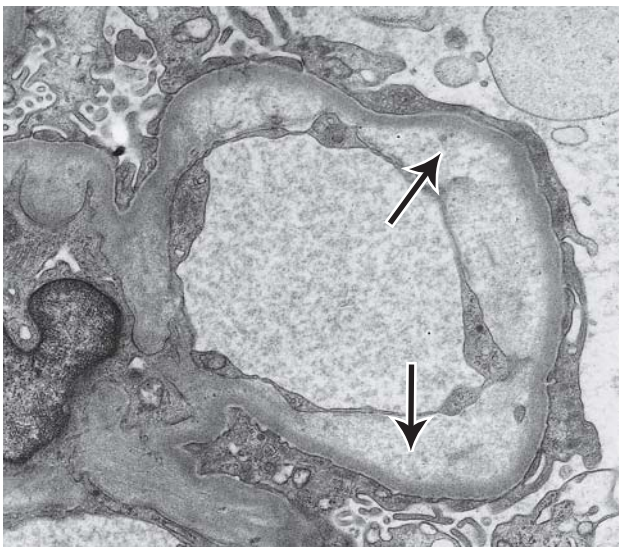

FIGURE 22-64. Thrombotic microangiopathy. An electron micrograph shows a wide band of lucent material in the subendothelial zone (*arrows*) corresponding to the subendothelial expansion shown in Fig. 22-62, which causes marked narrowing of the lumen.

worse than for typical HUS, often with multiple recurrences and more chance of progression to ESRD.

Thrombotic Thrombocytopenic Purpura

In TTP, systemic microvascular thrombosis is characterized clinically by thrombocytopenia, purpura, fever and changes in mental status. Unlike HUS, renal involvement is often absent or less important than other organ disease. Bleeding, caused by the consumptive thrombocytopenia, is also more severe in TTP than it is in HUS. TTP is more common in adults than children. Plasmapheresis and plasma infusion improve outcomes by respectively removing the anti-ADAMTS13 or replacing genetically deficient ADAMTS13 (see Chapter 26).

Hypertension, Proteinuria and Edema Occur in the Third Trimester of Pregnancy in Preeclampsia

If these features are complicated by **convulsions,** the process is called **eclampsia** (see Chapter 14). Glomeruli in preeclampsia are uniformly enlarged and endothelial cells are swollen, resulting in apparently bloodless glomerular tufts (Figs. 22-65, 22-66). Elevated levels in the maternal circulation of antiangiogenic factors released by the placenta may trigger these endothelial changes. By electron microscopy, the swollen endothelial cells contain large, irregular vacuoles. Vacuoles are also present in podocytes. Bed rest and antihypertensive agents suffice to control mild to moderate disease. More severe cases may require induction of delivery. Hypertension and proteinuria typically disappear 1–2 weeks after delivery.

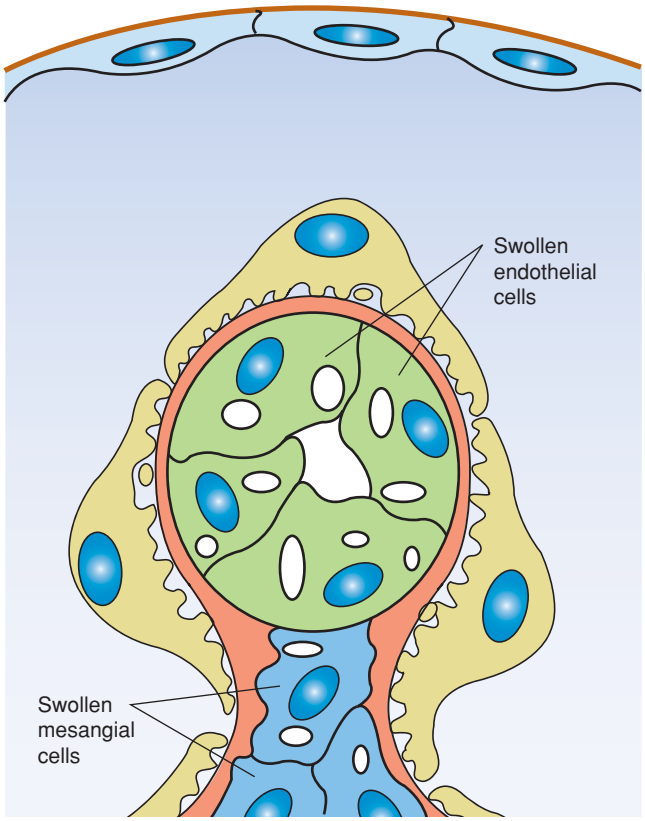

FIGURE 22-65. Preeclamptic nephropathy. Preeclamptic nephropathy, or pregnancy-induced nephropathy, exhibits marked swelling of endothelial cells with narrowing of the lumens. Both endothelial and mesangial cells are enlarged and have multiple vacuoles and vesicular structures.

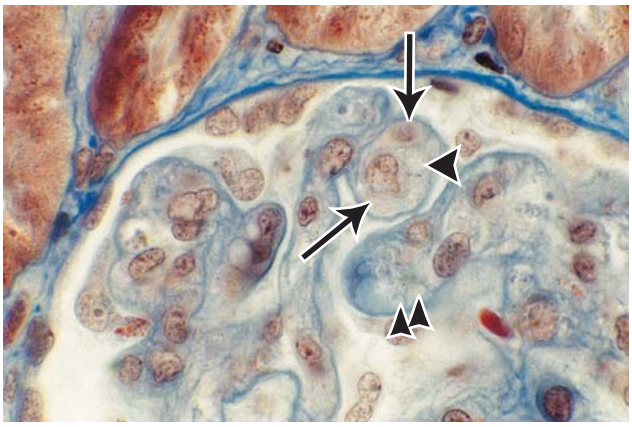

FIGURE 22-66. Preeclampsia. Capillary lumens (*large arrowhead*) are obliterated by swollen endothelial cells (*arrows*). Mesangial vacuolization is shown (*small double arrowheads*) (Masson trichrome stain).

Nephropathy Is the Most Common Organ Manifestation of Sickle Cell Disease

The interstitial tissue in which the vasa recta course is hypertonic and has a low oxygen tension. As a result, in sickle cell patients, erythrocytes tend to sickle as they go through the vasa recta. In so doing, they occlude the vascular lumens and cause infarcts in the medulla and papilla. The latter may be severe enough to cause papillary necrosis. Ischemic scarring of the medulla leads to focal tubular loss and atrophy. Glomeruli are conspicuously congested with sickled cells. FSGS or, less often, MPGN occurs in a minority of patients and may cause nephrotic syndrome.

Renal Infarcts Are Mostly Due to Embolic Arterial Obstruction

Such emboli most often involve interlobar or arcuate arteries.

ETIOLOGIC FACTORS: The size of the infarct varies with the size of the occluded vessel. Common sources of emboli include:

- **Mural thrombi** overlying myocardial infarcts or caused by atrial fibrillation
- **Infected valves** in bacterial endocarditis
- **Complicated atherosclerotic plaques** in the aorta

Occasionally, a branch of the renal artery is occluded by thrombosis superimposed on underlying atherosclerosis or arteritis. Lumens of the small branches of the renal artery may be so severely compromised in malignant hypertension, scleroderma or HUS that blood supply is insufficient to maintain tissue viability. Sickled erythrocytes in sickle cell anemia may cause renal infarcts, especially in the papillae, as noted above. Hemorrhagic renal infarction due to renal vein thrombosis may complicate severe dehydration, particularly in small infants, but also occurs in adults with septic thrombophlebitis and conditions associated with

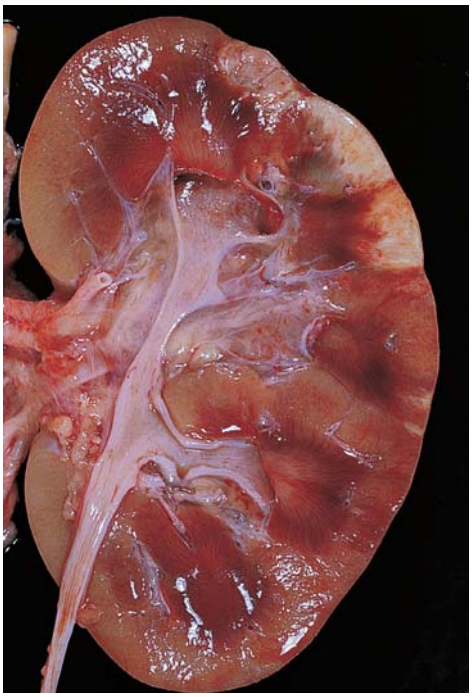

FIGURE 22-67. Renal infarcts. A bisected kidney shows three discrete areas of infarction characterized by marked pallor, which extends to the subcapsular surface.

hypercoagulability. Typically, an acute infarct causes sharp flank or abdominal pain and hematuria.

Infarction of an entire kidney by occlusion of the main renal artery is rare because collateral circulation generally maintains organ viability. Clearly, in such a circumstance, renal function ceases in that kidney.

PATHOLOGY: Variably sized, wedge-shaped areas of pale ischemic necrosis, with the base on the capsular surface, are typical (Fig. 22-67). All structures in affected zones show coagulative necrosis. A hemorrhagic zone borders acute infarcts. As in other tissues, the histologic response to the infarct progresses through phases of acute inflammation, granulation tissue and fibrosis. Healed infarcts are sharply circumscribed and depressed cortical scars containing ghosts of obliterated glomeruli, atrophic tubules, interstitial fibrosis and a mild chronic inflammatory infiltrate. Old infarcts may undergo dystrophic calcification. At the margins of a healed infarct, the viable tissue resembles that seen in chronic ischemia, with tubular atrophy, interstitial fibrosis and infiltration by chronic inflammatory cells.

Cortical Necrosis Is Due to Severe Ischemia

Cortical necrosis affects all or part of the renal cortex. The term **infarct** applies if there is one area (or a few areas) of necrosis caused by arterial occlusion, but **cortical necrosis** implies more-widespread ischemic necrosis.

ETIOLOGIC FACTORS: Renal cortical necrosis can complicate any condition associated with hypovolemic or endotoxic shock, the classical situation being premature placental separation late in pregnancy (see Chapter 12). All forms of shock can result in reversible prerenal or intrarenal ischemia, which can precede irreversible cortical necrosis.

Vasa recta that supply arterial blood to the medulla arise from juxtamedullary efferent arterioles, proximal to vessels supplying the outer cortex. Thus, occlusion of outer cortical vessels (e.g., by vasospasm, thrombi or thrombotic microangiopathy) leads to cortical necrosis and spares the medulla. Experimentally, renal cortical necrosis may be caused by vasoconstrictors such as vasopressin and serotonin, or by eliciting disseminated intravascular coagulation (see Chapter 26).

PATHOLOGY: Cortical necrosis may vary from patchy to confluent (Fig. 22-68). In the most severely involved areas, all parenchymal elements exhibit coagulative necrosis. The proximal convoluted tubules are invariably necrotic, as are most of the distal tubules. In adjacent viable portions of the cortex, glomeruli and distal convoluted tubules are usually unaffected, but many proximal convoluted tubules may show ischemic injury, such as epithelial flattening or necrosis.

With extensive necrosis, the cortex is pale and diffusely necrotic, except for thin rims of viable tissue just beneath the capsule and at the corticomedullary junction. These are supplied by capsular and medullary collateral blood vessels, respectively. Patients who survive cortical necrosis may develop dystrophic calcification of the necrotic areas.

CLINICAL FEATURES: Severe cortical necrosis manifests as acute renal failure, which initially may be indistinguishable from that produced by acute

FIGURE 22-68. Renal cortical necrosis. The cortex of the kidney is pale yellow and soft owing to diffuse cortical necrosis.

tubular necrosis (ATN). However, the former is more often irreversible. A renal arteriogram or biopsy may be required for diagnosis. Recovery is determined by the extent of the disease, but hypertension is common among survivors.

DISEASES OF TUBULES AND INTERSTITIUM

Acute kidney injury (AKI) is an acute rise in serum creatinine. It is classified as **prerenal** if caused by reduced blood flow to the kidneys, **intrarenal** if due to injury to the renal parenchyma and **postrenal** if caused by urinary tract obstruction. Intrarenal AKI is further categorized by the portion of the kidney that is mainly injured: **glomeruli** (e.g., acute glomerulonephritis), **vessels** (e.g., thrombotic microangiopathy), **tubules** (e.g., ischemic acute tubular injury) or **interstitium** (acute tubulointerstitial nephritis). ***The most common cause for intrarenal AKI is ischemic acute tubular injury.***

Acute Ischemic and Nephrotoxic Acute Tubular Injury Commonly Cause AKI

Ischemic AKI is severe, but potentially reversible, renal failure due to impaired tubular epithelial function caused by ischemia or toxic injury. Ischemic prerenal AKI is reversible pathophysiologic AKI with no structural tubular epithelial changes. ***If ischemia is severe enough to cause histologic tubular epithelial injury, it is considered intrarenal ischemic AKI.*** Extensive ischemia can cause overt necrosis of tubular epithelium, or **ATN**. However, most ischemic acute tubular injury does not produce widespread tubular epithelial necrosis, and thus in this setting, the term *ATN* would be a misnomer.

PATHOPHYSIOLOGY AND ETIOLOGIC FACTORS: Table 22-11 lists some causes of AKI due to acute tubular injury.

Ischemic acute tubular injury results from reduced renal perfusion, usually associated with hypotension. Tubular epithelial cells have a high metabolic rate and thus are particularly sensitive to oxygen deprivation, which rapidly depletes intracellular ATP. The most frequent histologic abnormality is flattening (simplification) of tubular epithelial cells due to sloughing of the apical cytoplasm into the urine. This generates granular pigmented casts that can be seen in the urine and detected by urinalysis. Tubular epithelial cells may be simplified (flattened) but not necrotic in some patients with typical clinical ischemic AKI. Overt necrosis is less common.

Nephrotoxic acute tubular injury is caused by chemical injury to epithelial cells. In addition to their sensitivity to ischemia, tubular epithelial cells' high needs makes them susceptible to injury by toxins that perturb oxidative or other metabolic pathways. At the same time, these cells absorb and concentrate toxins. Hemoglobin and myoglobin act as endogenous toxins that can induce acute tubular injury **(pigment nephropathy)** if they are present at high concentrations in the urine.

TABLE 22-11
CAUSES OF ACUTE ACUTE TUBULAR INJURY

Ischemic Prerenal Acute Renal Failure or Ischemic Acute Kidney Injury
Massive hemorrhage
Septic shock
Severe burns
Dehydration
Prolonged diarrhea
Congestive heart failure
Volume redistribution (e.g., pancreatitis, peritonitis)
Nephrotoxin Acute Tubular Injury
Antibiotics (e.g., aminoglycosides, amphotericin B)
Radiographic contrast agents
Heavy metals (e.g., mercury, lead, cisplatin)
Organic solvents (e.g., ethylene glycol, carbon tetrachloride)
Poisons (e.g., paraquat)
Heme Protein Cast Nephropathies
Myoglobin (from rhabdomyolysis, e.g., with crush injury)
Hemoglobin (from hemolysis, e.g., with transfusion reaction)

The pathophysiology of ischemic AKI involves decreased glomerular filtration and tubular epithelial dysfunction due to some or all of the following (Fig. 22-69):

- Intrarenal vasoconstriction
- Alteration of arteriolar tone by tubuloglomerular feedback
- Decreased glomerular hydrostatic pressure
- Decreased glomerular capillary permeability (K_f)
- Tubular obstruction by cellular debris, with increased hydrostatic pressure
- Back-leakage of glomerular filtrate into the interstitium through damaged tubular epithelium

PATHOLOGY: In ischemic AKI, kidneys are swollen, with a pale cortex and a congested medulla. Glomeruli and blood vessels are normal. Tubule injury is focal and is most pronounced in the proximal tubules and thick ascending limb of the loop of Henle of the outer medulla. The epithelium is flattened, lumens are dilated and brush borders are lost (epithelial simplification), due in part to sloughing of apical cytoplasm, which appears in distal tubular lumens and urine as brown granular casts. (The color reflects renal cytochrome pigments.) Electron microscopy shows decreased basolateral membrane infoldings of proximal tubular epithelial cells. Widespread necrosis of tubular epithelial cells is uncommon, but simplification may be evident. Instead, "necrosis" is subtle and appears as individual necrotic cells in some proximal or distal tubules. These single necrotic cells, plus a few viable cells, are shed into the tubular lumen, thus focally denuding the tubular basement membrane (Fig. 22-70). Interstitial edema is common. The vasa recta of the outer medulla are congested and

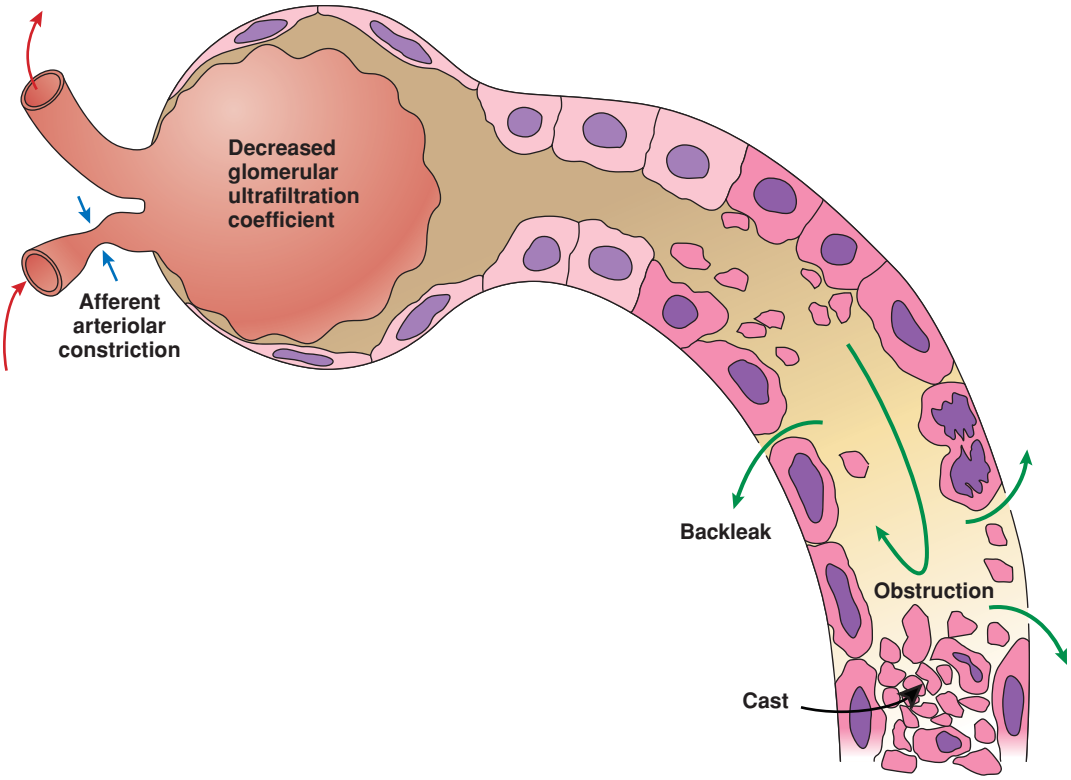

FIGURE 22-69. Pathogenesis of acute renal failure caused by acute tubular injury (acute tubular necrosis). Sloughing and necrosis of epithelial cells result in cast formation. Casts lead to obstruction and increased intraluminal pressure, which reduces glomerular filtration. Afferent arteriolar vasoconstriction, caused in part by tubuloglomerular feedback, results in decreased glomerular capillary filtration pressure. Tubular injury and increased intraluminal pressure cause fluid back-leakage from the lumen into the interstitium.

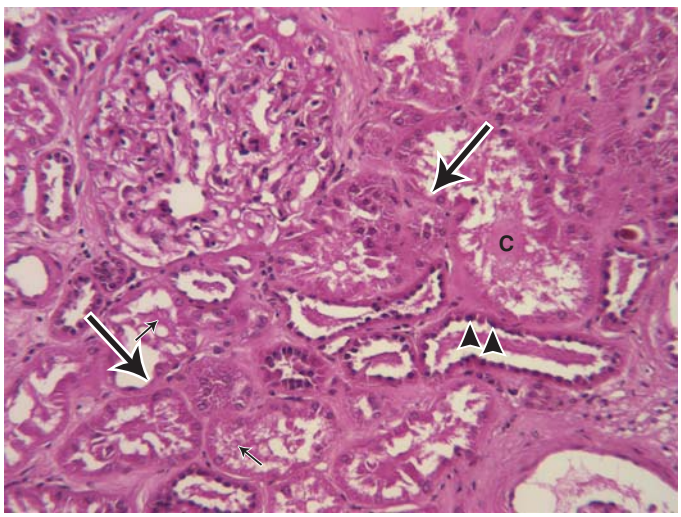

FIGURE 22-70. Ischemic acute tubular injury (ischemic acute kidney injury). Necrosis of individual tubular epithelial cells is evident both from focal denudation of the tubular basement membrane (*thick arrows*) and from the individual necrotic epithelial cells (*thin arrows*) present in some tubular lumina. Casts, the debris of dead tubular epithelium, fill many tubules (*C*). Some enlarged, regenerative-appearing epithelial cells are also present (*arrowheads*). Note the lack of significant glomerular or interstitial inflammation.

often contain nucleated cells, which are predominantly mononuclear leukocytes.

Toxic acute tubular injury shows more-extensive tubular epithelial necrosis than is typical for ischemic acute tubular injury (compare Figs. 22-70 and 22-71). However, toxic necrosis is largely limited to those tubular segments that are most sensitive to a particular toxin, usually the proximal tubule. In acute tubular injury due to hemoglobinuria or myoglobinuria, there are, as well, many red-brown tubular casts that are colored by heme pigments.

During the recovery phase of acute tubular injury, tubular epithelium regenerates, with mitoses, increased size of cells and nuclei, and cell crowding. Survivors eventually display complete restoration of normal renal architecture.

CLINICAL FEATURES: ***Ischemia is the leading cause of AKI.*** Rapidly rising serum creatinine, usually with decreased urine output **(oliguria),** is characteristic. **Nonoliguric** AKI is less common. Urinalysis shows degenerating epithelial cells and **"dirty brown" granular casts** (acute renal failure casts) with cell debris rich in cytochrome pigments. Urinalysis may help to differentiate among the three major intrinsic renal diseases that cause acute renal failure (Table 22-12). Prerenal ischemic acute tubular injury typically has a less than 1% fractional excretion of sodium, but intrarenal acute tubular injury has a fractional excretion of sodium greater than 2%, which is a marker of overt tubular epithelial damage.

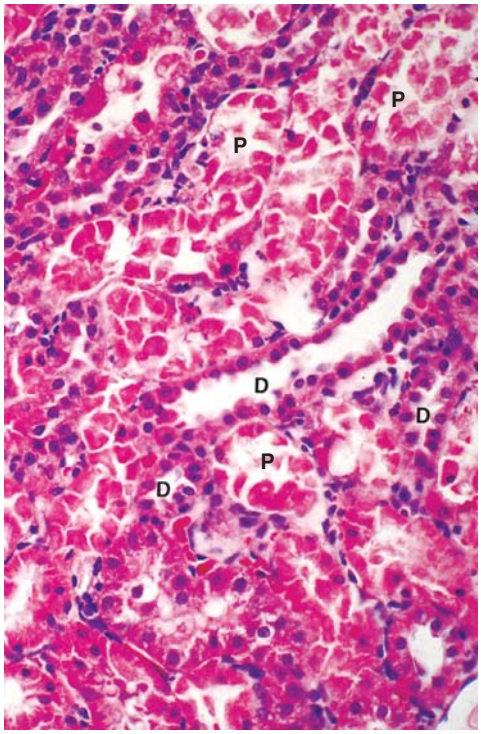

FIGURE 22-71. Toxic acute tubular necrosis due to mercury poisoning. There is widespread necrosis of proximal tubular (P) epithelial cells, with sparing of distal and collecting tubules (D). Interstitial inflammation is minimal.

The duration of renal failure in patients with ischemic acute tubular injury depends on many factors, especially the nature and reversibility of the cause. Many patients develop uremia (azotemia, fluid retention, metabolic acidosis, hyperkalemia), at least transiently, and may require dialysis. If the insult is removed right after injury begins, renal function may return within 1–2 weeks. However, recovery may take months. Increased urine output and decreased serum creatinine herald the recovery phase.

Pyelonephritis Usually Reflects Bacterial Infection of the Kidney

Acute Pyelonephritis

ETIOLOGIC FACTORS AND PATHOPHYSIOLOGY: Gram-negative bacteria from feces, mostly *E. coli,* cause 80% of acute pyelonephritis. *E. coli* that cause urinary tract infections **(uropathogenic *E. coli*)** have virulence factors that enhance their ability to cause not only urinary tract infections but also pyelonephritis. The best studied of these are adhesins on fimbria (pili) encoded by pyelonephritis-associated pili (*PAP*) genes. Uropathogenic *E. coli* pili attach to adhesin-binding sites on urothelial cells as well as epithelial cells of the kidney. Infection reaches the kidney by ascending through the urinary tract, a process that depends on several factors:

- Bacterial urinary infection
- Reflux of infected urine up the ureters into the renal pelvis and calyces
- Bacterial entry through the papillae into the renal parenchyma

Bladder infections (cystitis) usually precede acute pyelonephritis. These occur more commonly in females because they have short urethras, they lack antibacterial prostatic secretions and sexual intercourse facilitates bacterial migration. Normal urethral commensal flora are replaced by fecal organisms in women who are unusually prone to recurrent urinary tract infections. Many factors may contribute to this change in flora, including hygiene, hormonal effects and genetic predisposition (e.g., increased receptors for *E. coli* on urothelial cells).

Pregnancy predisposes to acute pyelonephritis for several reasons, including a high frequency of asymptomatic bacteriuria (10%), of which 1/4 develops into acute pyelonephritis. Other causes include increased residual urine volume because high levels of progesterone make bladder musculature flaccid and less able to expel urine.

The bladder normally empties all but 2–3 mL of residual urine. Subsequent addition of sterile urine from the kidneys dilutes any bacteria that may have gained access to the bladder. However, if residual urine volume is increased (e.g., with prostatic obstruction or bladder atony due to neurogenic disorders such as paraplegia or diabetic neuropathy), sterile urine from the kidneys may be insufficient to dilute residual bladder urine to prevent bacterial accumulation. Diabetic glycosuria also facilitates infection by providing a rich bacterial growth medium.

Bacteria in bladder urine usually do not ascend to infect the kidneys. The ureter commonly inserts into the bladder wall at a steep angle (Fig. 22-72), and its most distal portion courses parallel to the bladder wall, between the mucosa and muscularis. Increased intravesicular pressure during micturition occludes the distal ureteral lumen and prevents urinary reflux. An anatomic abnormality, a short passage of the ureter within the bladder wall, causes the ureter to insert more perpendicularly to the bladder mucosal surface. As a result, rather than occluding the lumen, micturition increases intravesicular pressure and pushes urine into the patent ureter. This reflux can force the urine into the renal pelvis and calyces.

Even if reflux pressure delivers bacteria to the calyces, the renal parenchyma is not necessarily contaminated. The convexity of the simple papillae of central calyces blocks reflux urine from entering (Fig. 22-72), but the concavity of peripheral compound papillae allows easier access to the collecting system. ***However, if pressure is prolonged, as in obstructive uropathy, even simple papillae are eventually vulnerable to retrograde entry of urine.*** From the collecting tubules, bacteria access the renal interstitium and tubules.

In addition to ascending through urine, bacteria and other pathogens can gain access to renal parenchyma through the

TABLE 22-12
URINALYSIS IN ACUTE KIDNEY INJURY

Causes of Acute Kidney Injury	Urinalysis Sediment Findings
Acute tubular injury	Dirty brown casts and epithelial cells
Acute glomerulonephritis	Red blood cell casts and proteinuria
Acute tubulointerstitial nephritis	White blood cell casts and pyuria

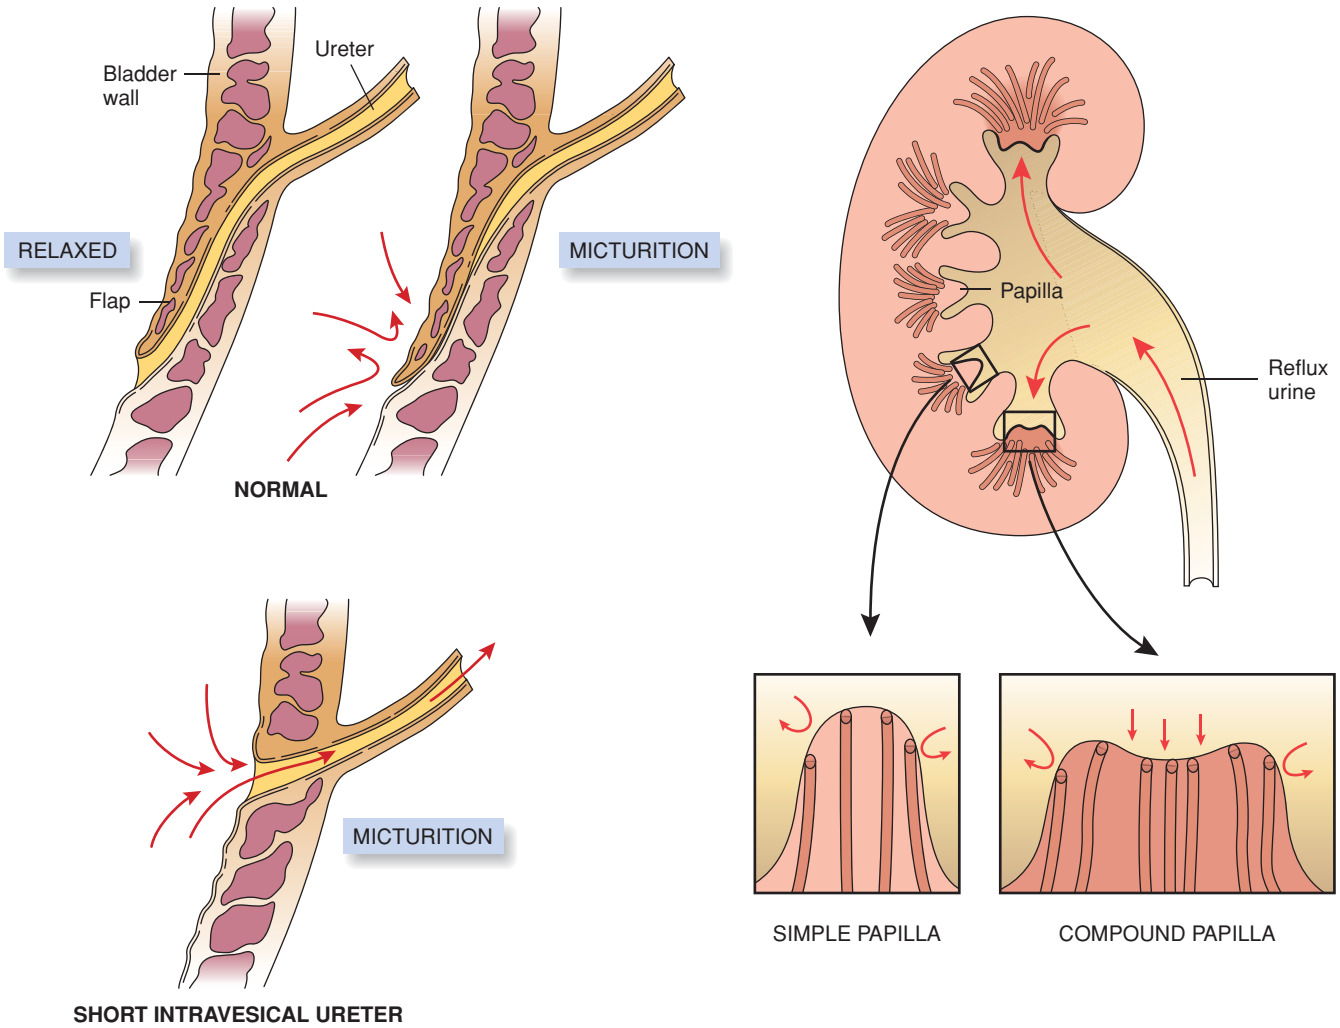

FIGURE 22-72. Anatomic features of the bladder and kidney in pyelonephritis caused by ureterovesical reflux. In the normal bladder, the distal portion of the intravesical ureter courses between the mucosa and the muscularis, forming a mucosal flap. On micturition, the elevated intravesicular pressure compresses the flap against the bladder wall, occluding the lumen. People with a congenitally short intravesical ureter have no mucosal flap, because the angle of entry of the ureter into the bladder approaches a right angle. Thus, micturition forces urine into the ureter. In the renal pelvis, simple papillae of the central calyces are convex and do not readily allow reflux of urine. By contrast, the peripheral compound papillae are concave and permit entry of refluxed urine.

bloodstream, causing **hematogenous pyelonephritis**. For example, in bacterial endocarditis, gram-positive organisms, such as staphylococci, can spread from an infected valve and establish infection in the kidney. The kidney is commonly involved in miliary tuberculosis. Fungi, such as *Aspergillus*, can seed kidneys in immunosuppressed hosts. Hematogenous infections preferentially affect the cortex.

PATHOLOGY: The kidneys in acute pyelonephritis are swollen and may have abscesses in the medulla, if infection is ascending, and in the cortex, when it is hematogenous. Pelvic and calyceal urothelium may be hyperemic and covered by purulent exudate. The disease is often focal, and much of the kidney may be normal.

Most infections involve only a few papillary systems. Renal parenchyma, particularly the cortex, typically shows extensive focal destruction by inflammation, although vessels and glomeruli often are preferentially preserved. Infiltrates mainly contain neutrophils, which often fill tubules and especially collecting ducts (Fig. 22-73). In severe cases of acute pyelonephritis, necrosis of the papillary tips may occur (Fig. 22-74) or infection may extend beyond the renal capsule to cause a perinephric abscess.

CLINICAL FEATURES: Symptoms of acute pyelonephritis include fever, chills, sweats, malaise, flank pain and costovertebral angle tenderness. Blood neutrophilia is common. Differentiating upper from lower urinary tract infections clinically is often difficult, but **leukocyte casts** in the urine suggest pyelonephritis.

Chronic Pyelonephritis

ETIOLOGIC FACTORS: Chronic pyelonephritis is caused by recurrent and persistent bacterial infection due to urinary tract obstruction, urine reflux or both (Fig. 22-75). Whether reflux without infection can produce chronic pyelonephritis is controversial.

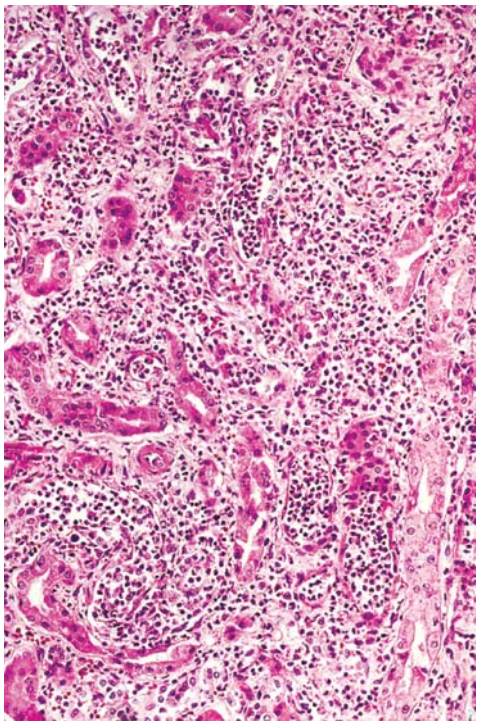

FIGURE 22-73. Acute pyelonephritis. An extensive infiltrate of neutrophils is present in the collecting tubules and interstitial tissue.

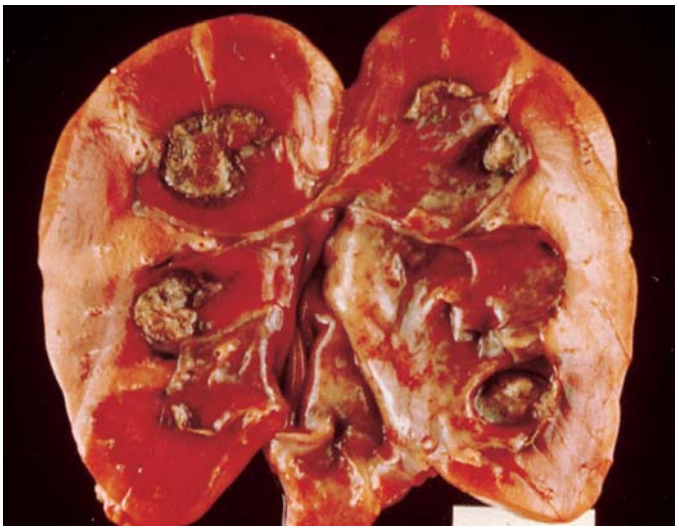

FIGURE 22-74. Papillary necrosis. The bisected kidney shows a dilated renal pelvis and dilated calyces secondary to urinary tract obstruction. The papillae are all necrotic and appear as sharply demarcated, ragged, yellowish areas.

In chronic pyelonephritis caused by reflux or obstruction, medullary tissue and overlying cortex are preferentially injured by recurrent acute and chronic inflammation. Progressive atrophy and scarring ensue, leading to contraction of involved papillary tips (or sloughing if there is papillary necrosis) and thinning of the overlying cortex. This process causes a distinctive gross appearance of broad depressed areas of cortical fibrosis and atrophy overlying a dilated calyx **(caliectasis)** (Fig. 22-76).

PATHOLOGY: The histology of chronic pyelonephritis is nonspecific. Many diseases cause chronic injury to the tubulointerstitial compartment and induce chronic interstitial inflammation, interstitial fibrosis and tubular atrophy. Thus, chronic pyelonephritis is one of many causes of a pattern of injury called **chronic tubulointerstitial nephritis**. The gross appearance of chronic pyelonephritis is distinctive. Only chronic pyelonephritis and analgesic

Chronic pyelonephritis caused by vesiculo-ureteral reflux
Dilated ureter
XXX
Chronic pyelonephritis caused by obstruction in the urinary tract

FIGURE 22-75. The two major types of chronic pyelonephritis. Left. Vesicoureteral reflux causes infection of the peripheral compound papillae and, therefore, scars in the poles of the kidney. **Right.** Obstruction of the urinary tract leads to high-pressure backflow of urine, which causes infection of all papillae, diffuse scarring of the kidney and thinning of the cortex.

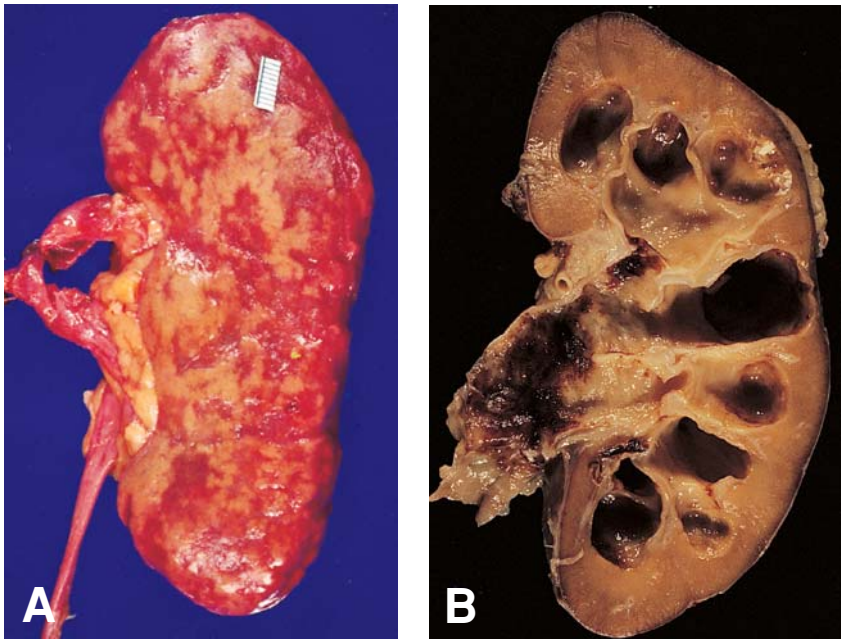

FIGURE 22-76. Chronic pyelonephritis. A. The cortical surface contains many irregular, depressed scars (reddish areas). **B.** There is marked dilation of calyces (caliectasis) caused by inflammatory destruction of papillae, with atrophy and scarring of the overlying cortex.

nephropathy produce both caliectasis and overlying corticomedullary scarring. In obstructive uropathy, all of the calyces and the renal pelvis are dilated, and the parenchyma is uniformly thinned (Fig. 22-76). In cases associated with vesicoureteral reflux, the calyces at the poles of the kidney are preferentially expanded and are associated with overlying discrete, coarse scars that indent the renal surface. The scars have atrophic dilated tubules surrounded by interstitial fibrosis and chronic inflammatory infiltrates (Fig. 22-77). The most characteristic (but not specific) tubular change is severe epithelial atrophy, with diffuse, eosinophilic, hyaline casts. Such tubules are "pinched-off" spherical segments, resembling colloid-containing thyroid follicles. This pattern, called **thyroidization,** results from breakup of tubules and residual segments forming spherules. Glomeruli may be uninvolved, show periglomerular fibrosis or be sclerotic. Loss of most functioning nephrons may lead to secondary FSGS. Fibrosis in arterial and arteriolar walls is common.

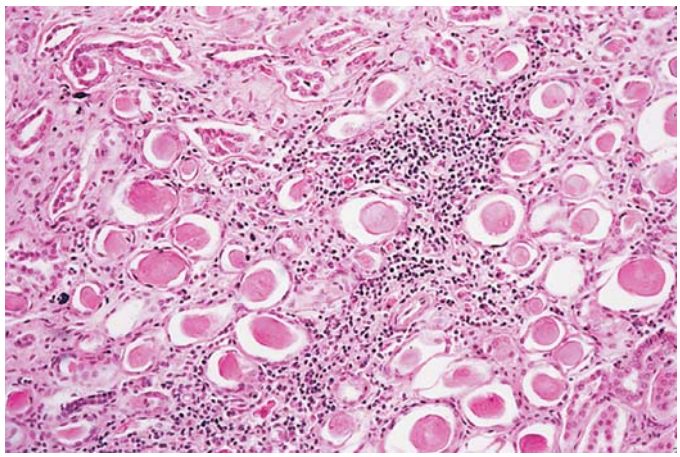

FIGURE 22-77. A light micrograph showing tubular dilation and atrophy. Many tubules contain eosinophilic hyaline casts resembling the colloid of thyroid follicles (so-called thyroidization). The interstitium is scarred and contains a chronic inflammatory cell infiltrate.

There is marked scarring and chronic inflammation of the calyceal mucosa.

Xanthogranulomatous pyelonephritis is an uncommon form of chronic pyelonephritis that is often caused by diverse pathogens, such as *Proteus, E. coli, Klebsiella* and *Pseudomonas.* Its name derives from the yellow gross appearance of nodular renal lesions, caused by numerous lipid-laden foamy macrophages **(xanthoma cells)** (Fig. 22-78A). The disease is usually unilateral. Because this form of inflammation often presents as a mass lesion (Fig. 22-78B), it can be confused with RCC.

CLINICAL FEATURES: Most patients with chronic pyelonephritis have episodic symptoms of urinary tract infection or acute pyelonephritis, such as recurrent fever and flank pain. Some have a silent course until ESRD develops. Urinalysis shows leukocytes, and imaging studies reveal caliectasis and cortical scarring.

Analgesic Nephropathy Results from Chronic Overconsumption of Phenacetin

Patients with analgesic nephropathy typically have taken more than 2 kg of analgesics, often in combinations, such as aspirin and phenacetin, or aspirin and acetaminophen. Phenacetin most often leads to nephropathy and is banned in many countries, including the United States. The pathogenesis of analgesic nephropathy is not clear. Possibilities include direct nephrotoxicity, ischemic damage due to drug-induced vascular changes or both. Analgesic nephropathy is distinct from AKI caused by analgesic-induced acute tubulointerstitial nephritis (e.g., caused by NSAIDs).

PATHOLOGY: Medullary injury with papillary necrosis occurs early in analgesic nephropathy. Atrophy, chronic inflammation and scarring of the overlying cortex follow. The earliest histologic abnormality is a distinctive homogeneous thickening of capillary walls just beneath the transitional epithelium of the urinary tract.

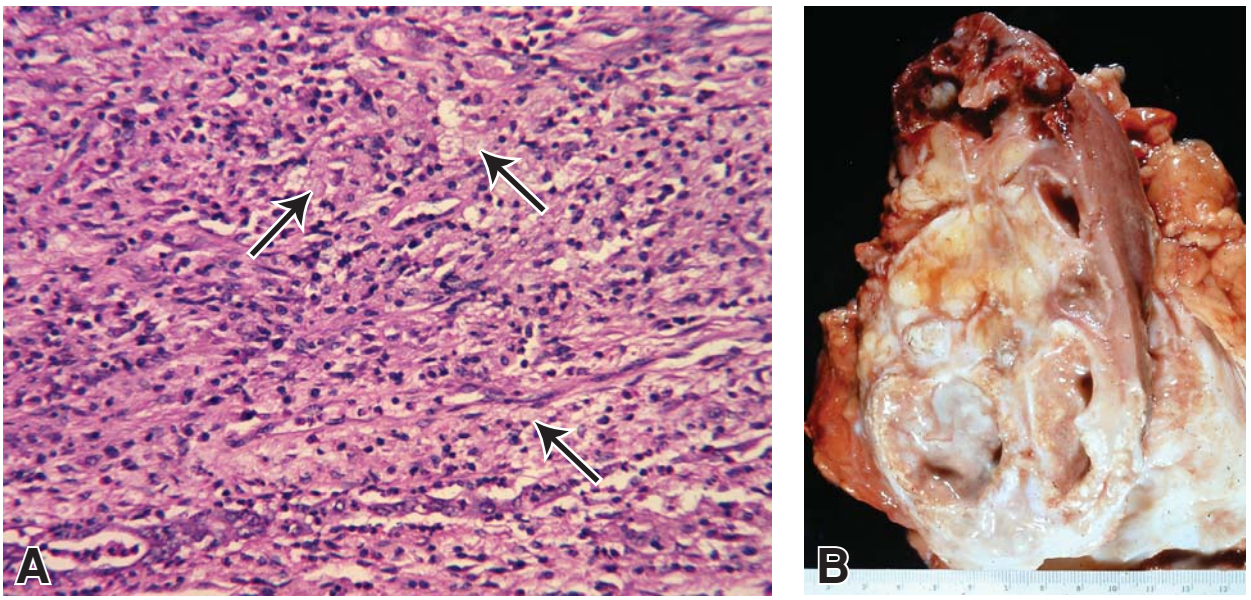

FIGURE 22-78. Xanthogranulomatous pyelonephritis. A. The lesion is characterized by a granulomatous reaction, full of foamy histiocytes (e.g., *arrows*), admixed with other types of inflammatory cells. **B.** This type of pyelonephritis can present as a mass lesion, simulating a tumor.

Early parenchymal changes are confined to papillae and the inner medulla, and they consist of focal basement membrane thickening of tubules and capillaries, interstitial fibrosis and focal coagulative necrosis. Necrotic areas eventually become confluent, first affecting the corticomedullary junction and then the collecting ducts. The necrotic foci contain few inflammatory cells. Eventually, the entire papilla becomes necrotic **(papillary necrosis),** often remaining in place as an amorphous mass. Dystrophic calcification of such necrotic papillae is common. Papillae may remain partly attached at the demarcation zone or be completely sloughed. There is secondary tubular atrophy, interstitial fibrosis and chronic inflammation in the overlying cortex.

CLINICAL FEATURES: Signs and symptoms occur only late in analgesic nephropathy and include an inability to concentrate the urine, distal tubular acidosis, hematuria, hypertension and anemia. Sloughing of necrotic papillary tips into the renal pelvis may result in colic as they pass through the ureters. Progressive renal failure often develops and leads to ESRD.

Drug-Induced (Hypersensitivity) Acute Tubulointerstitial Nephritis Is a Cell-Mediated Immune Response

PATHOPHYSIOLOGY: Acute drug-induced tubulointerstitial nephritis causes AKI. It entails infiltration by activated T cells and eosinophils, indicating a type IV cell-mediated immune reaction. The immunogen could be the drug itself, the drug bound to certain tissue components, a drug metabolite or a tissue component altered by the drug. Drugs most commonly implicated include NSAIDs, diuretics and certain antibiotics, especially β-lactam antibiotics (e.g., synthetic penicillins, cephalosporins).

PATHOLOGY: There is patchy cortical infiltration by lymphocytes and occasional eosinophils (5%–10% of the total leukocytes in the tissue) (Fig. 22-79). The medulla is usually less involved. Eosinophils tend to cluster, especially in tubular lumina and in the urine. Neutrophils are rare; their presence should raise suspicion of pyelonephritis or hematogenous bacterial infection. There may be

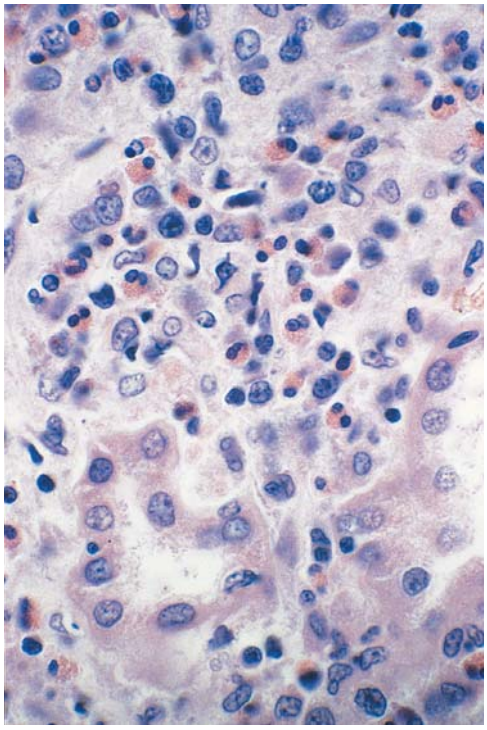

FIGURE 22-79. Hypersensitivity tubulointerstitial nephritis. There is interstitial edema and infiltration by mononuclear leukocytes, with admixed eosinophils.

granulomatous foci, especially later in the disease. Proximal and distal tubules are focally invaded by white blood cells ("tubulitis"). Glomeruli and vessels are not inflamed, but features of minimal-change disease may occur if drug-induced tubulointerstitial nephritis is caused by NSAIDs.

CLINICAL FEATURES: Acute tubulointerstitial nephritis usually presents as acute renal failure, typically about 2 weeks after a drug is started. Urinalysis shows erythrocytes, leukocytes (including eosinophils) and sometimes leukocyte casts. Tubular defects are common, including sodium wasting, glucosuria, aminoaciduria and renal tubular acidosis. Systemic allergic symptoms, such as fever and rash, may also be present. Most patients recover fully within several weeks or months if the offending drug is discontinued.

Light-Chain Cast Nephropathy May Complicate Multiple Myeloma

Light-chain cast nephropathy is renal injury caused by monoclonal immunoglobulin light chains in the urine. These cause tubular epithelial injury and tubular casts.

PATHOPHYSIOLOGY: As discussed above, multiple myeloma may produce AL amyloidosis, light-chain deposition disease, heavy-chain deposition disease and light-chain cast nephropathy. The latter is the most common kidney disease in patients with multiple myeloma. Glomeruli filter circulating light chains. However, at the acidic pH typical of urine, these light chains form casts by binding to Tamm-Horsfall glycoproteins that are secreted by distal tubular epithelial cells. Renal dysfunction results from both the toxicity of free light chains for tubular epithelium and obstruction by the casts. Light chain structure determines whether they will induce light-chain cast nephropathy, AL amyloidosis or light-chain deposition disease. Occasional patients show several of these renal diseases.

PATHOLOGY: Tubular lesions show many dense, brightly eosinophilic and glassy (hyaline) casts in distal renal tubules and collecting ducts (Fig. 22-80). Casts appear crystalline, often with fractures and angular borders. They may elicit foreign body reactions, with macrophages and multinucleated giant cells. Interstitial chronic inflammation and edema typically accompany the tubular lesions. More chronic lesions show interstitial fibrosis and tubular atrophy. Focal calcium deposits **(nephrocalcinosis)** often occur in the fibrotic tubular interstitium. Immunostaining visualizes antibody light chains and Tamm-Horsfall proteins.

CLINICAL FEATURES: Light-chain cast nephropathy may manifest as acute or chronic renal failure. Proteinuria, predominantly of immunoglobulin light chains, is usually present, although not necessarily in the nephrotic range. Nephrotic-range proteinuria in patients with multiple myeloma suggests AL amyloidosis or light-chain deposition disease rather than light-chain cast nephropathy.

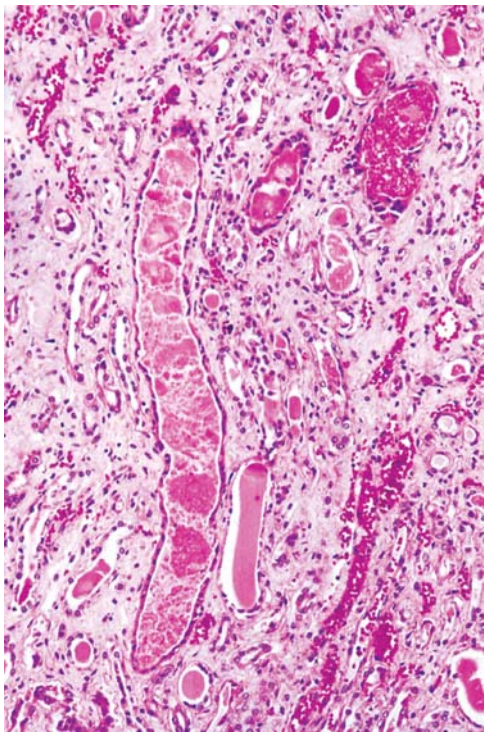

FIGURE 22-80. Light-chain cast nephropathy. A light micrograph shows numerous casts within tubular lumina.

Urate Crystals Deposit in the Tubules and Interstitium in Urate Nephropathy

Any condition with elevated blood levels of uric acid may cause urate nephropathy. The classic chronic disease in this category is primary gout (see Chapter 30).

PATHOPHYSIOLOGY: In **chronic urate nephropathy** due to gout, crystalline monosodium urate deposits in the tubules and interstitium. **Acute urate nephropathy** can be due to increased cell turnover. For example, chemotherapy for malignant neoplasms may cause tumor cell death. In **tumor lysis syndrome,** blood uric acid suddenly increases as massive numbers of tumor cells die. Catabolism of huge amounts of purines from DNA released by dying tumor cells leads to hyperuricemia. Uric acid crystals precipitate in the acidic pH of collecting ducts, obstruction them and causing acute renal failure. Interference with uric acid excretion (e.g., chronic intake of certain diuretics) can also cause hyperuricemia. Chronic lead intoxication interferes with uric acid secretion by proximal tubules and leads to **saturnine gout**.

PATHOLOGY: In acute urate nephropathy, uric acid precipitated in collecting ducts appears as yellow streaks in the papillae (Fig. 22-81A). The tubular deposits are amorphous after tissue processing, but birefringent crystals are visible in frozen sections (Fig. 22-81B). Tubules are dilated upstream of the obstruction. Uric acid crystals in collecting ducts may also elicit foreign body reactions.

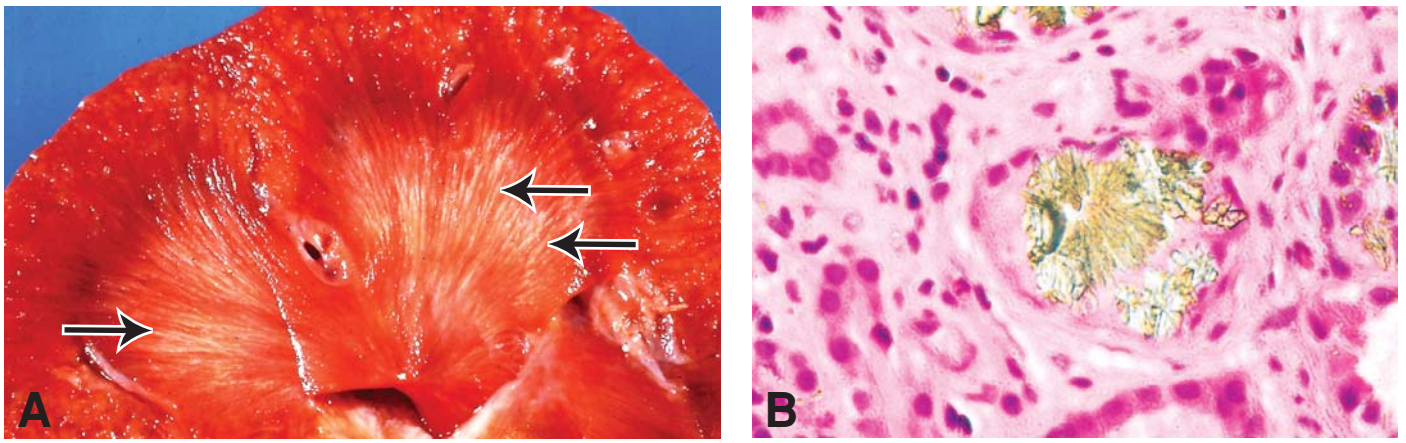

FIGURE 22-81. Urate nephropathy. A. Urate deposits appear as golden streaks in the medulla (*arrows*). **B.** A frozen section demonstrates tubular deposits of uric acid crystals.

The pathogenesis of chronic urate nephropathy is similar to that of the acute form, but because the course is prolonged, more urate deposits in the interstitium, causing interstitial fibrosis and cortical atrophy. The **gouty tophus** is diagnostic. It is a focal accumulation of urate crystals surrounded by inflammatory cells, which may appear granulomatous and include multinucleated giant cells. Uric acid stones account for 10% of **urolithiasis** and occur in 20% of patients with chronic gout and 40% of those with acute hyperuricemia.

CLINICAL FEATURES: Acute urate nephropathy presents as acute renal failure; chronic urate nephropathy causes chronic renal tubular defects. Although histologic renal lesions occur in most patients with chronic gout, less than 1/2 have significant renal functional impairment.

Nephrocalcinosis Is Deposition of Calcium in the Renal Parenchyma

PATHOPHYSIOLOGY: Hypercalciuria may lead to **nephrocalcinosis** (Table 22-13), formation of calcium-containing stones **(nephrolithiasis)** or both. Nephrocalcinosis may impair renal function, especially tubular defects such as poor concentrating ability, salt wasting and renal tubular acidosis. If nephrocalcinosis is caused by hypercalcemia, it is **metastatic calcification,** whereas calcification at sites of renal parenchymal injury (e.g., infarcts or cortical necrosis) is representative of **dystrophic calcification**.

Acute phosphate nephropathy is a form of nephrocalcinosis that is an uncommon complication of phosphate bowel-cleansing preparations used in patients about to undergo colonoscopy. Risk factors for this complication include older age, renal insufficiency and use of ACE inhibitors or ARBs. Risk is reduced by avoiding excessive dehydration during bowel cleansing. In acute phosphate nephropathy, AKI occurs several weeks after use of phosphate bowel-cleansing preparations. Pathologically, calcium phosphate deposits in injured distal tubules and collecting ducts, usually accompanied by interstitial fibrosis and chronic inflammation.

PATHOLOGY: At autopsy, 20% of kidneys have small calcium deposits that have no functional significance or recognized association with hypercalcemia. In patients with nephrocalcinosis caused by hypercalcemia, calcification varies from tiny deposits to grossly and radiologically visible calcium aggregates. If hypercalcemia is severe (e.g., as in primary hyperparathyroidism), kidneys may contain wedge-shaped scars interspersed with relatively normal renal tissue. These scars reflect parenchymal atrophy and interstitial fibrosis caused by the calcification. Renal tubular basement membrane calcification may be striking, particularly in proximal convoluted tubules. Interstitial tissues also contain calcium precipitates. Such deposits also accumulate in the cytoplasm of tubular epithelial cells, which eventually degenerate and are sloughed into the lumens to aggregate as calcified casts. Scattered glomeruli show calcification of the Bowman capsule. Intrarenal arteries may also be calcified. Calcium deposits stain deeply blue with hematoxylin. They are black with the more specific von Kossa stain. By electron microscopy, the mitochondria of renal tubular epithelial cells contain abundant calcium deposits.

TABLE 22-13
CAUSES OF HYPERCALCEMIA THAT LEAD TO NEPHROCALCINOSIS

Increased Resorption of Calcium from Bone
Renal osteodystrophy
Primary hyperparathyroidism
Neoplasms producing parathormone or parathormone-like protein
Osteolytic neoplasms and metastases
Increased Intestinal Absorption of Calcium
Idiopathic hypercalcemia
Vitamin D excess
Milk-alkali syndrome
Sarcoidosis

RENAL STONES (NEPHROLITHIASIS AND UROLITHIASIS)

Nephrolithiasis is stones within the renal collecting system and **urolithiasis** is stones elsewhere in the collecting system of the urinary tract. Calculi often form and accumulate in the renal pelvis and calyces. Stones vary in composition, depending on geography, metabolic alterations and the presence of infection.

For unknown reasons, renal stones are more common in men than in women. They vary in size from gravel (<1 mm) to large stones that dilate the entire renal pelvis. Although they may be well tolerated, in some cases they lead to severe hydronephrosis and pyelonephritis. They can also erode the mucosa and cause hematuria. Passage of a stone into the ureter causes excruciating flank pain, **renal colic**. Larger kidney stones required surgical removal in the past, but ultrasonic disintegration (lithotripsy) and endoscopic removal are now effective.

A urinary stone is usually associated with increased blood levels and urinary excretion of its principal component. This is the case with uric acid and cystine stones. However, many patients with calcium stones have hypercalciuria without hypercalcemia. Mixed urate and calcium stones are common with hyperuricemia, as urate crystals act as a nidus for calcium salts to precipitate.

- **Calcium stones:** Most (75%) renal stones are calcium complexed with oxalate or phosphate, or a mixture of these anions. Calcium oxalate is more common in the United States, whereas in England, calcium phosphate predominates. Calcium oxalate stones are hard and occasionally dark, because they are covered by hemorrhage from the mucosa of the renal pelvis injured by the sharp calcium oxalate crystals. Calcium phosphate stones tend to be softer and paler.
- **Infection stones:** Infection, often with urea-splitting bacteria like *Proteus* or *Providencia* spp., causes 15% of stones. Resulting alkaline urine favors magnesium ammonium phosphate **(struvite)** and calcium phosphate **(apatite)** precipitation. Such stones may be hard, or soft and friable. Infection stones occasionally fill the pelvis and calyces to form a cast of these spaces, a **staghorn calculus** (Fig. 22-82). Infection stones cause frequent complications, such as intractable urinary tract infection, pain, bleeding, perinephric abscess and urosepsis.
- **Uric acid stones:** These stones occur in 25% of patients with hyperuricemia and gout, but most patients with uric acid stones have neither **(idiopathic urate lithiasis)**. Urate stones are smooth, hard and yellow, and are usually less than 2 cm. Unlike calcium-containing stones, pure uric acid stones are radiolucent.
- **Cystine stones:** These account for only 1% of renal stones overall but are a significant fraction of childhood calculi. They occur only in hereditary cystinuria. Although composed only of cystine, they may be enveloped by a layer of calcium phosphate.

OBSTRUCTIVE UROPATHY AND HYDRONEPHROSIS

Obstructive uropathy is caused by structural or functional abnormalities in the urinary tract that impede urine flow, which may cause renal dysfunction (obstructive nephropathy) and dilation of the collecting system (hydronephrosis). Urinary tract obstruction is detailed in Chapter 23.

FIGURE 22-82. Staghorn calculi. The kidney shows hydronephrosis and stones that are casts of the dilated calyces.

PATHOLOGY: The most prominent microscopic finding in early hydronephrosis is dilation of collecting ducts. This is followed by dilation of proximal and distal convoluted tubules. Eventually, the proximal tubules become widely dilated and are lost. Glomeruli are usually spared. Progressive dilation of the renal pelvis and calyces leads to renal parenchymal atrophy (Fig. 22-83). Hydronephrotic kidneys are more susceptible to pyelonephritis, adding injury to insult.

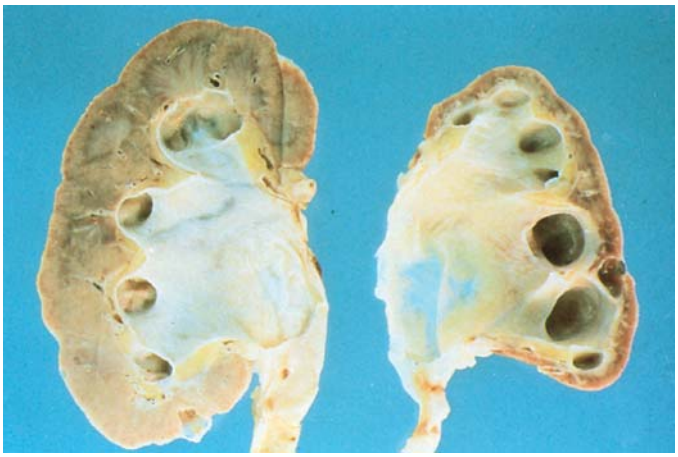

FIGURE 22-83. Hydronephrosis. Bilateral urinary tract obstruction has led to conspicuous dilation of the ureters, pelves and calyces. The kidney on the right shows severe parenchymal atrophy.

CLINICAL FEATURES: Bilateral acute urinary tract obstruction causes acute renal failure **(postrenal acute renal failure)**. Unilateral obstruction is often asymptomatic. Many causes of acute obstruction are reversible; thus, prompt recognition is important. Left untreated, an obstructed kidney undergoes atrophy. If obstruction is bilateral, chronic renal failure ensues.

RENAL TRANSPLANTATION

Kidney transplantation is the treatment of choice for most patients with ESRD. The major obstacle is allograft rejection. However, the transplanted organ is also susceptible to recurrence of the disease that destroyed the native kidneys and to nephrotoxicity from immunosuppressive drugs. Table 22-14 lists distinct, but often coexisting, patterns of antibody-mediated and cellular renal allograft rejection.

ABO blood group antigens and **HLA antigens** are the main antigenic targets on transplanted kidneys. ABO antigens are expressed on endothelial cells and red blood cells, and are the most problematic barriers to transplantation. Because anti-ABO antibodies are preformed, they bind to graft endothelial cells and cause immediate (hyperacute) rejection (see below). ***More common (and more gradual) patterns of acute and chronic rejection are mainly due to recipient reactivity against donor HLA antigens (see Chapter 4).*** HLA antigens are expressed on most cells, including endothelial cells, but not erythrocytes. Development of donor-specific HLA immunity in allograft recipients causes cell-mediated and antibody-mediated reactions (see Chapter 4). Renal allograft rejection can be classified on the basis of its clinical course, pathologic features and presumed pathogenesis (Table 22-14). However, an allograft may undergo more than one type of rejection at the same time.

TABLE 22-14
CATEGORIES OF RENAL ALLOGRAFT REJECTION

Category	Most Characteristic Lesion
Hyperacute antibody-mediated rejection	Neutrophils in peritubular capillaries, hemorrhage and necrosis
Acute antibody-mediated rejection	
Acute antibody-mediated capillary rejection	Leukocytes and C4d in peritubular capillaries
Acute necrotizing transplant arteritis	Arterial fibrinoid necrosis
Acute T-cell–mediated rejection	
Acute tubulointerstitial rejection	Tubulitis (mononuclear leukocytes between epithelial cells of tubules) and interstitial activated lymphocytes
Acute endarteritis	Mononuclear leukocytes in arterial intima
Acute transplant glomerulitis	Mononuclear leukocytes in glomerular capillaries
Acute transplant arteritis	Acute transmural inflammation or necrosis
Chronic rejection	
Interstitial fibrosis and tubular atrophy	Tubular atrophy, interstitial fibrosis, interstitial chronic inflammatory cells and thickening of peritubular capillary basement membranes
Chronic transplant arteriopathy	Arterial fibrotic intimal thickening
Chronic transplant glomerulopathy	Glomerular capillary wall thickening and glomerular basement membrane remodeling

HYPERACUTE ANTIBODY-MEDIATED REJECTION: Hyperacute rejection is rare (<0.5% of grafts). If recipient blood contains antibodies to major graft alloantigens (usually ABO or class I HLA), those antibodies immediately bind endothelial cells in the transplanted organ and cause irreversible injury within minutes. The graft may become mottled, cyanotic and flaccid intraoperatively. Antibody binds endothelial cell antigens, activates complement and thus attracts neutrophils. The cytotoxic effects of complement and neutrophils cause endothelial cells to swell, become vacuolated and lyse. Accumulation of neutrophils in glomerular capillaries portends impending rejection. Endothelial cell changes are followed by platelet thrombi and later by fibrin thrombi (Fig. 22-84). Interstitial edema, hemorrhage (Fig. 22-84) and cortical necrosis develop over the next 12–24 hours.

ACUTE ANTIBODY-MEDIATED REJECTION: The most common type of acute antibody-mediated rejection is directed primarily at capillaries and may cause only subtle or no pathologic changes by light microscopy. Neutrophils or mononuclear leukocytes are increased in peritubular and glomerular capillaries, and in tubules. Complement activation products, especially C4d, localize consistently to the walls of peritubular and glomerular capillaries (Fig. 22-85A). The most severe, but least common, pattern of acute antibody-mediated rejection involves **necrotizing arteritis** with fibrinoid necrosis of the media (Fig. 22-85B). It occurs in less than 1% of allografts in patients whose immunosuppression includes a calcineurin inhibitor, although before these agents

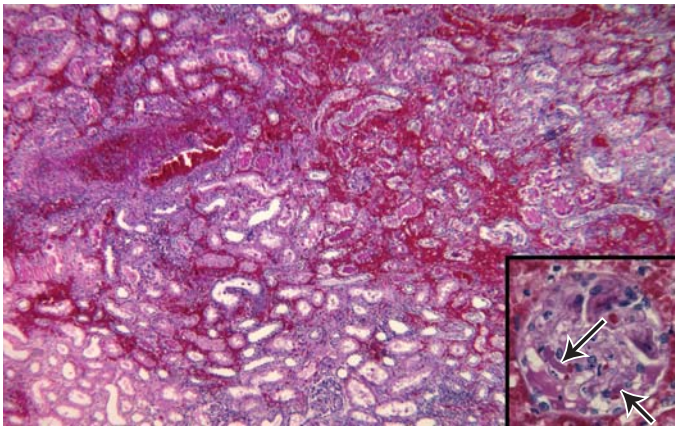

FIGURE 22-84. Hyperacute rejection. Preformed antibody against recipient antigens causes an immediate in situ reaction, with hemorrhage developing due to vascular necrosis. Fibrin thrombi (*inset*) are abundant in glomeruli.

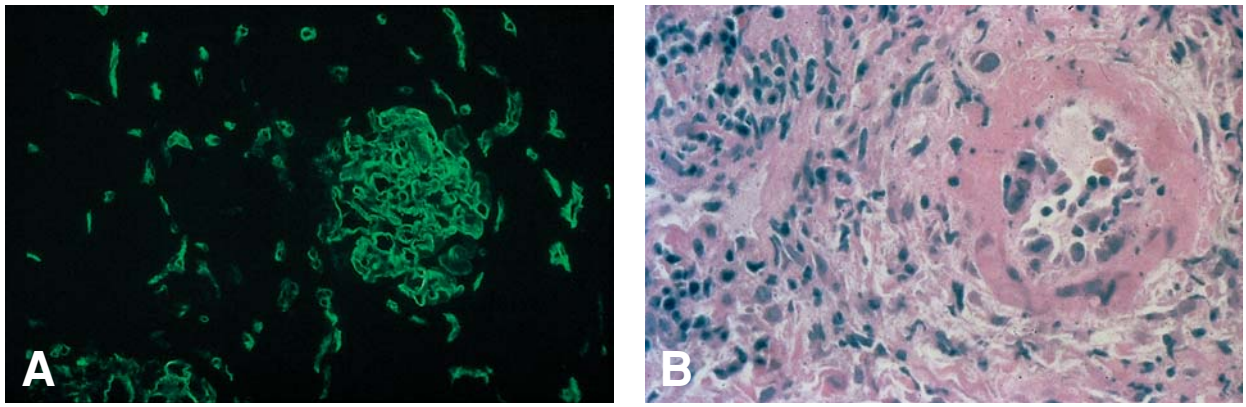

FIGURE 22-85. Acute antibody-mediated allograft rejection. A. Staining of peritubular and glomerular capillaries with an anti-C4d antibody showing evidence of complement activation by antibodies directed against donor antigens on endothelial cells. **B.** Acute antibody-mediated necrotizing acute vasculitis in an interlobular artery with extensive fibrinoid necrosis of the muscularis. The vascular and interstitial infiltrates of mononuclear leukocytes indicate concurrent acute cellular rejection.

were introduced it occurred in 5% of renal allografts. If necrotizing arteritis develops, fewer than 30% of grafts survive 1 year, even with aggressive immunosuppression.

ACUTE CELLULAR REJECTION: This is the most common form of acute rejection. It is characterized by infiltration of the interstitium, tubules, arteries, arterioles or glomeruli by T lymphocytes and macrophages. Nuclei of infiltrating lymphocytes vary in size and shape because the cells are at various stages of activation and include immunoblasts (see Chapter 26). Usually, interstitial infiltrates are patchy rather than diffuse. Involvement of tubules **(tubulitis)** is manifested by lymphocytes crossing tubular basement membranes and lying between tubular epithelial cells (Fig. 22-86A). Arterial involvement by cellular rejection involves T lymphocytes and monocytes traversing the endothelium, expanding the intima with mononuclear leukocytes **(endarteritis)** (Fig. 22-86B). Arterioles may be similarly affected. Glomerular infiltration by mononuclear leukocytes with obliteration of capillary lumens causes **acute transplant glomerulitis)**. Renal transplants with tubulitis but not endarteritis have an 80% chance of 1-year graft survival, compared with 60% for allografts with endarteritis.

CHRONIC REJECTION: Chronic rejection features interstitial fibrosis and tubular atrophy, interstitial mononuclear infiltrates, thickening (multilamination) of peritubular capillary basement membranes, **chronic transplant arteriopathy** and **chronic transplant glomerulopathy** (see below) (Table 22-14).

Chronic transplant arteriopathy affects arteries of all sizes, including the main renal artery. The intima is thickened by stromal cell proliferation and matrix deposition (Fig. 22-87), but without the dense fibrosis and elastic lamination seen in nonspecific arteriosclerosis. Inflammation is absent—or is much less prominent than in active acute cell-mediated intimal arteritis (compare to Fig. 22-83). Foam cells may be conspicuous, and the internal elastic lamina may be interrupted. Peritubular capillaries show basement membrane thickening and replication.

In chronic transplant glomerulopathy, glomerular capillary walls are thickened, due to expansion of the glomerular capillary subendothelial zone and GBM replication. This also occurs in peritubular capillaries. The mesangium is widened. Ischemia due to arterial and capillary narrowing may lead to tubular atrophy and interstitial fibrosis.

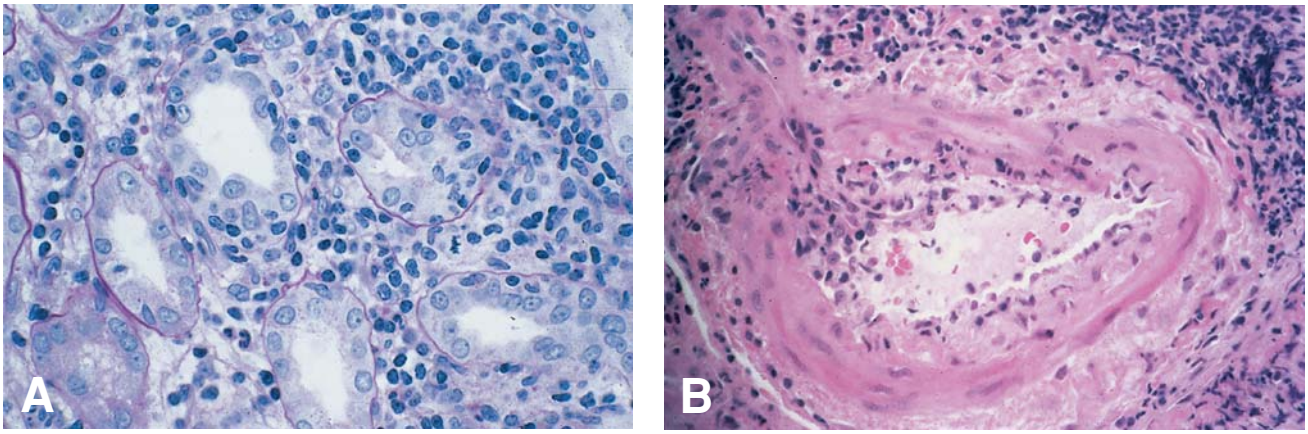

FIGURE 22-86. Acute cellular allograft rejection. A. Acute tubulointerstitial cellular rejection with tubulitis indicated by lymphocytes on the epithelial side of the basement membrane (periodic acid–Schiff stain). **B.** Acute cellular vascular rejection with endarteritis indicated by mononuclear leukocytes infiltrating the intima of an arcuate artery.

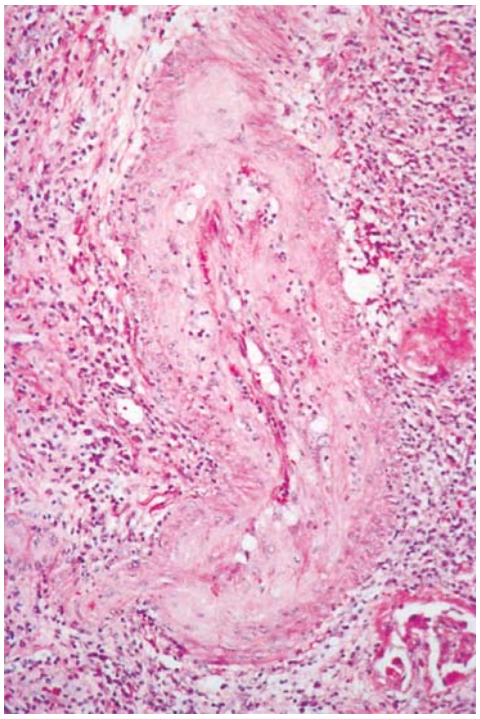

FIGURE 22-87. Chronic allograft rejection. The lumen of this medium-sized artery is occluded by a thickened intima, which contains a few inflammatory cells.

Tubulointerstitial injury may also result from indolent tubulitis.

RECURRENCE OF KIDNEY DISEASE: The same disease that caused the native kidneys to fail may recur in a transplanted kidney. The frequency and significance of recurrence vary among different types of glomerular disease (Table 22-15).

TABLE 22-15
RECURRENCE OF DISEASE IN RENAL ALLOGRAFTS

Disease	Recurrence Rate (%)	Rate of Graft Loss (%)
C3 glomerulopathy (dense deposit disease)	>90	15
Diabetic glomerulosclerosis	>90	<5
IgA nephropathy	40	<10
Focal segmental glomerulosclerosis	35	30
Type I membranoproliferative glomerulonephritis	30	<10
Membranous glomerulonephritis	20	<5
ANCA glomerulonephritis	15	<5
Anti-GBM glomerulonephritis	5	<5
Lupus glomerulonephritis	5	<5

ANCA = antineutrophil cytoplasmic autoantibody; GBM = glomerular basement membrane; IgA = immunoglobulin A.

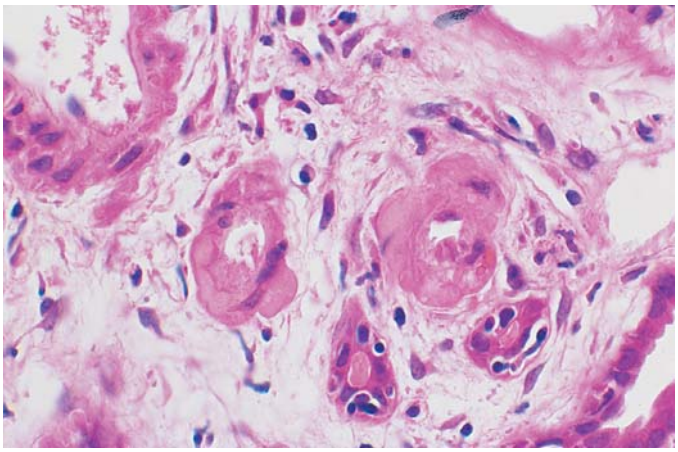

FIGURE 22-88. Cyclosporine nephrotoxicity with arteriolopathy. Marked destructive hyalinosis of arterioles is present.

CALCINEURIN INHIBITOR NEPHROTOXICITY OF CYCLOSPORINE AND TACROLIMUS: Cyclosporine and tacrolimus are immunosuppressive inhibitors of calcineurin that have dramatically improved allograft survival for kidneys and other organs (e.g., liver, heart, lungs). Unfortunately, both drugs are nephrotoxic and can injure both kidney allografts and native kidneys of patients given these drugs for other reasons. Acute or chronic renal failure can result.

The most characteristic renal lesion is an **arteriolopathy** that begins with smooth muscle cell degeneration and necrosis. The destroyed arteriolar muscle cells are replaced by acidophilic hyaline material (Fig. 22-88). In fulminant cases, vascular lesions resemble full-blown thrombotic microangiopathy, with circumferential fibrinoid arteriolar necrosis. In chronic toxicity, there are zones of interstitial fibrosis and tubular atrophy ("striped fibrosis").

BK POLYOMAVIRUS INFECTION: Immunosuppression can reactivate latent BK virus infection in a transplanted kidney and can lead to acute tubular injury and tubulointerstitial nephritis. Intranuclear viral inclusions in tubular cells may suggest this possibility, and immunochemical staining can confirm the diagnosis.

Tumors of the Kidney

BENIGN RENAL TUMORS

PAPILLARY RENAL ADENOMA: There is controversy as to whether any epithelial renal cell tumor should be considered benign. Tumor size, which has been used to separate adenomas from carcinomas, is problematic because all carcinomas start out as small lesions. Renal epithelial neoplasms smaller than 3 cm rarely metastasize, but "rarely" is not "never." Tumors composed of cells resembling clear cell, chromophobe or collecting duct RCCs should not be referred to as adenomas even if they are small. Neoplasms smaller than 5 mm with papillary or tubulopapillary growth patterns can be considered adenomas. Papillary renal adenomas occur more often with advancing age and are incidental autopsy findings in 40% of patients older than 70.

RENAL ONCOCYTOMA: This benign neoplasm accounts for 5%–10% of primary renal tumors removed surgically. It derives from collecting duct intercalated cells. They are plump, with abundant, finely granular, acidophilic cytoplasm and round nuclei that lack atypia. The distinctive appearance of the tumor is due to abundant mitochondria in the cytoplasm. Oncocytomas are typically mahogany-brown due to mitochondrial lipochrome pigments. These tumors rarely metastasize.

MEDULLARY FIBROMA: Medullary fibromas (renomedullary interstitial cell tumors) are typically small (<0.5 cm in diameter), pale gray, well-circumscribed tumors, usually in the midportion of medullary pyramids. They are composed of small stellate to polygonal cells in a loose stroma. Renal medullary fibromas are incidental findings in as many as 1/2 of all adult autopsies (Fig. 22-89).

ANGIOMYOLIPOMA: These tumors are strongly associated with tuberous sclerosis. Of patients with tuberous sclerosis, 80% have angiomyolipomas, but most patients with angiomyolipomas do not have tuberous sclerosis. These lesions are mixtures of well-differentiated adipose tissue, smooth muscle and thick-walled vessels. Grossly, they are yellow and bosselated, and may resemble RCC. However, they are always well encapsulated and lack necrosis.

MESOBLASTIC NEPHROMA: Mesoblastic nephromas are benign congenital neoplasms or hamartomas usually found in the first 3 months of life. They must be differentiated from Wilms tumors. The lesions range from smaller than 1 cm to larger than 15 cm and are composed of spindle cells of fibroblastic or myofibroblastic lineage. Tumor margins are usually irregular, with bands of cells interdigitating with adjacent renal parenchyma. Mesoblastic nephromas may recur if some of these tongues of tumor tissue are left behind after surgical resection.

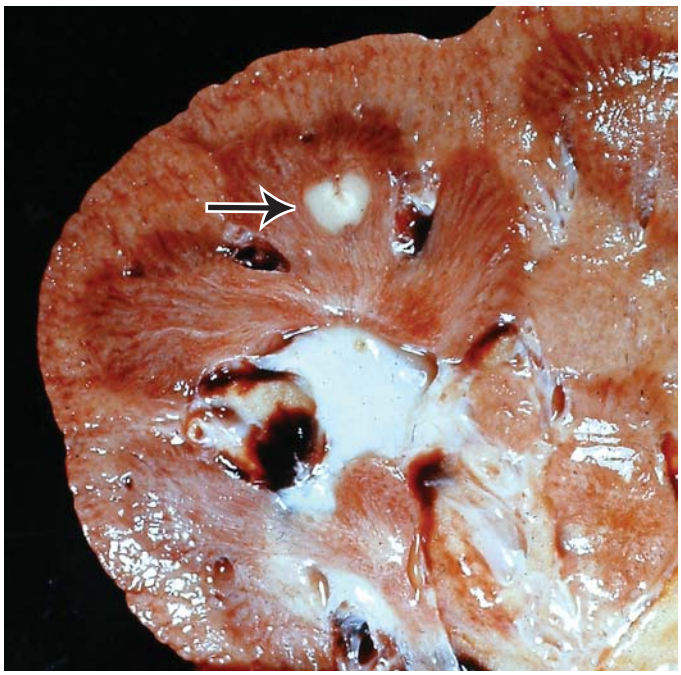

FIGURE 22-89. **Medullary fibroma (*arrow*).**

MALIGNANT TUMORS OF THE KIDNEY

Wilms Tumor (Nephroblastoma) Is a Malignancy of Embryonal Renal Elements

Component nephrogenic elements include admixed blastema, stroma and epithelium. Its incidence is 1 in 10,000, making it the most common abdominal solid tumor in children.

MOLECULAR PATHOGENESIS: In most (90%) cases, the Wilms tumor is sporadic and unilateral. In 5% of cases, however, it arises as part of three different congenital syndromes, all of which increase the risk of developing Wilms tumors at an early age and often bilaterally:

- **WAGR syndrome: W**ilms tumor, ***a***niridia, ***g***enitourinary anomalies, mental ***r***etardation
- **Denys-Drash syndrome (DDS):** Wilms tumor, intersexual disorders, glomerular mesangial sclerosis
- **Beckwith-Wiedemann syndrome (BWS):** Wilms tumor, overgrowth ranging from gigantism to hemihypertrophy, visceromegaly and macroglossia

Approximately 6% of Wilms tumors are familial, have an early onset and are bilateral but are not associated with any other syndrome.

WAGR syndrome is caused by a deletion in the short arm of chromosome 11 (11p13). Affected genes include the aniridia gene (*PAX6*) and **Wilms tumor gene 1 (*WT1*)**. WT1 protein (see below) is expressed in kidneys, thymus, spleen and gonads. Loss or mutation of one *WT1* allele leads to genitourinary anomalies. A defect in *PAX6* causes aniridia. Of children with WAGR syndrome, 1/3 develop Wilms tumors. The presence of a germline mutation in one *WT1* allele and loss of heterozygosity (LOH) at this locus in the tumors of WAGR syndrome implies that acquired somatic mutation in the remaining *WT1* allele is needed for Wilms tumor to occur (as in retinoblastomas; see Chapter 5). Unlike deletions in WAGR syndrome, mutations in the *WT1* gene in DDS are considered dominant negative mutations, possibly accounting for the fact that the DDS phenotype is far more severe than that of WAGR syndrome. *WT1* mutations also occur in Frasier syndrome, but affected patients develop gonadoblastomas, not Wilms tumors.

WT1 is a tumor-suppressor protein that regulates transcription of several other genes, including insulin-like growth factor-II (*IGF-II*), *Snail*, E-cadherin (*Cdh1*) and platelet-derived growth factor (*PDGF*). Wilms tumors arising in the context of WAGR syndrome all have *WT1* mutations, but only 10%–20% of sporadic Wilms tumors do. Thus, other genes besides *WT1* must contribute to the genesis of sporadic Wilms tumors. Among sporadic Wilms tumors, 10% have a gain-of-function mutation in β-catenin (*CTNNB1*), a part of the developmentally important WNT signaling pathway. An additional 5% have mutations in the p53 gene (*TP53;* see Chapter 5).

Approximately 70% of Wilms tumors show LOH or loss of imprinting (LOI) at a second locus on chromosome 11 (11p15.5). This site, also linked to BWS, is distinct from, but close to, the *WT1* gene. Interestingly, LOH at this locus in sporadic Wilms tumors invariably results in loss of the maternal allele. In addition, some BWS patients have germline duplications of the paternal locus, whereas others have two copies of chromosome 11 with the same imprinting

pattern at this locus as the father (*paternal uniparental isodisomy*). Because *IGF-II 2* maps to chromosome 11p15 and has paternal imprinting, an increased dose of *IGF-II 2* might contribute to BWS and to tumorigenesis. Another possibility is that another closely linked gene, such as the *H19* gene, expressed only by the maternal allele, is a tumor suppressor or regulates imprinting in the region.

The *WTX* gene on the X chromosome is mutated in 20%–30% of Wilms tumors with about 2/3 of these carrying deletions of the entire gene. WTX may act as a tumor suppressor by downregulating WNT/β-catenin signaling by causing degradation of β-catenin. Mutations in *CTNNB1* that increase WNT /β-catenin stability occur in approximately 15% of Wilms tumors. Thus, constitutive activation of WNT/β-catenin signaling may be important in Wilms tumorigenesis. About 3/4 of Wilms tumors with mutant *WT1* also have *CTNNB1* mutations, suggesting that WT1 loss does not fully activate WNT/β-catenin signaling.

Nephrogenic rests (small foci of persistent primitive blastemal cells) are found in the kidneys of all children with syndromic Wilms tumors and in 1/3 of sporadic cases. Given that such rests in the nontumorous kidney have the same somatic *WT1* mutations as are present in the tumors, these rests may represent clonal precursor lesions one or more steps along the pathway to tumor formation.

PATHOLOGY: Wilms tumors tend to be large when detected, with bulging, pale tan, cut surfaces enclosed by a thin rim of renal cortex and capsule (Fig. 22-90). Wilms tumors resemble normal fetal renal tissue (Fig. 22-91), including metanephric blastema, immature stroma (mesenchymal tissue) and immature epithelial elements.

Most Wilms tumors contain all three elements in varying proportions, but only two elements or even only one may be present on occasion. The blastema-like component contains small ovoid cells with scanty cytoplasm, in nests and trabeculae. The epithelial component appears as small tubular structures. Structures resembling immature glomeruli may sometimes be seen. The tumor stroma contains spindle cells, which are mostly undifferentiated but may show smooth muscle or fibroblast differentiation. Skeletal muscle is the most common heterotopic stromal element, although bone, cartilage, fat or neural tissue may rarely be encountered.

FIGURE 22-90. Wilms tumor. A cross-section of a pale tan neoplasm attached to a residual portion of the kidney.

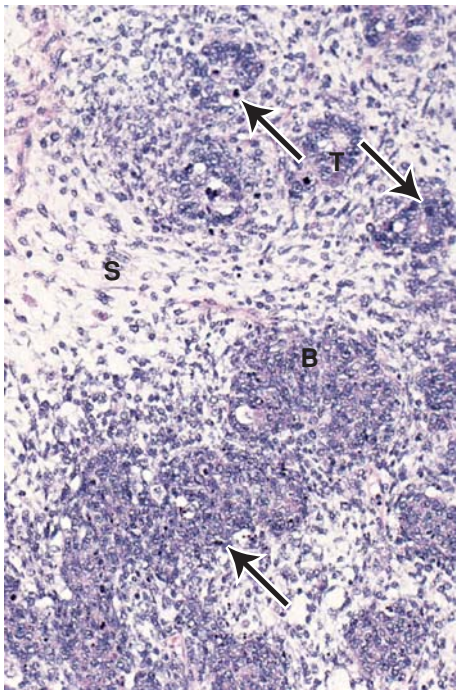

FIGURE 22-91. Wilms tumor (nephroblastoma). This Wilms tumor shows highly cellular areas composed of undifferentiated blastema (*B*), loose stroma (*S*) containing undifferentiated mesenchymal cells and immature tubules (*T*). Note the many mitotic figures (*arrows*).

CLINICAL FEATURES: Wilms tumors represent 85% of pediatric renal neoplasms. They occur in 1 in 10,000 children, usually 1–3 years old, and 98% present before age 10. Familial cases usually show autosomal dominant inheritance. Only 5% of sporadic cases are bilateral, in contrast to 20% of familial cases. Most often, diagnosis is made after recognition of an abdominal mass. Additional manifestations include abdominal pain, intestinal obstruction, hypertension, hematuria and symptoms of traumatic tumor rupture.

Several histologic and clinical parameters are used to predict the behavior of these tumors, with varying success. Patients younger than 2 years tend to fare better. Presence of tumor outside the renal capsule at the time of surgery is a negative prognostic sign. Anaplasia (large, hyperchromatic nuclei and atypical mitoses) occurs more commonly in older patients and correlates with their overall worse prognosis. Chemotherapy and radiation therapy, plus surgical resection, provide long-term survival rates of 90%.

Renal Cell Carcinoma Is the Most Common Primary Cancer of the Kidney

RCC is a malignant neoplasm of renal tubular or ductal epithelial cells. It accounts for 80%–90% of primary renal

cancers. More than 30,000 cases occur each year in the United States.

MOLECULAR PATHOGENESIS: Most RCCs are sporadic, but about 5% are inherited. Hereditary RCCs occur in the context of three distinct syndromes:

- **von Hippel-Lindau (VHL) syndrome,** an autosomal dominant cancer syndrome (see Chapter 5), with cerebellar hemangioblastomas, retinal angiomas, clear cell RCC (40% of cases of VHL disease), pheochromocytoma and cysts in various organs
- **Autosomal dominant RCC,** in which a clear cell tumor is the main manifestation and occurs in 1/2 of at-risk patients with genetic abnormalities like those in VHL syndrome
- **Hereditary papillary RCC,** an autosomal dominant inherited cancer characterized by multiple bilateral papillary tumors
- **Birt-Hogg-Dube (BHD) syndrome,** a hereditary disease with risk for bilateral, multifocal chromophobe RCC

Hereditary RCCs tend to be multifocal and bilateral, and appear in younger patients than do sporadic RCCs. A family history of RCC increases the risk for RCC four- to fivefold.

Several translocations involving a breakpoint on chromosome 3 contribute to VHL and autosomal dominant RCC syndromes. Patients with sporadic RCC may have deletions and LOH in the short arm of chromosome 3 (3p) in the tumor tissue. Finally, the *VHL* tumor suppressor gene is at 3p25. ***In virtually all (98%) sporadic clear cell RCCs, one VHL allele is lost;* VHL *mutations occur in more than 50% of these tumors.*** Thus, loss of *VHL* tumor-suppressor function plays a key role in clear cell RCC tumorigenesis.

Abnormal *VHL* gene function causes the transcriptional regulatory molecule, hypoxia-inducible factor-α (HIF-α), to accumulate. In turn, genes that make proteins that activate kinase-dependent signaling pathways are transcriptionally upregulated. Components of these pathways are targets for kinase inhibitors and mTOR (see Chapter 5) inhibitors that have proven useful for treating RCC.

Unlike clear cell RCC, hereditary papillary RCC is not linked to *VHL*. Trisomies or tetrasomies of chromosomes 7, 16 and 17, and loss of the Y chromosome, occur in many cases. Mutations in c-*met* proto-oncogene (*MET*) at 7q31 are implicated in the development of hereditary papillary RCC.

Chromophobe RCCs derive from intercalated cells of renal collecting ducts, and collecting duct RCCs originate in the ducts of Bellini of the medullary pyramids. Patients with BDH have germline inactivating mutations in the *BHD* gene, which produces folliculin (FLCN). These patients are at risk for developing bilateral, multifocal chromophobe RCCs.

Tobacco, whether smoked or chewed, increases the risk of RCC: 1/3 of RCCs are linked to tobacco use. Inherited and acquired renal cystic diseases may lead to RCC, especially papillary RCC. The cancer has also been tied to analgesic nephropathy.

PATHOLOGY: The pathologic variants of RCC reflect differences in histogenesis and predict different outcomes. The most common histologic categories of RCC are shown in Table 22-16.

TABLE 22-16
CATEGORIES OF RENAL CELL CARCINOMA

Category	Frequency (%)
Clear cell type	70–80
Papillary type	10–15
Chromophobe type	5
Collecting duct type	1

- **Clear cell RCC** is the most common type. It arises from proximal tubular epithelial cells. It is typically yellow-orange, solid or focally cystic, and focal hemorrhage and necrosis are common (Fig. 22-92). The removal of abundant cytoplasmic lipids and glycogen in tissue preparation accounts for the tumor cells' clear cytoplasm (Fig. 22-93). The cells are often arranged in round or elongated collections demarcated by a network of delicate vessels. Little cellular or nuclear pleomorphism is present.
- **Papillary RCC** contains tumor cells on fibrovascular stalks. Type 1 papillary RCC has small basophilic cells, and type 2 has large acidophilic cells. The latter is more aggressive, with a worse prognosis. Cytoplasm may be eosinophilic or basophilic. These tumors arise from proximal tubular epithelial cells (Fig. 22-94).
- **Chromophobe RCC** has a mixture of acidophilic granular cells and pale transparent cells with prominent cell borders, which impart a plant cell–like appearance (Fig. 22-95). Many cytoplasmic vesicles are filled with a distinctive mucopolysaccharide that stains with the Hale colloidal iron technique. These vesicles displace other organelles to the periphery, causing central cytoplasmic pallor. Chromophobe RCCs appear to arise from intercalated cells of the renal collecting ducts.

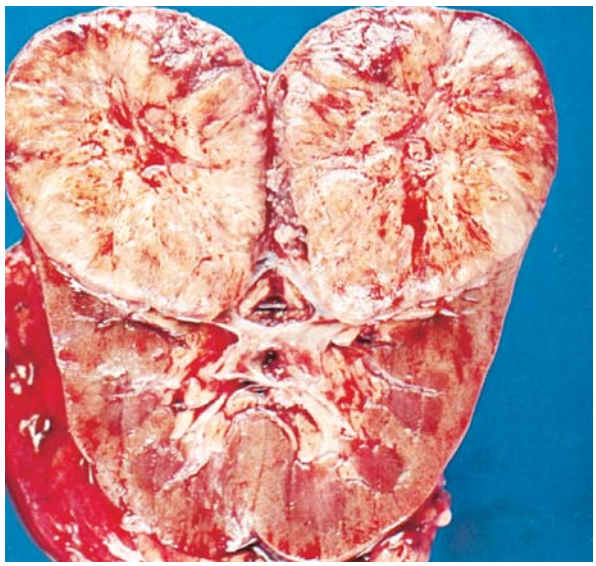

FIGURE 22-92. Clear cell renal cell carcinoma. The kidney contains a large irregular neoplasm with a variegated cut surface. Yellow areas correspond to lipid-containing cells.

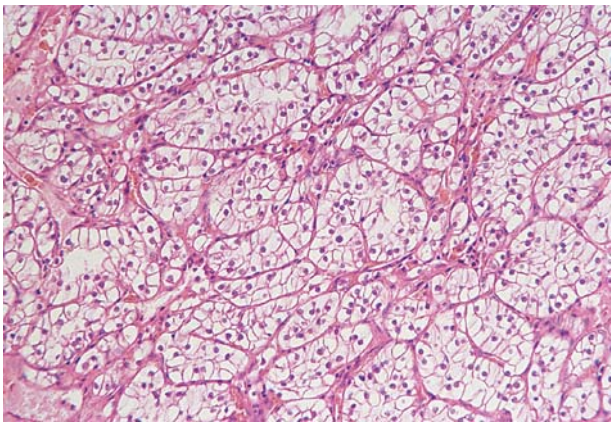

FIGURE 22-93. Clear cell renal cell carcinoma. Photomicrograph showing islands of neoplastic cells with abundant clear cytoplasm.

- **Collecting duct RCC** is a rare variety that originates in medullary collecting ducts (ducts of Bellini) but may extend into the cortex. It contains tubular and papillary structures lined by a single layer of cuboidal cells with a hobnail appearance. Renal medullary carcinomas are variants of collecting duct carcinomas that develop almost exclusively in blacks who have sickle cell trait or disease.
- **"Sarcomatoid" changes** may occur in any RCC and carry a worse prognosis.

Recommended histologic grading for RCC applies the Fuhrman system:

- **Grade I:** Nuclei round, uniform, 10 µm; nucleoli inconspicuous or absent
- **Grade II:** Nuclei irregular, 15 µm; nucleoli evident
- **Grade III:** Nuclei very irregular, 20 µm; nucleoli large and prominent
- **Grade IV:** Nuclei bizarre and multilobated, 20 µm or more; nucleoli prominent

CLINICAL FEATURES: RCC incidence of peaks in the sixth decade, and the tumor occurs twice as often in men as in women. ***Hematuria is the most common presenting sign, but incidental discoveries are common, in imaging studies of the abdomen done for other reasons. The classic clinical triad of hematuria, flank pain and a palpable abdominal mass occurs in fewer than 10% of patients.*** RCC is known as a "great mimic," and it produces ectopic hormones that may cause fever and paraneoplastic syndromes. For example, secretion of a PTH-like substance leads to symptoms of hyperparathyroidism, production of erythropoietin causes erythrocytosis and RCC secretion of renin results in hypertension. Patients with RCC often come to medical attention because of symptoms from a metastasis. A sudden convulsion or a cough in a previously healthy person leads to discovery of an unsuspected tumor in the brain or lung, which on further examination proves to be RCC.

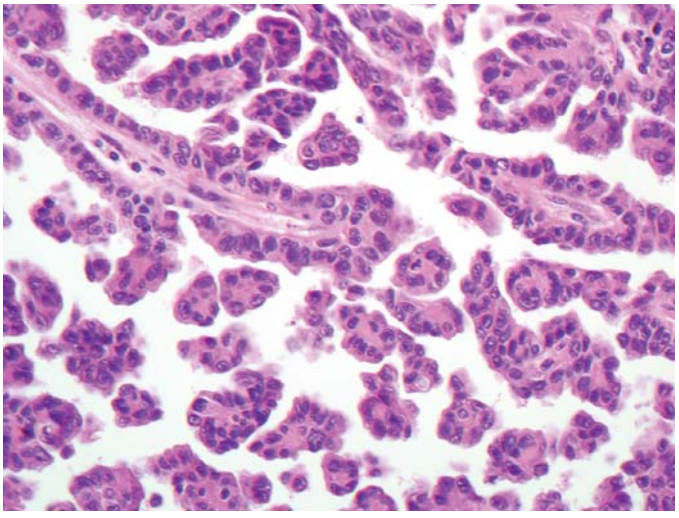

FIGURE 22-94. Papillary renal cell carcinoma. Photomicrograph showing papillary fronds covered by neoplastic cells.

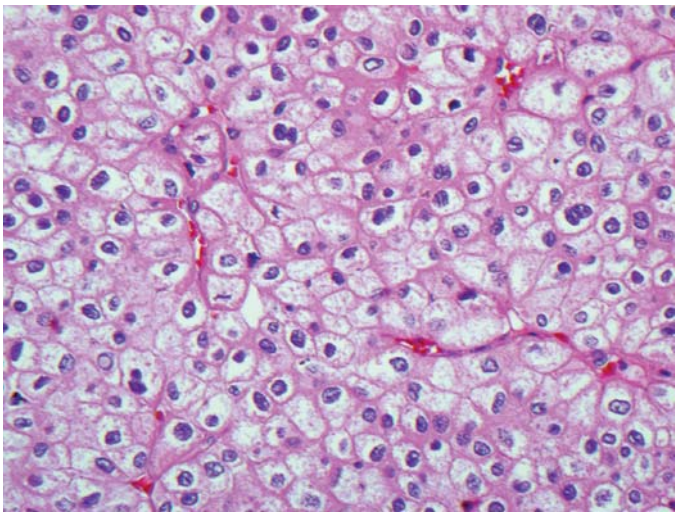

FIGURE 22-95. Chromophobe renal cell carcinoma. Photomicrograph showing pale acidophilic granular cells with prominent cell borders.

Prognosis for RCC reflects tumor size, extent of invasion and metastasis, histologic type and nuclear grade. Patients whose tumors show prominent sarcomatoid features rarely survive more than 1 year. By contrast, 1-year survival after nephrectomy for clear cell RCC is 50%. Papillary and chromophobe types have better prognoses than clear cell tumors, whereas collecting duct tumors have a worse prognosis. ***Tumor stage is the single most important prognostic factor.*** If RCC remains inside the renal capsule, 5-year survival is 90%. This drops to 30% if there are distant metastases. The tumor spreads most frequently to the lungs and bones.

Renal medullary carcinomas are rapidly growing neoplasms that are almost always associated with sickle cell disease.

Transitional Cell Carcinoma

Between 5% and 10% of primary kidney cancers are transitional cell carcinomas of the pelvis or calyces (see Chapter 23). These are morphologically identical to the more common transitional cell carcinomas of the urinary bladder and are associated with them in 1/2 of cases. Fewer than 5% of transitional cell carcinomas occur in the collecting system proximal to the bladder.

Anatomy and Embryology

LOWER URINARY TRACT

The ureters, urinary bladder and urethra—collectively known as the lower urinary tract—are the outflow part of the urinary system (Fig. 23-1). In males, the lower urinary tract is closely related to the reproductive system.

The Urinary Bladder Is in the Retroperitoneal Space of the Lower Abdomen

In males, the urinary bladder is anterior to the rectum and superior to the prostate. In females, it is anterior to the lower uterine corpus and anterior vaginal fornix.

The bladder is subdivided anatomically into the apex (dome), midportion and base, the last comprising the trigone and bladder neck. The apex is located behind the symphysis pubis and is linked in the midline to the umbilicus by the umbilical ligament, a fibrous remnant of the fetal **urachus**. The bladder neck in males rests on the upper surface of the prostate, where the smooth muscle fibers of the two organs intertwine. Inside the bladder, the **trigone** is the triangular area at the posterior aspect of the bladder base. It lacks mucosal folds and appears flattened. Superiorly, the trigone is bound by a muscular ridge joining the laterally placed orifices of the ureters. The inferior tip of the trigone is formed by the funnel-shaped internal orifice of the urethra.

The Ureters Are in the Posterior Retroperitoneal Space, Lateral to the Vertebrae

The ureters are paired organs linking each renal pelvis to the bladder. The lowermost part of the ureters is obliquely embedded in the smooth muscular wall of the urinary bladder, which acts as sphincters known as the **ureterovesical**

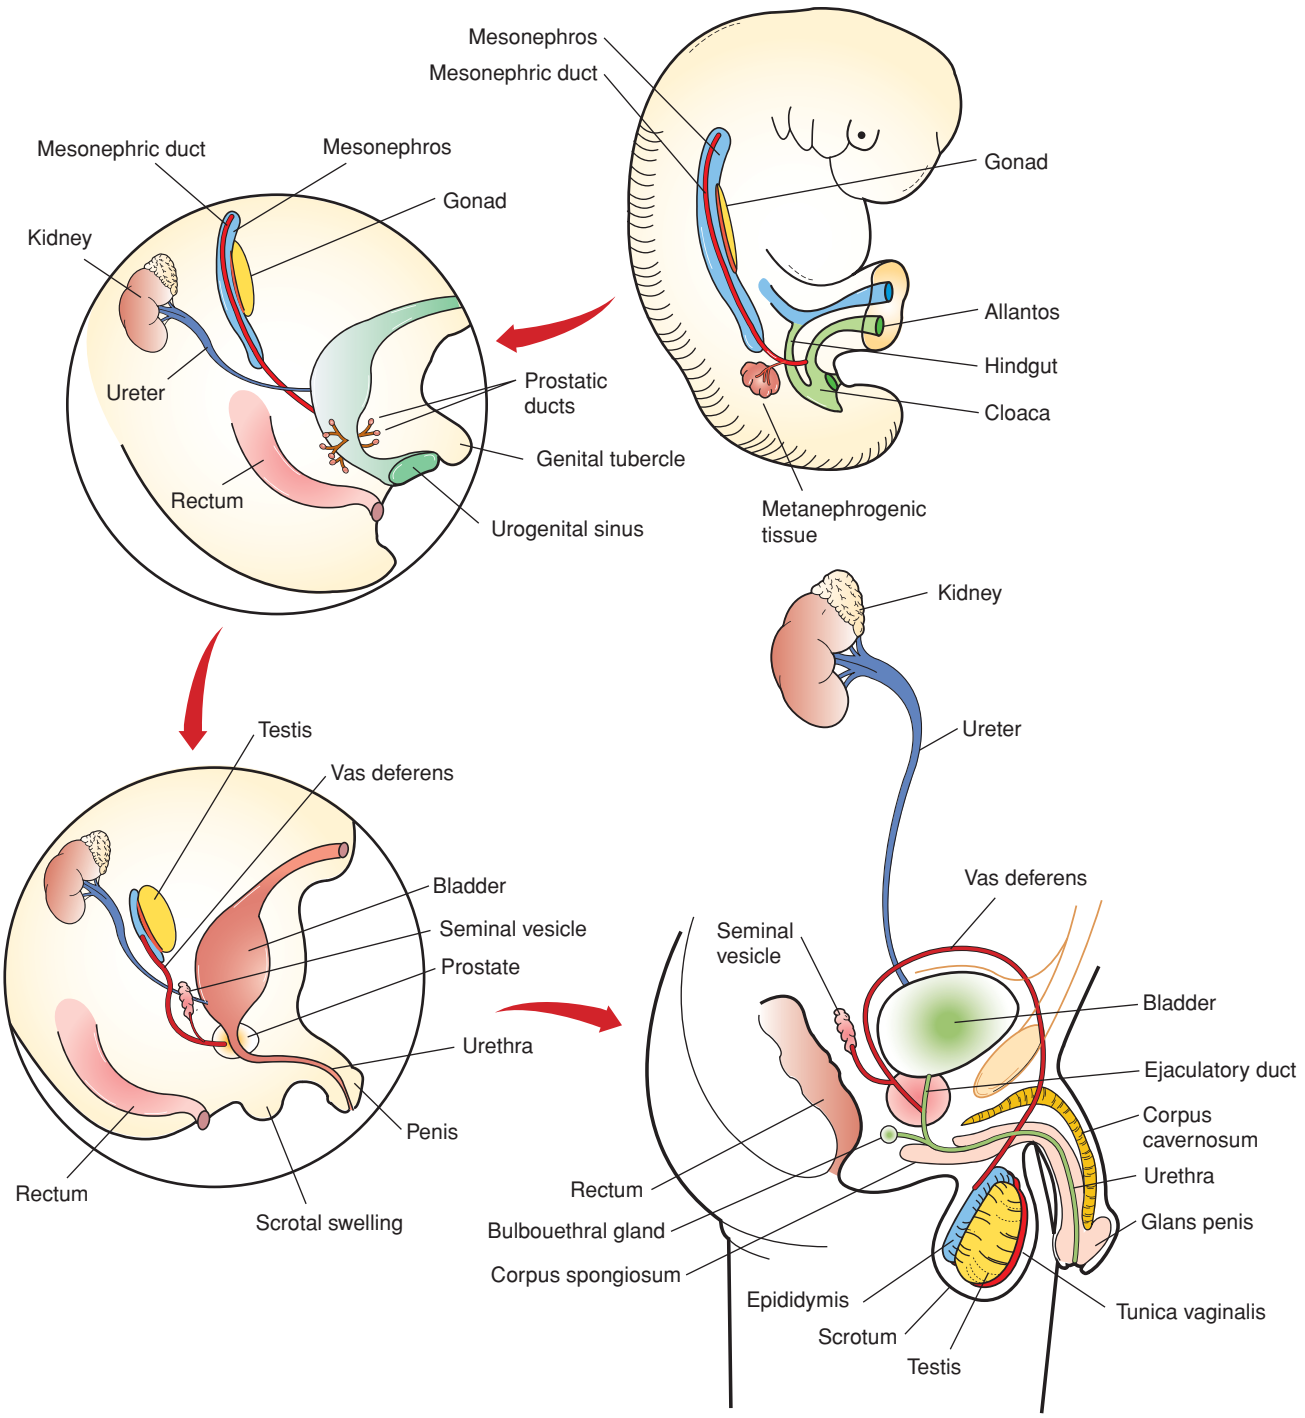

FIGURE 23-1. Embryologic development of the urinary tract and male reproductive system.

valves. These valves let urine pass downward into the bladder but not in the opposite direction.

The Urethra Is the Terminal Outflow Conduit of the Urinary Tract

The male urethra averages 20 cm long and has three parts: (1) **prostatic urethra,** traversing the prostate; (2) **membranous urethra,** penetrating the pelvic floor; and (3) **spongy or penile urethra,** in the central portion of the penis. The prostatic urethra contains ostia of the ejaculatory and prostatic ducts. The posterior part of the penile urethra, also called the **bulbous urethra,** receives secretions from the mucous bulbourethral (Cowper) glands. The anterior part of the penile urethra contains scattered mucus-secreting glands of Littré. The penile urethra terminates in the fossa navicularis, just proximal to the external orifice, or meatus, on the tip of the penis.

The female urethra is shorter, only 3–4 cm in length. It extends from its internal orifice at the urinary bladder to its external orifice in the vulva, immediately below the clitoris. The wall of the female urethra also contains mucous glands.

Transitional Epithelium (Urothelium) Lines the Ureters, Bladder and Posterior Urethra

The urothelium has three epithelial zones. The **basal layer** lies on a basement membrane and contains cells that can divide and replace damaged superficial cells. Above the basal layer is the **intermediate zone,** 3–4 layers of polygonal cells. Both basal and polygonal cells can flatten when the bladder dilates. The **superficial layer** consists of "umbrella cells," which are resistant to the urine that constantly bathes them.

Under the epithelium, the lamina propria contains mainly loose connective tissue, smooth muscle cells and blood vessels. The muscularis mucosa is poorly developed and consists of thin discontinuous wisps of smooth muscle cells. Beyond the lamina propria lies a thick smooth muscle layer, covered by adventitia. Since the bladder, ureters and urethra are retroperitoneal, they do not have an external serosa. Only part of the bladder dome has a serosal covering.

The Lower Urinary Tract Develops Mostly from the Cloaca

The **cloaca** is a fetal structure that is partitioned early in ontogenesis into an anterior part, the **urogenital sinus,** and a posterior part, which is the primordium of the rectum (Fig. 23-1). The urogenital sinus is the anlage of the urinary bladder, proximal urethra and **urachus,** the latter being a temporary fetal structure that connects the urinary tract and umbilicus. Caudally, the urogenital sinus makes contact with an invagination of the urogenital membrane, to form the urethra. The urachus gradually involutes into the umbilical ligament. The fetal urinary bladder forms symmetrical lateral **ureteric buds** that grow cranially. When these epithelial buds reach the nephrogenic zone, they induce formation of the metanephros, the kidney primordium.

MALE REPRODUCTIVE SYSTEM

The male reproductive system includes the testis, epididymis, ductus (vas) deferens, seminal vesicles, prostate and penis (Fig. 23-1).

Testes Are Linked to the Epididymis and are Located in the Scrotum

Testes are paired oval organs measuring 4 × 3 × 3 cm. Each is invested with a **tunica vaginalis,** a layer of mesothelial cells that covers the outer fibrous capsule of the testis, which is called the **tunica albuginea**. This capsule has internal septal ramifications that divide the testis into about 250 **lobules**. Each lobule consists of coiled seminiferous tubules and loose interstitial tissue containing blood vessels and Leydig interstitial cells.

Testicular arteries originate from the abdominal aorta and nourish the testes. The right internal spermatic vein empties into the inferior vena cava, while the left drains into the left renal vein. This anatomic difference has several clinical implications discussed below.

Spermatogenesis Occurs in the Seminiferous Tubules

These tubules are the principal functional unit of the testes. They contain seminiferous epithelium and **Sertoli cells,** which support spermatogenesis. Sertoli cells also secrete **inhibin,** which communicates with the pituitary to regulate secretion of **gonadotropins** (i.e., follicle-stimulating hormone [FSH] and luteinizing hormone [LH]). The interstitial spaces of the testis contain **Leydig cells,** the primary source of testosterone.

In prepubertal testes, seminiferous tubules contain primitive **germ cells** (spermatogonia) and Sertoli cells. At puberty, LH stimulates testosterone production by Leydig cells to initiate spermatogenesis, and FSH acts on germ cells and Sertoli cells to drive spermatogenesis.

Hormonal stimuli increase numbers of germ cells, primarily **spermatogonia,** which also begin differentiating into **primary spermatocytes.** Meiotic division of the diploid primary spermatocytes produces **secondary spermatocytes,** which carry a haploid number (23) of chromosomes. Secondary spermatocytes mature to **spermatids,** and then to **spermatozoa,** which are discharged through the channels of rete testis into the epididymal ducts.

The **epididymis** lies along the lateral–posterior aspect of the testis and extends into the ductus deferens. In the epididymis, spermatozoa are admixed with fluid secreted by epididymal lining cells and travel through the **vas deferens,** which empties its contents into the urethra. Finally, semen is ejaculated through the penile urethra as a mixture of spermatozoa in epididymal secretions and fluids made by **accessory glands,** namely, the seminal vesicles, prostate, Cowper bulbourethral glands and urethral glands.

The Prostate Is an Accessory Gland Located in the Pelvis

It contacts the posterior and inferior external layers of the urinary bladder, close to the rectum. Posteriorly it is attached to **seminal vesicles**. Microscopically it is a tubuloalveolar gland with a rich fibromuscular stroma. It develops under the influence of testosterone, which is essential for maintaining its production of seminal fluid.

Functionally, the prostate is organized into three distinct zones. The **transition zone** is around the prostatic urethra. The **central zone** sits slightly posterior and extends toward the seminal vesicles. The **peripheral zone** envelops the other zones and defines the boundaries of the gland. Precise anatomic boundaries of the zones may be inapparent by light microscopy. However, the biological discrimination between the zones is important, as most cancers arise in the peripheral zone, while hyperplasias generally originate in the transition zone.

The gland lacks a true **capsule**. In some areas, there is a concentric band of fibromuscular tissue that blends into the adjacent glandular stroma. In the apex of the prostate, the capsular plane of dissection is essentially inseparable from the adjacent soft tissue. Thus, what constitutes capsular invasion by tumor is somewhat arbitrary, which carries important implications in cancer staging for the surgeon who removes the organ and for the pathologist assessing the extent of disease.

The Male Genital System Develops from Several Primordia

The testes develop from **genital ridges,** which occur on the posterior surface of the celomic cavity. These ridges are populated by migratory **primordial germ cells** (initially

formed in the yolk sac) that enter the fetal body through the midline, then migrate laterally into the right and left genital ridges. Complex interactions of germ cells and stromal cells in the genital ridges lead to formation of the fetal testes on the posterior wall of the midabdomen. At the same time, the testes connect with the future epididymis and vas deferens, which develop from the **wolffian ducts**. At that point the testes begin a gradual descent into the inguinal canal to the scrotum.

The scrotum and penis develop simultaneously with the testes but from a different anlage that corresponds mostly to the genital tubercle and partly to the anterior urogenital sinus. These primordia of the external genital organs are initially identical in both sexes. In a male fetus, testosterone drives their development into penis, penile urethra and scrotum; in a female fetus, they become clitoris, labia minora and labia majora.

Renal Pelvis and Ureter

CONGENITAL DISORDERS

Developmental anomalies of the renal pelvis and ureters occur in 2%–3% of all people. They do not usually cause clinical problems, but on occasion may predispose to obstruction and urinary tract infections. The most important developmental anomalies include agenesis, ectopia, duplications, obstructions and dilations (Fig. 23-2).

AGENESIS OF THE RENAL PELVIS AND URETERS: This rare anomaly always entails agenesis of the corresponding kidney. Unilateral agenesis is usually asymptomatic. Bilateral agenesis of ureters and kidneys, a feature of **Potter syndrome,** is incompatible with extrauterine life (see Chapter 22).

ECTOPIC URETERS: Ureteric buds may develop at the wrong anatomic site during embryogenesis. The lower orifices of ectopic ureters can be found in many anomalous places, such as the midportion of the urinary bladder, seminal vesicles, urethra or vas deferens.

DUPLICATIONS: Ureteral duplication is the most common congenital abnormality of the urinary system. Duplicate or multiple ureteric buds may originate on the side of the fetal bladder and may be unilateral or bilateral, complete or partial. Usually there are two parallel ureters, each with its own renal pelvis and separate vesical orifice. **Bifid ureters** (subdivided by a septum), **bifurcate ureters** and many variations thereof may be encountered, but most are of no clinical significance.

URETERAL OBSTRUCTION: Obstructions can be traced to congenital **atresia** or abnormal **ureteral valves**. However, congenital **obstruction of the ureteropelvic junction (UPJ),** which is the most common form of hydronephrosis in infants and children, is thought to be related to abnormal layering of smooth muscle cells and/or fibrous tissue replacing the smooth muscle cells at the UPJ. Urinary obstruction in these children is usually unilateral but is bilateral in 20% of cases. Obstruction is more common in boys than girls and is usually diagnosed during the first 6 months of life. Congenital UPJ obstruction is often associated with other urinary tract anomalies, including, in some cases, agenesis of the contralateral kidney.

DILATIONS OF THE RENAL PELVIS OR URETERS: If dilations of the renal pelvis or ureters are localized, they are called **diverticula**. Generalized dilation of the entire ureter, **congenital megaureter,** may be unilateral or bilateral. Affected ureters are tortuous and lack peristalsis. Resulting stagnation of urine **(hydroureter)** is typically associated with progressive hydronephrosis, ultimately leading to renal failure.

URETERITIS AND URETERAL OBSTRUCTION

Ureteritis, or inflammation of the ureters, is a complication of descending infections from the kidneys or ascending infections due to vesicoureteric reflux. Ureteritis is often associated with ureteral obstruction, which may be intrinsic or extrinsic (Fig. 23-3).

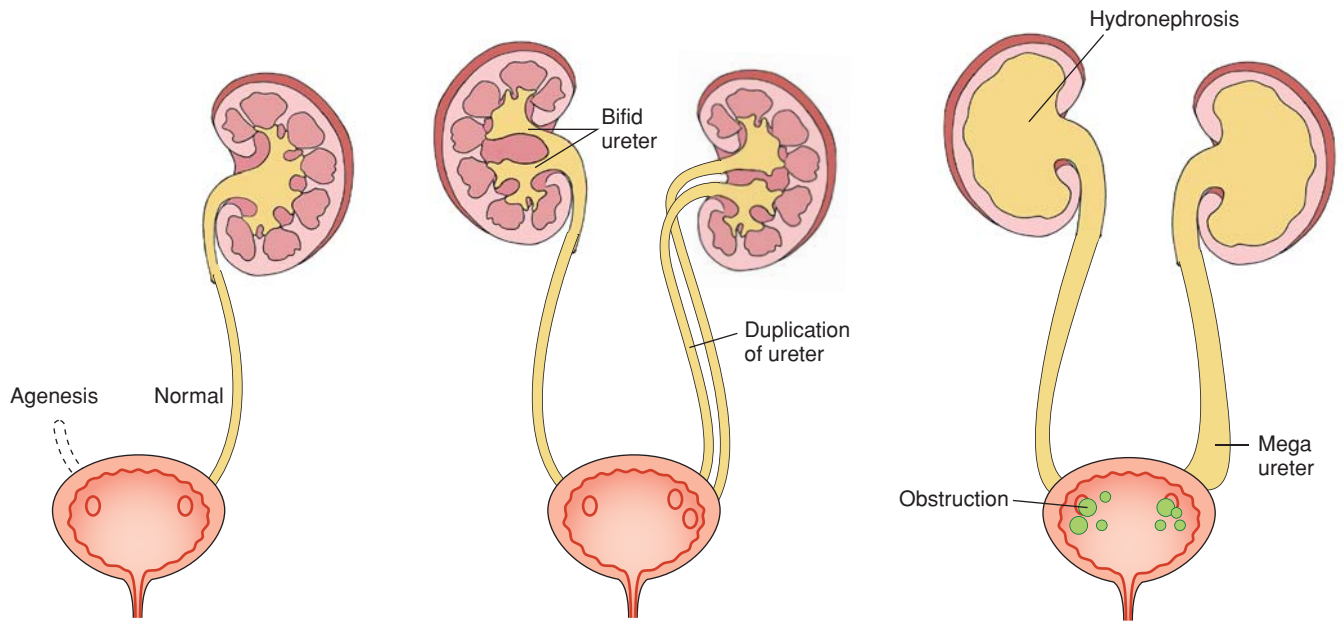

FIGURE 23-2. Anomalies of the renal pelvis and ureters.

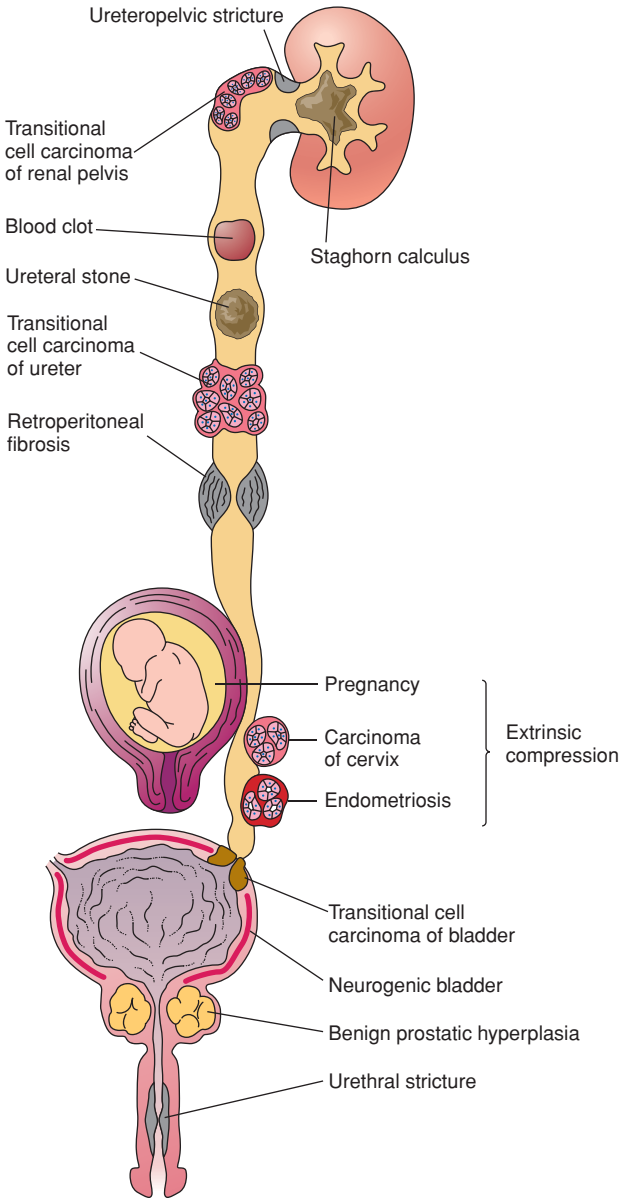

FIGURE 23-3. Most common causes of ureteral obstruction.

Intrinsic ureteral obstruction may be caused by calculi, intraluminal blood clots, fibroepithelial polyps, inflammatory strictures, amyloidosis or tumors of the ureter.

Extrinsic causes of ureteral obstruction include the enlarged uterus during pregnancy, aberrant renal vessels to the lower pole of the kidney that cross the ureter or endometriosis. Tumors that compress the ureters usually originate from the digestive and female genital tracts, and may compress the ureters by direct extension or through metastases to retroperitoneal lymph nodes.

Ureteral obstruction can also result from diseases of the urinary bladder, prostate and urethra (e.g., bladder cancer near a ureteral orifice or bladder neck, neurogenic bladder and prostatic hyperplasia or cancer). Proximal causes of ureteral obstruction tend to be unilateral, while more distal ones, such as prostatic diseases, lead to bilateral hydronephrosis, with the possibility of renal failure in untreated cases.

Idiopathic retroperitoneal fibrosis (Ordmond disease) is a rare cause of ureteral obstruction, with dense fibrosis of retroperitoneal soft tissues and modest, nonspecific, chronic inflammation. On occasion, idiopathic retroperitoneal fibrosis is accompanied by inflammatory fibrosis in other areas, including Riedel struma (thyroid), primary sclerosing cholangitis (liver) and mediastinal fibrosis. Some of these multisystemic cases are associated with elevated serum immunoglobulin G4 (IgG4), and thus belong to the group of **IgG4-related diseases**. The fibrotic lesions are infiltrated with IgG4-positive plasma cells, which play an undefined pathogenetic role in the genesis of fibrosis. The disease may respond to treatment with corticosteroids or immunosuppression. **Secondary retroperitoneal fibrosis** resembles the idiopathic form of the disease clinically and pathologically and may evolve as a complication of surgery or radiation therapy, or as an adverse reaction to certain drugs such as methysergide or β-adrenergic blockers.

TUMORS OF THE RENAL PELVIS AND URETER

Tumors of the renal pelvis and ureter resemble those of urinary bladder (see below) except that they are 1/10 as common. Most (>90%) are **urothelial (transitional) cell carcinomas**. Etiologies associated with such tumors of the renal pelvis and ureter are similar to those found in bladder cancer, suggesting a "field effect" in which the entire urothelial mucosa is a continuous "target organ." About 2%–4% of tumors are bilateral, and almost half of treated patients develop subsequent urothelial bladder tumors.

CLINICAL FEATURES: Patients most often present in their sixth and seventh decades with hematuria (80%) and flank pain (25%). Urothelial cell carcinoma of the ureter or renal pelvis requires radical nephroureterectomy. The entire ureter must be removed because of the high frequency of concurrent and subsequent urothelial carcinomas. Prognosis reflects tumor stage at the time of diagnosis.

Urinary Bladder

CONGENITAL DISORDERS

Congenital developmental malformations of the urinary bladder include (1) bladder exstrophy, (2) diverticula, (3) urachal remnants and (4) congenital vesicoureteral valve incompetence.

EXSTROPHY OF THE BLADDER: This malformation is characterized by absence of the anterior bladder wall and part of the anterior abdominal wall. It occurs in 1 in 50,000 births. In some boys it is associated with **epispadias** (i.e., incomplete formation of the penile urethra).

Bladder exstrophy results from incomplete resorption of the anterior cloacal membrane. In normal embryogenesis, this membrane is replaced by smooth muscle, but if it persists, it forms the anterior vesical wall. As the membrane is thin, it ultimately ruptures to leave a large defect that is accompanied by defective closure of the anterior abdominal muscular wall. These two defects expose the posterior bladder wall to the exterior and transform the bladder into a cup-like organ that cannot hold urine (Fig. 23-4). The posterior wall of the exstrophic bladder is exposed to mechanical

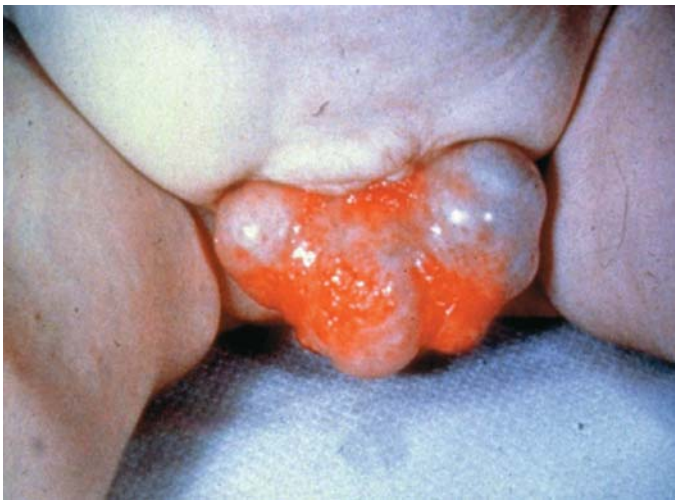

FIGURE 23-4. Exstrophy of the urinary bladder.

injury and prone to frequent infection, causing squamous or glandular metaplasia. Exstrophy can be surgically repaired, but the metaplastic mucosa is at increased risk of bladder cancer, even 50 to 60 years after surgical repair of exstrophy.

DIVERTICULA: These sac-like outpouchings of bladder wall are related to incomplete formation of muscular layers. They can be solitary or multiple. Urine retained inside such diverticula is commonly infected, which may lead to urinary stone formation. Congenital diverticula must be distinguished from **acquired vesical diverticula,** which typically occur in long-standing urinary tract obstruction due to prostatic hyperplasia in adults.

URACHAL REMNANTS: The urachus is the fetal allantoic stalk connecting the bladder and umbilicus. *If it persists and remains patent throughout, it forms a* ***vesical–umbilical fistula***. Incomplete regression of the urinary end, midportion or umbilical end of the urachus leads to a **urachal diverticulum, umbilical–urachal sinus** or **urachal cyst,** respectively. The columnar epithelium of urachal remnants may give rise to **adenocarcinoma**. Only 0.2% of bladder cancers—but one third of bladder adenocarcinomas—arise in such remnants.

CONGENITAL VESICOURETERAL VALVE INCOMPETENCE: This anomaly results from an abnormal junction between the ureters and the urinary bladder. The ureters normally enter the bladder wall obliquely and have a long intravesical portion. The muscular layer of the bladder compresses the ureters and acts as a sphincter, to prevent backflow of urine into ureters. However, if ureters enter the bladder at right angles, they have a short intravesical segment that does not adequately prevent urine backflow during micturition. **Vesicoureteric reflux** (VUR) is more common in young girls than boys and is often familial. In 75% of cases, VUR is asymptomatic, but it may lead to reflux pyelonephritis. Congenital VUR is distinguished from acquired VUR that occurs during pregnancy or with bladder hypertrophy.

CYSTITIS

Cystitis is inflammation of the bladder. It may be acute or chronic. It is the most common urinary tract infection. Cystitis often occurs in hospitalized patients, especially those who have had indwelling bladder catheters.

ETIOLOGIC FACTORS: ***Cystitis is usually secondary to infection of the lower urinary tract.*** Factors related to bladder infection include a patient's age and gender, the presence of bladder calculi, bladder outlet obstruction, diabetes mellitus, immunodeficiency, prior instrumentation or catheterization, radiation therapy and chemotherapy. ***The risk of cystitis is greater in females because of a short urethra, especially during pregnancy.*** Bladder outlet obstruction due to prostatic hyperplasia predisposes men to cystitis. Instrumentation (cystoscopy) may also introduce pathogens into the bladder, and cystitis is especially common in patients in whom indwelling catheters remain for prolonged periods.

Coliform bacteria are the most common cause of cystitis, mostly *Escherichia coli, Proteus vulgaris, Pseudomonas aeruginosa* and *Enterobacter* spp. Tuberculosis of the bladder is rarely seen in the Western world today and almost always follows renal tuberculosis. Fungal cystitis may be seen in immunosuppressed patients. Gas-forming bacilli, usually in people with diabetes, may produce characteristic interstitial bubbles in the lamina propria of the urinary bladder **(emphysematous cystitis)**. Schistosomiasis as a common cause of cystitis in North Africa and the Middle East, where *Schistosoma haematobium* is endemic.

Iatrogenic cystitis is common after radiation therapy and chemotherapy. **Radiation cystitis** usually develops 4–6 weeks following radiation treatment of pelvic tumors, and is most often seen in patients with uterine, rectal or bladder cancer. Inflammation of the bladder is usually associated with epithelial cell atypia, which is usually transient and should not be mistaken for malignancy. Late consequences of radiation cystitis include extensive fibrosis, which may be transmural and incapacitating.

Drug-induced cystitis is most common after cyclophosphamide treatment, which typically produces hemorrhagic cystitis. Other cytotoxic drugs can also cause cystitis, but the injury is less prominent. These drugs also induce cytologic atypia, which is usually transient.

PATHOLOGY: Stromal edema, hemorrhage and a neutrophilic infiltrate of variable intensity are typical of acute cystitis (Fig. 23-5). Focal petechial mucosal hemorrhages **(hemorrhagic cystitis)** are often seen in acute bacterial cystitis. Bleeding diatheses (e.g., leukemia or treatment with cytotoxic drugs) and disseminated intravascular coagulation often cause extensive hemorrhagic cystitis. ***Acute cystitis that does not resolve is associated with chronic cystitis, including an infiltrate mainly of lymphocytes and plasma cells (Fig. 23-6), and fibrosis of the lamina propria.*** Occasionally, an inflamed bladder mucosa may contain lymphocytic follicles **(follicular cystitis)** or dense infiltrates of eosinophils **(eosinophilic cystitis)**. **Granulomatous cystitis** is characteristic of tuberculosis, but may also be seen in patients with bladder cancer treated with intravesical instillation of attenuated *Mycobacterium tuberculosis,* bacillus Calmette-Guerin (BCG). Ova of *Schistosoma hematobium* can cause simultaneous granulomatous reactions and eosinophilic infiltrates. Specific forms of chronic cystitis include:

- **Ulcerative cystitis:** Chronic irritation caused, for example, by indwelling catheters or traumatic cystoscopy may lead to ulceration and focal mucosal hemorrhage.

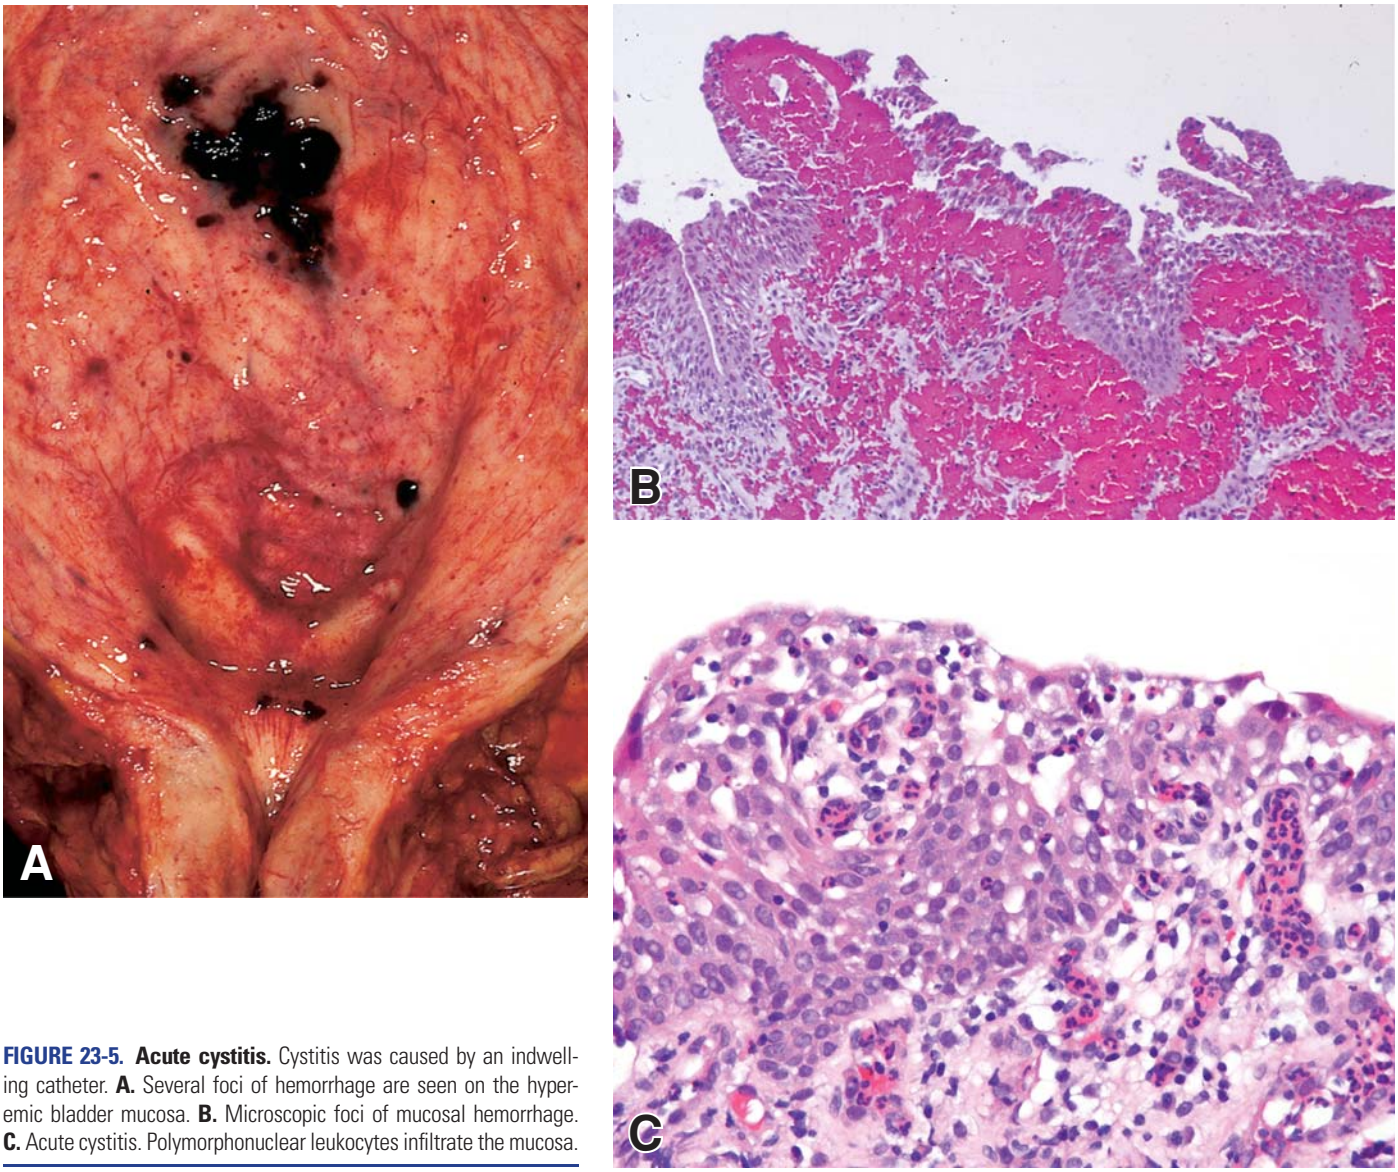

FIGURE 23-5. Acute cystitis. Cystitis was caused by an indwelling catheter. **A.** Several foci of hemorrhage are seen on the hyperemic bladder mucosa. **B.** Microscopic foci of mucosal hemorrhage. **C.** Acute cystitis. Polymorphonuclear leukocytes infiltrate the mucosa.

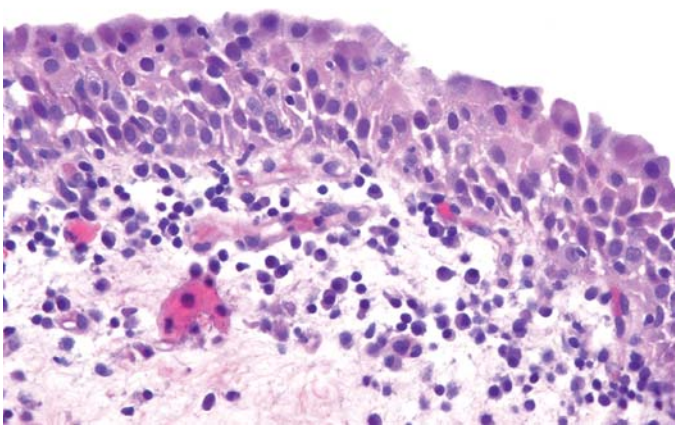

FIGURE 23-6. Chronic cystitis. A chronic inflammatory infiltrate of lymphocytes and plasma cells is present in the edematous lamina propria.

Solitary mucosal ulcer is also found in interstitial cystitis (see below).

- **Suppurative cystitis:** Pus may cover the bladder mucosa, fill the lumen or permeate the bladder wall. Suppurative cystitis may develop during local infection but more often is a complication of sepsis, pyelonephritis or purulent infections after bladder surgery.
- **Pseudomembranous cystitis:** Pseudomembranes—shaggy layers of necrotic, gray or yellow cell detritus; fibrin; inflammatory cells; and blood—sometimes cover the bladder mucosa. Underlying mucosa is hemorrhagic and ulcerated. Pseudomembranous cystitis typically complicates infections that follow treatment with cytotoxic drugs, such as cyclophosphamide.
- **Calcific cystitis:** This form of chronic inflammation is typically found in schistosomiasis. Calcification of ova produces bladder wall encrustations resembling grains of sand. These gradually coalesce, to transform the entire urinary bladder into a calcified rigid vessel.

CLINICAL FEATURES: Virtually all patients with acute or chronic cystitis complain of excessive urinary frequency, painful urination **(dysuria)** and lower abdominal or pelvic discomfort. The urine usually contains inflammatory cells, and the causative agent can be identified by culture. Most cases of acute cystitis respond well to treatment with antimicrobial agents. Recurrent and chronic cystitis may pose therapeutic problems.

CHRONIC INTERSTITIAL CYSTITIS: This persistent painful inflammation of the bladder affects over 100,000 middle-aged women in the United States. It is has no known cause, and presents with suprapubic pain, an urge for frequent urination, hematuria and dysuria. During cystoscopic dilatation of the bladder, the mucosa typically develops hemorrhagic cracks and petechial hemorrhages. Urine cultures are almost always negative. In chronic stages of the disease, transmural inflammation of the bladder wall is occasionally associated with mucosal ulceration **(Hunner ulcer)** (Fig. 23-7). Chronic inflammation, including fibrosis and increased mast cells, is common in the mucosa and muscularis. Hunner ulcers contain intense acute inflammation. The disease is typically persistent and refractory to therapy.

MALAKOPLAKIA (from the Greek, **malakos,** ***"soft";*** **plax,** ***"plaque"): This is an uncommon inflammatory disorder of unknown etiology***. Originally described in the bladder, malakoplakia may be seen in many other sites, within and outside the urinary tract. It occurs at all ages, with peak incidence in the fifth to seventh decades, and has a marked female preponderance.

Malakoplakia is often associated with urinary tract infection by *E. coli,* although a direct causal relationship is dubious. A clinical background of immunosuppression, chronic infections or cancer is common.

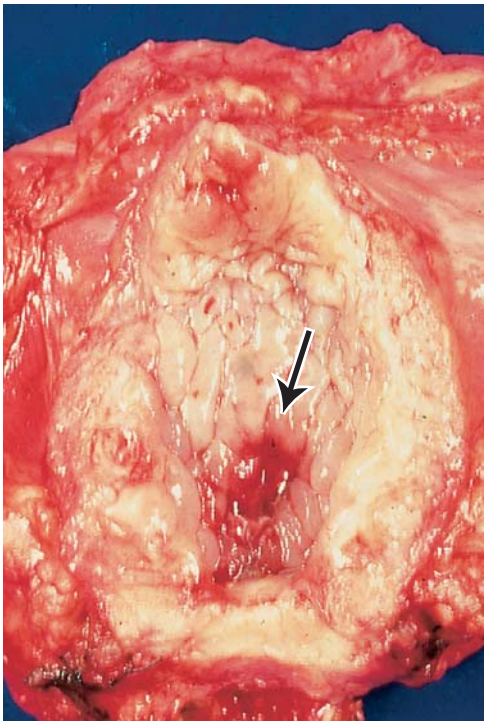

FIGURE 23-7. Interstitial cystitis. The hemorrhagic defect (*arrow*) in the edematous mucosa of the posterior wall of the bladder is clinically known as Hunner ulcer.

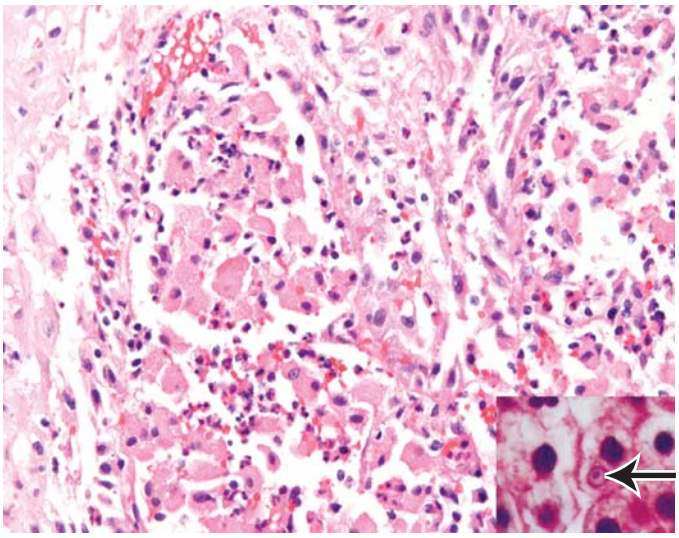

FIGURE 23-8. Malakoplakia. Inflammatory cells are mainly macrophages, with fewer lymphocytes. **Inset.** A Michaelis-Gutmann body (*arrow*) is seen at high magnification.

PATHOLOGY: Malakoplakia is characterized by soft, yellow plaques on the mucosal surface of the bladder. There is a striking chronic inflammatory cell infiltrate mainly of large macrophages with abundant, eosinophilic cytoplasm containing periodic acid–Schiff (PAS)-positive granules (Fig. 23-8). Ultrastructurally, these granules are engorged lysosomes that contain fragments of bacteria, suggesting that malakoplakia may reflect an acquired defect in lysosomal degradation. Some of these macrophages have laminated, basophilic calcospherites, called **Michaelis-Gutmann bodies,** caused by calcium salt deposition in the enlarged lysosomes.

The clinical symptoms of malakoplakia of the bladder are indistinguishable from those of other forms of chronic cystitis. Treatment is ineffective.

BENIGN PROLIFERATIVE AND METAPLASTIC UROTHELIAL LESIONS

Benign proliferative and metaplastic lesions of urothelium occur mostly in the urinary bladder but may be found anywhere in the urinary tract. These nonneoplastic lesions are characterized by hyperplasia (Fig. 23-9B) or combined hyperplasia and metaplasia, mostly in association with chronic inflammation due to urinary tract infections, calculi, neurogenic bladder and (rarely) bladder exstrophy. They may also occur without a known preexisting inflammatory condition.

- **Brunn buds** are bulbous invaginations of the surface urothelium into the lamina propria (Fig. 23-9C). They are found in over 85% of bladders and are considered normal variants of the urothelium. **Brunn nests** are similar to Brunn buds, but the urothelial cells are seen within the lamina propria, detached from the surface.
- **Cystic lesions of the urinary bladder (cystitis cystica)** appear as fluid-filled groups of cysts. Similar cysts can be seen in the urethra or ureter **(urethritis cystica, ureteritis cystica)** (Fig. 23-10). Cystitis cystica is found in 60% of otherwise normal bladders. Histologically, all these

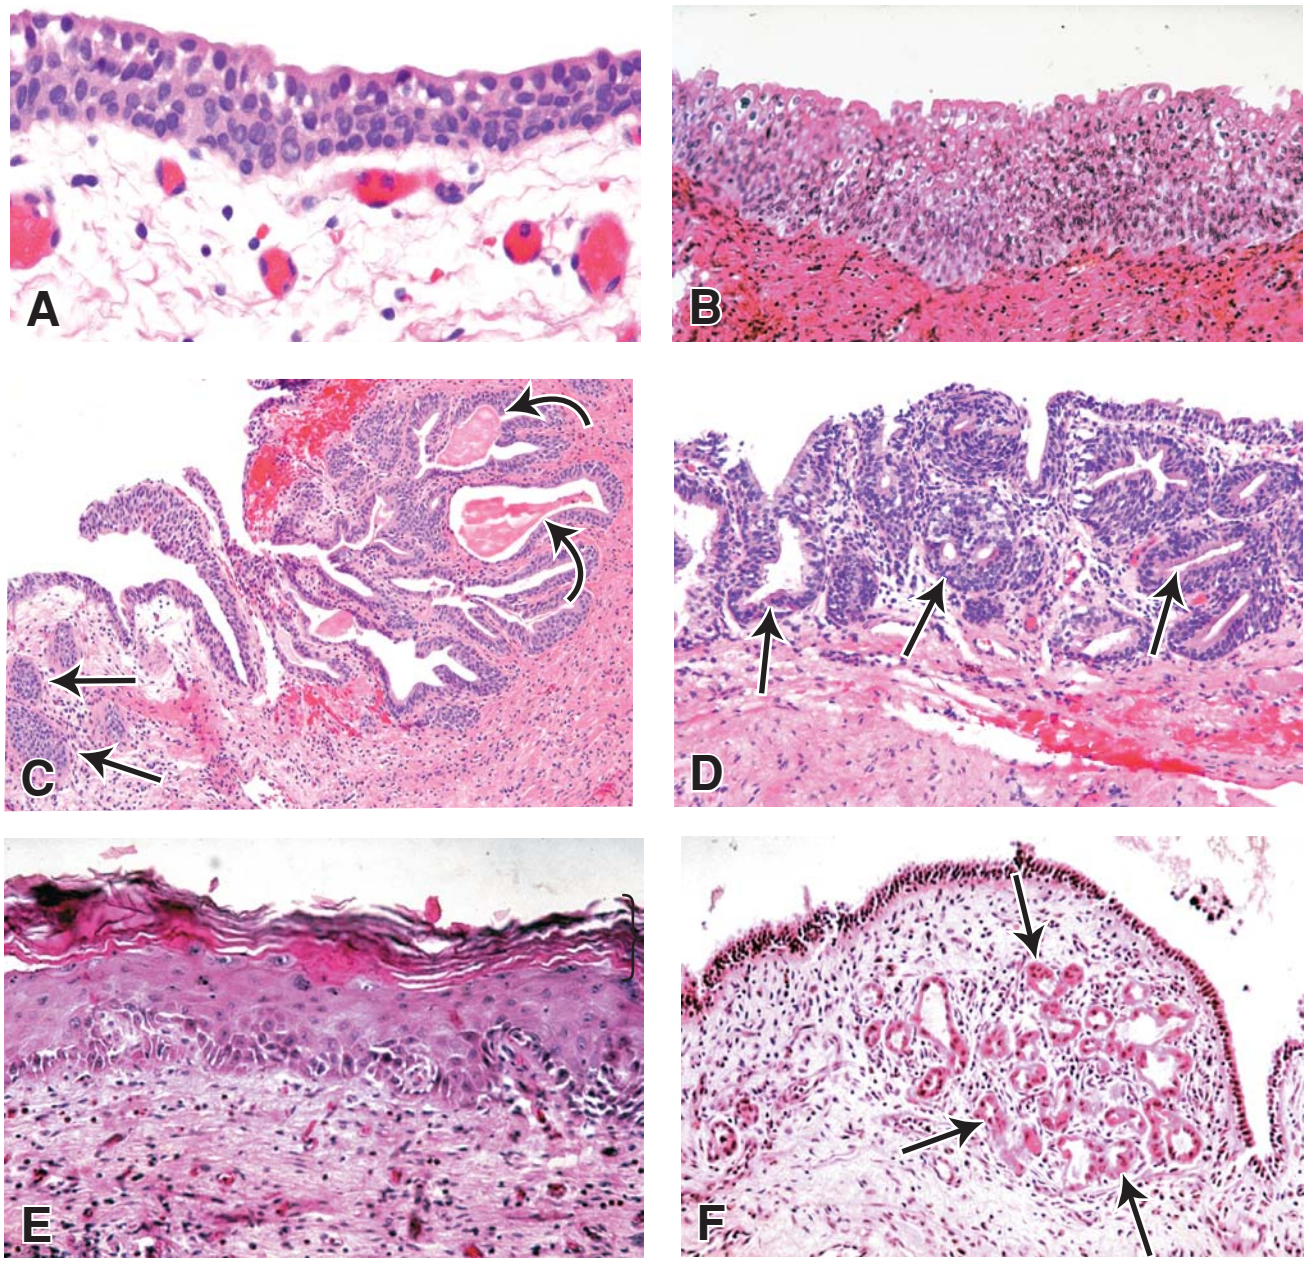

FIGURE 23-9. Proliferative and metaplastic changes of the urinary bladder. A. Normal bladder mucosa. B. Hyperplasia. Note the expansion of the normal 6–7 layers of urothelial cells. **C. Cystitis cystica.** Brunn nests (*straight arrows*) and cysts (*curved arrow*) protrude into the lamina propria. **D. Cystitis glandularis.** Metaplastic glandular mucosa is highlighted by the arrows. **E. Squamous metaplasia.** Note the keratinizing layer on the superficial epithelium (*bracket*). **F. Nephrogenic metaplasia** (*arrows*).

lesions correspond to cystic Brunn nests, lined by normal urothelium. Transitional epithelium may undergo metaplasia into mucus-secreting epithelium, which is then diagnosed as **cystitis glandularis** (Fig. 23-9D).

- **Squamous metaplasia** (Fig. 23-9E) is a reaction to chronic injury and inflammation and is particularly associated with calculi. It is seen in up to half of normal women and 10% of men.
- **Nephrogenic metaplasia** is a lesion caused by transformation of transitional epithelium to resemble renal tubules (Fig. 23-9F). It is most common in the urinary bladder but is also seen in the urethra and ureter. Many small tubules clustered in the lamina propria make a papillary exophytic nodule. The histogenesis is unclear, but some cases seem to result from implants of detached renal tubular cells carried downstream by urine. The lesion may produce tumor-like protrusions in the bladder, which may obstruct the ureters and require surgical treatment.

CLINICAL FEATURES: These proliferative and metaplastic urothelial lesions should not be confused with cancer. However, patients with such changes have higher risk of urothelial bladder carcinoma and, in the case of cystitis glandularis, of **adenocarcinoma** as well. Yet there is no evidence to suggest that these lesions themselves are preneoplastic.

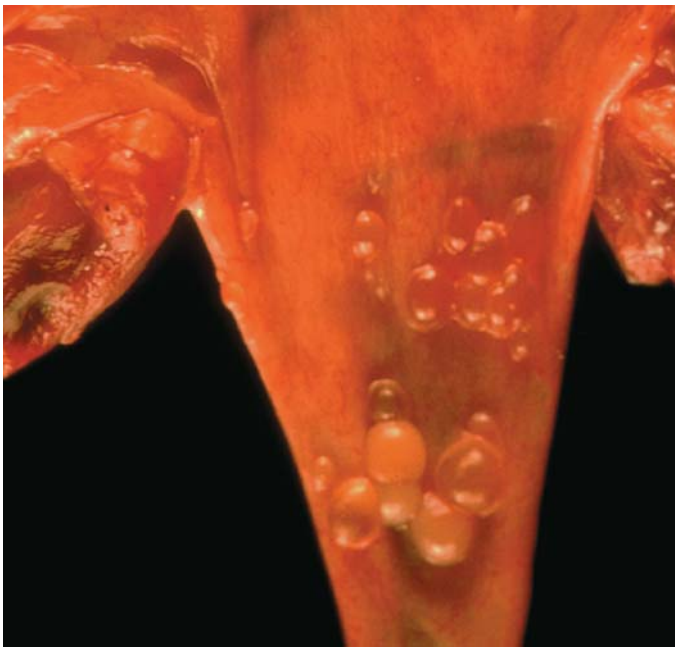

FIGURE 23-10. Ureteritis cystica. The mucosa of the proximal ureter exhibits small cystic structures.

TUMORS OF THE URINARY BLADDER

The most important facts about bladder cancer are:

- The urinary bladder is the most common site of urinary tract tumors.
- They mostly occur in older patients (median, 65 years) and are rare in patients under age 50.
- Tumors are much more common in men than in women.
- Most tumors (90%) are urothelial malignant neoplasms (formerly, "transitional cell" neoplasms). Squamous cell cancers, adenocarcinomas, neuroendocrine malignancies and sarcomas are rare.
- Tumors are often multifocal and can occur in any part of the urinary tract lined by transitional epithelium, from the renal pelvis to the posterior urethra.
- Local treatment is often followed by tumor recurrence.
- Tumor invasion into the muscularis propria markedly decreases the 5-year survival rate.

EPIDEMIOLOGY: Bladder cancer represents 7% of all new cancers in men and 2% in women. It accounts for 3% of all cancer-related deaths in men and less than 1% in women. Bladder cancer shows significant geographic and sex differences throughout the world. The highest frequencies are among urban whites in the United States and western Europe. It is less common in Japan and among American blacks.

A high incidence of bladder cancer in Egypt, Sudan and some other African countries is due to endemic schistosomiasis. Most schistosomiasis-related cases are squamous cell carcinomas.

Bladder cancer may occur at any age, but most patients (80%) are 50–80 years old. Men are affected three times as often as women. There is no genetic predisposition to bladder cancer and no hereditary factors have been identified in the vast majority of cases.

The most important risk factors are:

- Cigarette smoking (4-fold increased risk)
- Industrial exposure to azo dyes
- Infection with *S. haematobium* (in endemic regions)
- Drugs, such as cyclophosphamide and analgesics
- Radiation therapy (following cervical, prostate or rectal cancer)

ETIOLOGIC FACTORS: Bladder cancer following occupational exposure to certain organic chemicals was described in 1895 among workers in the German aniline dye industry and was subsequently confirmed in similar workers in the United States. This was one of the first occupational cancers known. Increased risk of bladder cancer was later noted in the leather, rubber, paint and organic chemical industries. Improved industrial hygiene has reduced this risk. ***Today, polycyclic hydrocarbons from cigarette smoke are the most important risk factor for bladder carcinoma.***

A role for chemicals in bladder cancer has been strengthened by the demonstration that β-naphthylamine, to which the dye industry workers were exposed, produces bladder cancer in dogs. The metabolism of naphthylamines explains their organ specificity. Arylamines are conjugated to glucuronic acid in the liver, and the conjugates are excreted in the urine. In the bladder, β-glucuronidase in acidic urine hydrolyzes the glucuronic acid conjugate, producing reactive arylnitrenium ions that act as mutagens by binding guanines in DNA.

MOLECULAR PATHOGENESIS: ***Specific cytogenetic abnormalities occur in 50% of bladder cancers.*** These often include deletion of chromosome 9 or its short (p) or long arm (q) (thus, 9p- or 9q-) and deletions of 11p, 13p, 14q or 17p, as well as aneuploidy of chromosomes 3, 7 and 17. Deletions within 9p, which contains the tumor suppressor gene ***p16,*** are the consistent findings in low-grade papillary tumors and flat carcinomas in situ. Deletions in 17p, the site of the tumor suppressor gene ***TP53,*** are often identified in invasive bladder cancers.

These genetic abnormalities suggest that cell cycle dysregulation due to mutated *p53* allows propagation of genetically abnormal urothelial cells. Unregulated proliferation reflects accumulated mutations in cyclin-dependent kinase inhibitors (e.g., p16/INK4a) or deletion of the tumor suppressor gene *RB1* (Fig. 23-11).

PATHOLOGY: Over 90% of all primary bladder tumors are epithelial tumors, mostly urothelial carcinomas. Neoplastic urothelial lesions arising from the bladder mucosa make up a spectrum. One end includes benign papillomas and low-grade exophytic papillary carcinomas and the other end is invasive transitional cell carcinomas and highly malignant tumors (Fig. 23-12). Other tumors (Table 23-1) are considerably less common.

Urothelial Papilloma Is a Rare Benign Tumor

These papillomas are usually discovered incidentally in men aged 50 or older, during cystoscopy for an unrelated condition or for painless hematuria. They represent less than 1% of bladder tumors and have two forms: classical exophytic papilloma and inverted papilloma.

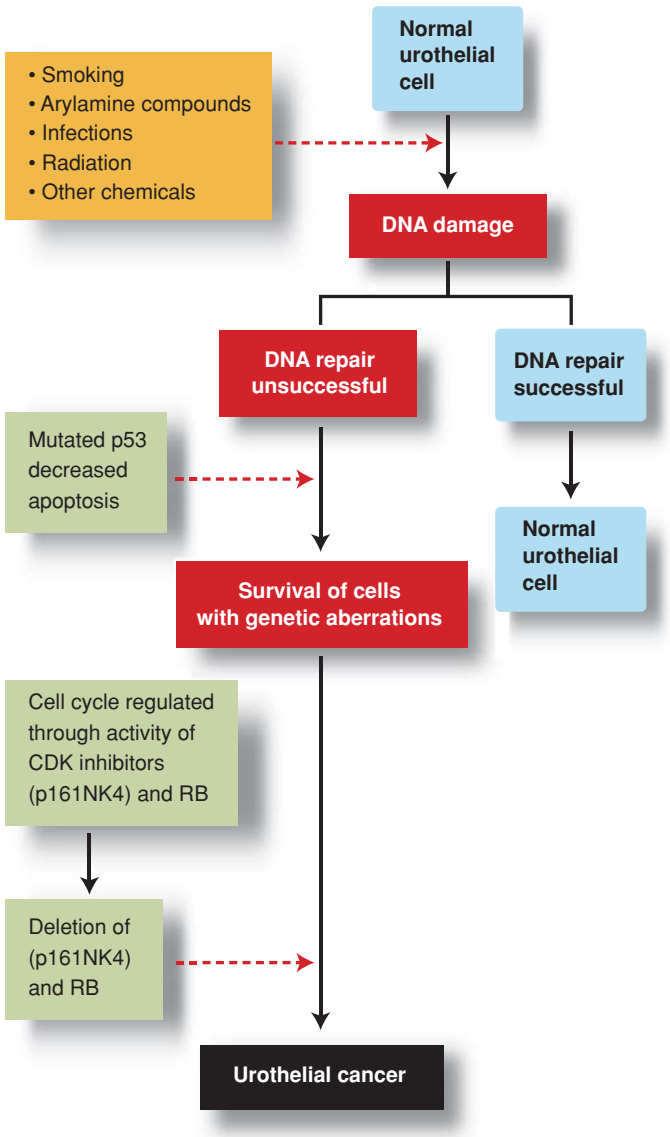

FIGURE 23-11. Hypothetical molecular model of urothelial neoplasms. The transition from normal urothelium to carcinoma occurs gradually in several steps.

Exophytic papilloma features papillary fronds lined by transitional epithelium, virtually indistinguishable from normal urothelium. On cystoscopy, most patients show single lesions 2–5 cm in diameter, but some tumors may be multiple. Although considered benign, some recur or progress to carcinoma, mandating regular follow-up. Most "recurrences" are new tumors that develop elsewhere in the urinary bladder.

Inverted papillomas are rare and typically present as nodular mucosal lesions, usually in the trigone area. They have also been observed in the renal pelvis, ureter and urethra. Inverted papillomas are covered by normal urothelium, from which cords of transitional epithelium descend into the lamina propria. These lesions are most common in men in their sixth and seventh decades. Hematuria of recent onset is the usual clinical presentation. Inverted papillomas are benign tumors and are usually cured by simple excision.

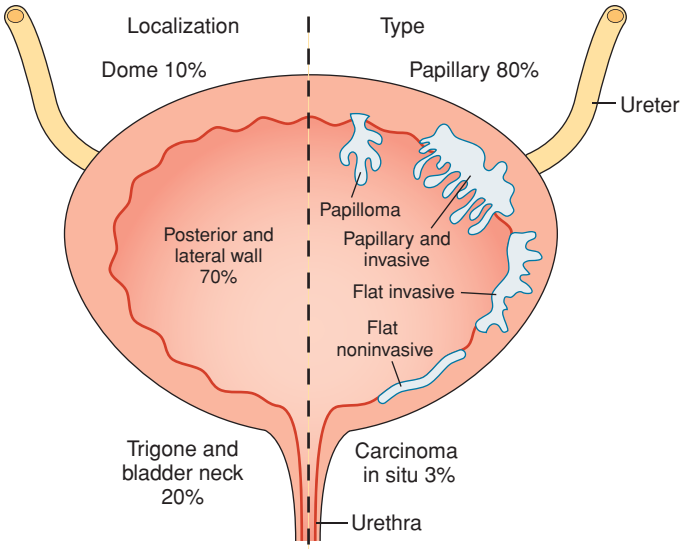

FIGURE 23-12. Urothelial neoplasms. Most tumors localize to the posterior and lateral walls; trigone and bladder neck are involved less often and the dome least. Malignant tumors may be papillary or flat. Both flat and papillary tumors may be invasive or noninvasive. Benign transitional cell papillomas are rare.

Urothelial Carcinoma In Situ Is a Flat, Full-Thickness Intraepithelial Lesion

This term is reserved for full-thickness lesions in which malignant changes are confined to nonpapillary bladder mucosa. The involved urothelium is of variable thickness, with cellular atypia from the basal layer to the surface (Fig. 23-13).

TABLE 23-1
TUMORS OF URINARY BLADDER

Urothelial Tumors
Urothelial cell papilloma
Exophytic papilloma
Inverted papilloma
Urothelial carcinoma in situ
Papillary urothelial neoplasm of low malignant potential (PUNLMP)
Papillary urothelial carcinoma, low grade[a]
Papillary urothelial carcinoma, high grade[a]
Invasive urothelial carcinoma
Other Malignant Tumors
Squamous cell carcinoma
Adenocarcinoma
Neuroendocrine (small cell) carcinoma
Carcinosarcoma
Sarcomas

[a]Papillary carcinomas may be invasive or noninvasive.

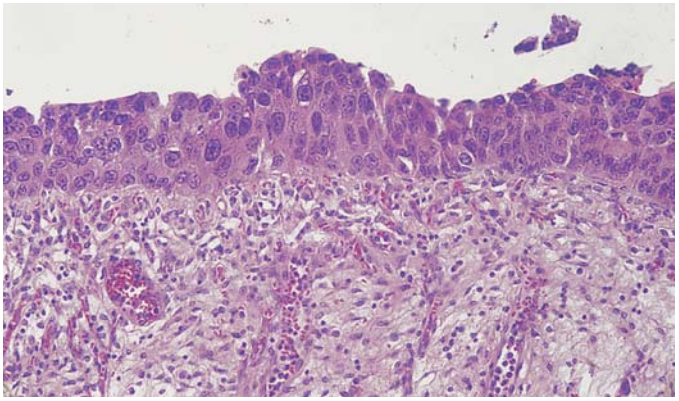

FIGURE 23-13. Urothelial carcinoma in situ. The urothelial mucosa shows nuclear pleomorphism and lack of polarity from the basal layer to the surface, without evidence of maturation.

FIGURE 23-14. Urothelial carcinoma of the urinary bladder. A large exophytic tumor (*arrow*) is situated above the bladder neck.

Atypia entails loss of nuclear polarity, nuclear irregularity, enlargement, hyperchromatism and prominent nucleoli. *The basement membrane is intact and there is no invasion into underlying stroma.*

One third of carcinomas in situ of the bladder are associated with subsequent invasive carcinoma. In turn, most invasive transitional cell carcinomas arise from carcinoma in situ rather than from papillary transitional cell cancers. Confined to the mucosal surface, in situ lesions most often appear as multiple, red, velvety, flat patches that often are near exophytic papillary transitional cell carcinomas (see below). Concurrent in situ cancers elsewhere in the bladder or ureters, urethra and prostatic ducts are common. Carcinoma in situ is often multifocal at the time of discovery, or similar lesions may develop shortly thereafter. Lesions involving the bladder neck or the urethra may extend into the periurethral prostatic ducts.

Urothelial Carcinomas Vary from Superficial and Papillary to Deeply Invasive

PATHOLOGY: Papillary cancers arise most frequently in the lateral or posterior bladder walls. Grossly, tumors may be small, delicate, low-grade papillary lesions limited to the mucosal surface or larger, high-grade, solid masses that are invasive and ulcerated (Fig. 23-14).

They are graded as papillary urothelial neoplasms of low malignant potential (PUNLMP) and papillary urothelial carcinomas, low grade and high grade. The latter may be invasive.

- **Papillary urothelial neoplasms of low malignant potential:** These papillary tumors resemble urothelial papillomas but show increased cellularity. They are considered intermediate between benign papillomas and low-grade papillary urothelial carcinomas. These lesions are usually larger than papillomas but lack architectural and cytologic atypia that are characteristic of low-grade carcinomas. PUNLMP may recur or occasionally progress to higher-grade tumors.
- **Low-grade papillary urothelial carcinoma:** Low-grade tumors have fronds lined by neoplastic urothelial epithelium with minimal architectural and cytologic atypia (Fig. 23-15A, B). The cells are moderately hyperchromatic with little nuclear pleomorphism and low mitotic activity. Papillae are long and delicate. Fusion of papillae is focal and limited. Invasion of the lamina propria or the deep muscularis propria occurs in 10%.
- **High-grade papillary urothelial carcinoma:** These tumors show significant nuclear hyperchromasia and pleomorphism. The epithelium is disorganized (Fig. 23-15C, D) with mitoses in all layers. Approximately 80% of all high-grade tumors invade the lamina propria and, less often,

TABLE 23-2
TNM STAGING OF UROTHELIAL CARCINOMA OF URINARY BLADDER

T—Primary Tumor
T0 No grossly visible tumor
Ta Noninvasive papillary carcinoma
Tis Carcinoma in situ
T1 Invasion of the lamina propria
T2 Invasion of the muscularis propria T2a Superficial invasion of the muscularis (inner half) T2b Invasion of deep muscle (outer half)
T3 Invasion of the perivesical tissue
T4 Extravesical spread into adjacent organs or distant metastases
N—Regional Lymph Nodes
N0 No lymph node involvement
N1 Single lymph node metastasis
N2, N3 More lymph nodes involved
M—Distant Metastases
M0 No metastases
M1 Distant metastases

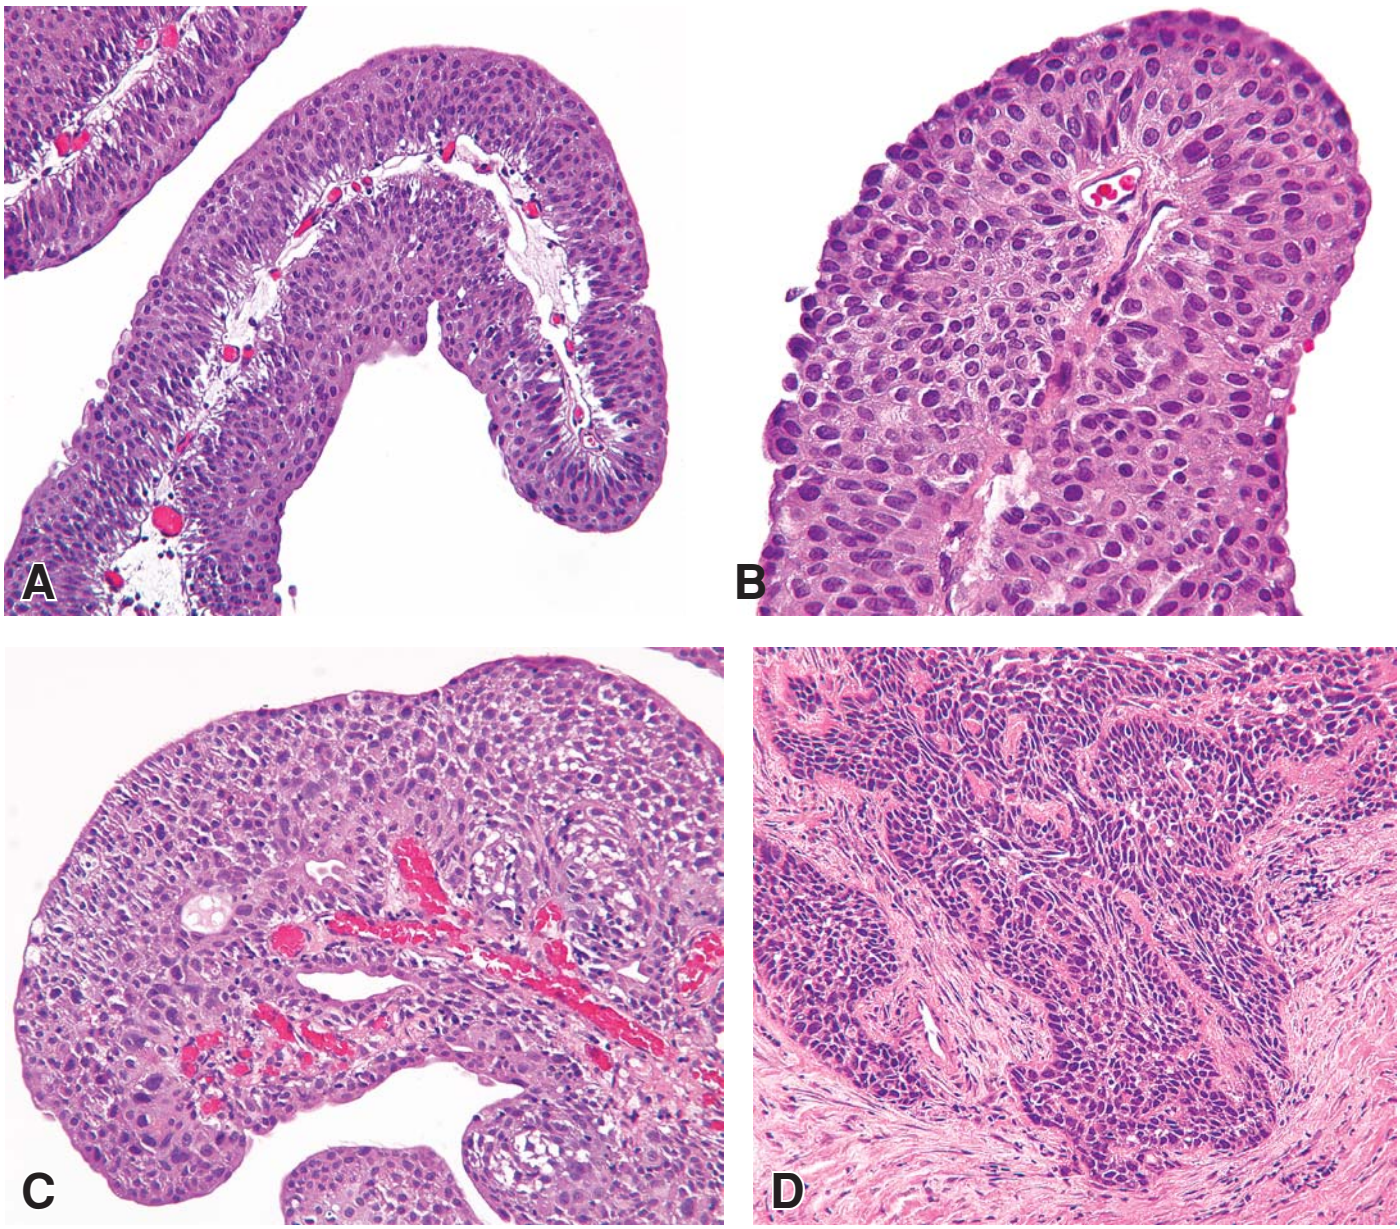

FIGURE 23-15. Urothelial tumors of the urinary bladder. A. Low-grade papillary urothelial carcinoma consists of exophytic papillae that have a central connective tissue core and are lined by slightly disorganized transitional epithelium. **B.** Low-grade papillary urothelial carcinoma at higher magnification shows mild architectural and cytologic atypia. **C.** High-grade papillary urothelial carcinoma displays prominent architectural disorganization of the epithelium, which contains cells with pleomorphic hyperchromatic nuclei. **D.** Invasive high-grade papillary urothelial carcinoma consists of irregular nests of hyperchromatic cells invading into the muscularis.

the muscularis propria or through the entire thickness of the bladder wall. Regional lymph nodes contain metastatic tumor in half of patients with these invasive tumors.

- **Invasive urothelial carcinoma:** These highly malignant tumors may evolve from papillary lesions or flat carcinomas in situ. In many cases the nature of the initial lesion is unknown. Most, if not all, invasive carcinomas are high-grade tumors. Depth of invasion into the bladder wall, or beyond, determines the prognosis.

Bladder cancers are staged according to the tumor–node–metastasis (TNM) system (Table 23-2). In order of decreasing frequency, metastases involve the regional and periaortic lymph nodes, liver, lung and bone.

CLINICAL FEATURES: Urothelial carcinoma of the bladder typically manifests as sudden **hematuria** and, less often, **dysuria**. Cystoscopy reveals one or more tumors. At the time of presentation, 85% of tumors are confined to the urinary bladder; 15% show regional or distant metastases. Papillary lesions limited to the mucosa or lamina propria (stage T1) are commonly treated conservatively by transurethral resection. Radical cystectomy is done for patients whose tumors show muscle invasion, and occasionally for advanced-stage tumors. In bladder cancer patients, the most common causes of death are uremia (from urinary outflow tract obstruction), extension into adjacent organs and effects of distant metastases.

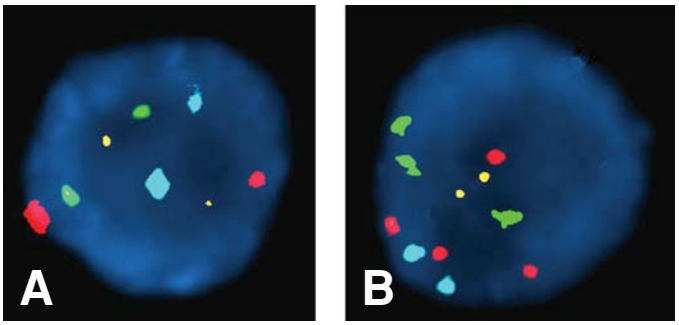

FIGURE 23-16. Fluorescence in situ hybridization of bladder cancer. A. Normal. Single urothelial cell collected from urine of normal person. Red fluorescence represents chromosome 3, green is chromosome 7, aqua is chromosome 17 and gold represents 9p21. The probe signals are present in two copies. **B.** Urothelial carcinoma of the bladder. There is aneuploidy of chromosomes 3 and chromosome 7. Chromosome 17 and 9p21 locus are euploid.

The probability of tumor extension and subsequent recurrence increases with:

- Increased tumor size
- High stage
- High grade
- Presence of multiple tumors
- Vascular or lymphatic invasion
- Urothelial dysplasia (including carcinoma in situ) at other sites in the bladder

The overall 10-year survival rate with noninvasive or superficially invasive low-grade urothelial tumors exceeds 95% irrespective of the number of recurrences. Only 10% of low-grade tumors progress to higher-grade tumors, and thus there is a worse prognosis. Conservative treatment includes fulguration, intravesicular immunotherapy with BCG or instillation of conventional chemotherapeutic agents. Invasive tumors or those refractory to conservative therapy are treated by cystectomy, possibly with adjuvant systemic chemotherapy. Tumors invading the bladder muscle bladder have 25%–30% overall mortality.

Recurrent or progressive disease is detected by cystoscopy and biopsy, or by less invasive techniques such as urinalysis for tumor markers, urine cytology and cytogenic analysis of desquamated cells. The latter analyzes cells from the patient's urine for ploidy values of specific chromosomal regions (see above) by fluorescence in situ hybridization (FISH) (Fig. 23-16; see Chapter 6). Currently, aneuploidy for chromosomes 3, 7 and 17 and loss of 9p21 are detected.

Nonurothelial Bladder Cancers Are Rare

Squamous cell bladder carcinomas develop in foci of squamous metaplasia, usually due to schistosomiasis. Bladder wall invasion is common by initial presentation and prognosis is poor.

Adenocarcinomas are 1% of malignant bladder tumors. They derive from urachal epithelial remnants, foci of cystitis glandularis or intestinal metaplasia. Most bladder adenocarcinomas are deeply invasive when they initially present and are not curable.

Neuroendocrine carcinoma, resembling small cell lung carcinoma, occurs uncommonly in the urinary bladder. It is highly malignant and has a poor prognosis.

Sarcomas of the bladder are rare. They are highly malignant, form bulky masses and are often inoperable. **Leiomyosarcoma** is the most common form in adults.

Rhabdomyosarcoma, typically of the embryonal type, occurs mostly as **sarcoma botryoides** in children, as edematous, mucosal, polypoid masses resembling a cluster of grapes. Combined treatment with radiation therapy and chemotherapy has greatly increased survival rates.

Penis, Urethra and Scrotum

CONGENITAL DISORDERS OF THE PENIS

Developmental anomalies of the penis include anomalies of the penile urethra and prepuce, as well as rare and infrequent conditions such as agenesis or hypoplasia.

HYPOSPADIAS: This term is a congenital anomaly in which the urethra opens on the underside (ventral) of the penis; the meatus is thus proximal to its normal location on the tip of the penis. It results from incomplete closure of the urethral folds of the urogenital sinus.

Hypospadias occurs in 1 in 350 male babies. Most cases are sporadic but familial occurrence is known. It may be associated with other urogenital anomalies and complex, multisystemic, developmental syndromes. In 90% of cases, the meatus is located on the underside of the glans, or the corona (Fig. 23-17). Less often, it occurs midshaft, in the scrotum or even in the perineum. Surgical repair is usually uncomplicated.

EPISPADIAS: In this rare congenital anomaly, the urethra opens on the upper side (dorsum) of the penis. In its most common form, all the penile urethra is open along the whole shaft. Severe epispadias may be associated with bladder exstrophy (Fig. 23-4). In its mildest form, the defect is limited to the glandular urethra. Surgical treatment of epispadias is more complicated than that of hypospadias.

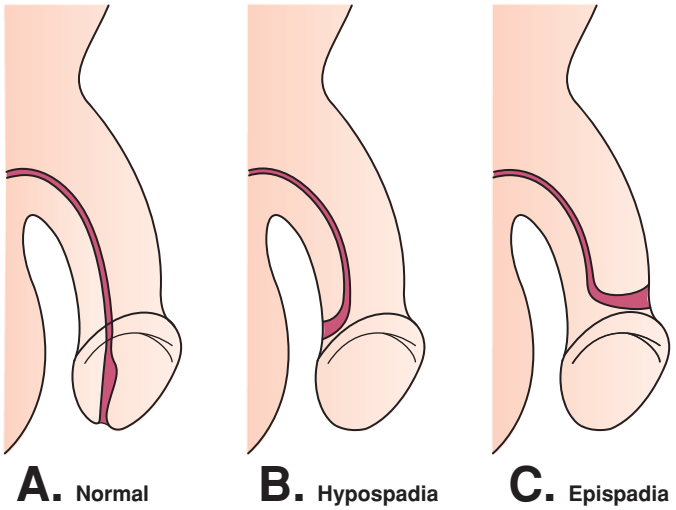

FIGURE 23-17. Congenital anomalies of the penis. A. Normal penis has the urethral opening on the tip of the glans. **B.** Hypospadias is characterized by a urethral opening on the ventral side of the penis. **C.** Epispadias is characterized by a urethral opening on the dorsal side of the penis.

PHIMOSIS: The orifice of the prepuce may be too narrow to allow retraction over the glans penis. Phimosis may be congenital or acquired. The latter is usually a consequence of recurrent infections or trauma of the prepuce in uncircumcised men. Phimosis predisposes to penile infections. A narrow prepuce, if forcefully retracted, may strangulate the glans and impede the outflow of venous blood, a condition called **paraphimosis**. Circumcision is curative.

SCROTAL MASSES

Scrotal masses and conditions that lead to scrotal swelling or enlargement often reflect abnormalities of testicular, epididymal and scrotal development. Clinical problems related to these conditions are most often seen in children but may be found in adults (Fig. 23-18A–D).

HYDROCELE: This is a collection of serous fluid in the mesothelially lined scrotal sac between the two layers of the tunica vaginalis. Hydroceles may be congenital or acquired.

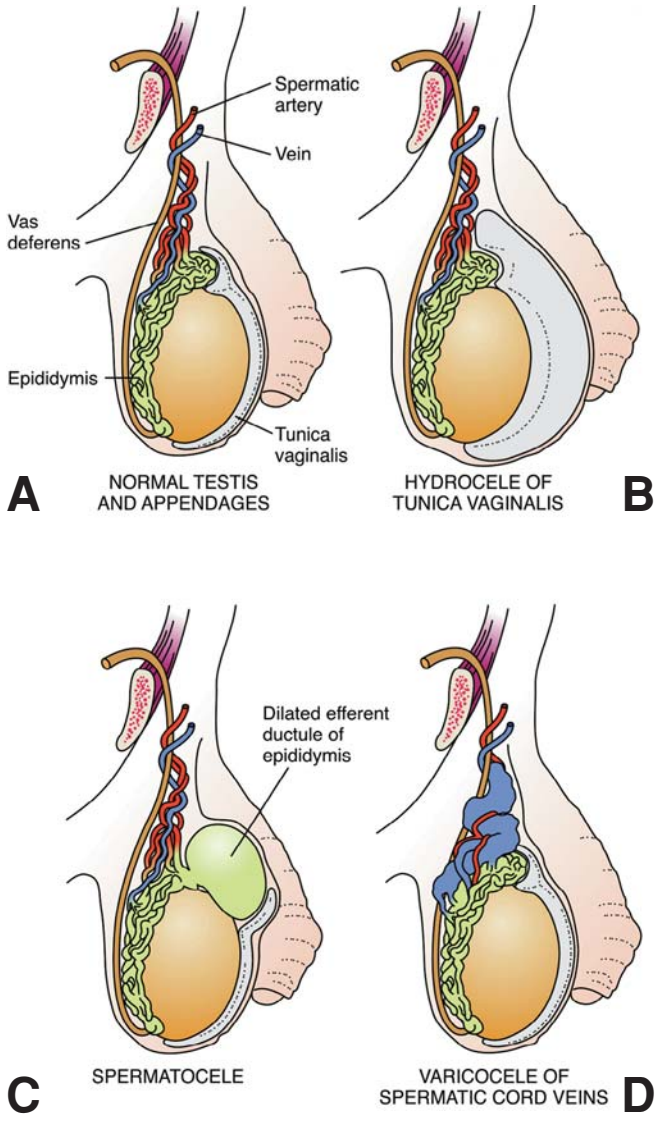

FIGURE 23-18. Scrotal masses. A. Normal testis. **B.** Hydrocele. **C.** Spermatocele. **D.** Varicocele.

Congenital hydrocele reflects patency or incomplete obliteration of the processus vaginalis testis. It is the most common cause of scrotal swelling in infants and is often associated with inguinal hernia.

Acquired hydrocele in adults is due to some other disease affecting the scrotum, such as infection, tumor or trauma. The diagnosis is made by ultrasound or by transluminating the fluid in the cavity. Hydrocele is a benign condition that disappears once the cause has been addressed. However, long-standing hydrocele may cause testicular atrophy or compress the epididymis, or the fluid may become infected and lead to **periorchitis**.

HEMATOCELE: Blood may accumulate between the layers of tunica vaginalis after trauma or hemorrhage into a hydrocele, or as a result of testicular tumors and infections.

SPERMATOCELE: This mass is a cyst formed from protrusions of widened efferent ducts of the rete testis or epididymis. It manifests as a hilar paratesticular nodule or a fluctuating mass filled with milky fluid. The cyst is lined by cuboidal epithelium that contains spermatozoa in various stages of degeneration.

VARICOCELE: This dilation of testicular veins appears as a nodularity on the lateral side of the scrotum. Most are asymptomatic and are discovered during physical examination of infertile men. Massive varicocele is described as resembling a "bag of worms." Varicoceles are considered a common cause of infertility and oligospermia, although it is unclear why dilation of veins should have such effects. Testicular atrophy occurs only rarely and only in long-standing cases. Surgical ligation of the internal spermatic vein often improves reproductive function.

SCROTAL INGUINAL HERNIA: Intestinal protrusion into the scrotum through the inguinal canal is a scrotal hernia. The bowel may be repositioned, but if it remains untreated, such a hernia may cause adhesions or testicular atrophy. Hernias can only be repaired surgically.

CIRCULATORY DISTURBANCES

SCROTAL EDEMA: Lymph or serous fluid may accumulate in the scrotum from obstruction to lymphatic or venous drainage. Lymphedema from lymphatic obstruction can be caused by pelvic or abdominal tumors, surgical scars or infections such as filariasis. **Transudation** of plasma is common in patients with heart failure, anasarca due to cirrhosis or nephrotic syndrome. Fluid accumulates in the loose connective tissue and the cavity lined by the tunica vaginalis testis.

ERECTILE DYSFUNCTION: This condition, also known as impotence, is *inability to achieve or maintain an erection sufficient for satisfactory sexual performance.* Its prevalence increases with age, from 20% at age 40 years to 50% by age 70.

Erection requires adequate filling of the penile corpora cavernosa and spongiosa with blood. Penile tumescence is the result of a complex interaction of mental, neural, hormonal and vascular factors. Filling of these vascular spaces depends on nitric oxide (NO•)-mediated relaxation of vascular smooth muscle cells in the erectile cylinders. NO• release is related to cyclic guanosine monophosphate (cGMP), so drugs that inhibit the phosphodiesterase that degrades cGMP (e.g., sildenafil [Viagra], vardenafil hydrochloride [Levitra], tadalafil [Cialis]) are used to treat erectile dysfunction. Disorders associated with erectile dysfunction are listed in Table 23-3.

TABLE 23-3
ERECTILE DYSFUNCTIONS

Drugs
Antihypertensives
Psychotropic drugs
Estrogens, anticancer drugs, etc.
Idiopathic
"Performance anxiety"
Age-related "impotence"

PRIAPISM: Priapism is ***continuous penile erection unrelated to sexual excitation.*** It may be primary or secondary. Primary priapism is idiopathic and painful. Treatment is usually ineffective. Secondary priapism may occur in (1) pelvic diseases that impede outflow of blood from the penis (e.g., pelvic tumors or hematomas, thrombosis of pelvic veins, infections); (2) hematologic disorders (e.g., sickle cell anemia, polycythemia vera, leukemia); and (3) brain and spinal cord diseases (e.g., tumors, syphilis).

INFLAMMATORY DISORDERS

The most important inflammatory diseases of the penis are (1) sexually transmitted diseases (STDs); (2) nonspecific infections; (3) diseases of unknown etiology, such as balanitis xerotica obliterans; (4) dermatoses; and (5) dermatitis of the penile shaft and scrotum (Table 23-4).

Sexually Transmitted Diseases Cause Discrete Penile Lesions

STDs (see Chapter 9) as lower urinary tract infections (Fig. 23-19) include the following:

- **Genital herpes** is most often caused by herpes simplex virus (HSV)-2 or, less commonly, by HSV-1. It is the most

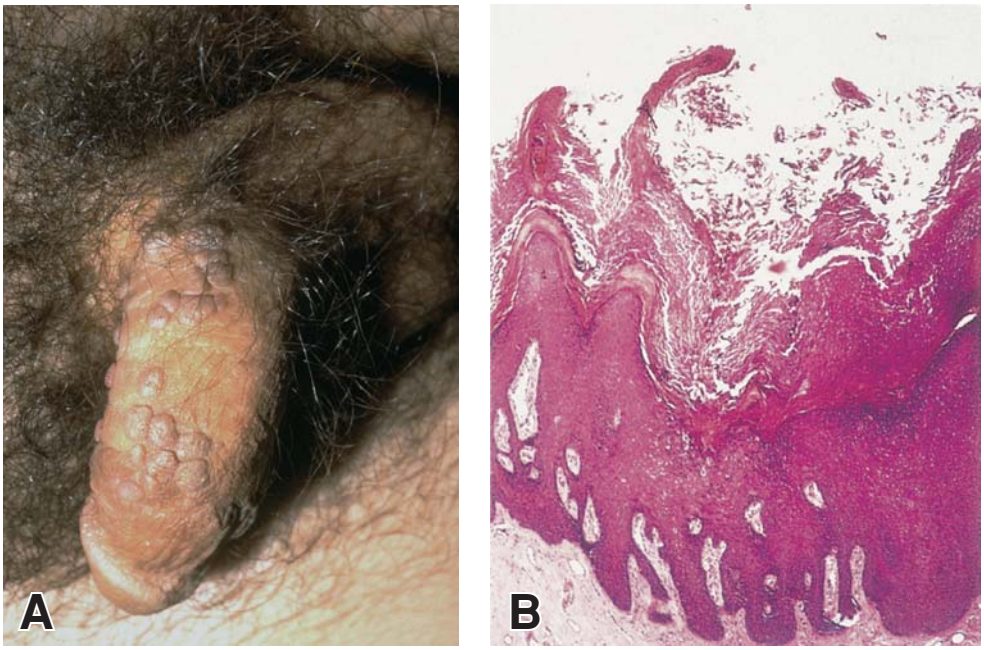

FIGURE 23-20. Condylomata acuminata of the penis. A. Raised, circumscribed lesions are seen on the shaft of the penis. **B.** Section of a lesion shows epidermal hyperkeratosis, parakeratosis, acanthosis and papillomatosis.

common STD affecting the glans and manifests typically as grouped vesicles that ulcerate and transform into crusts.

- **Primary syphilis,** caused by a spirochete, *Treponema pallidum,* may manifest as a solitary, soft ulcer **(chancre)** accompanied by palpable inguinal lymphadenopathy.
- **Chancroid** is caused by *Haemophilus ducreyi* and presents as a papule that transforms into a pustule and finally ulcerates. Shallow ulcers on the glans or the skin of the shaft are often associated with painful suppurative inguinal lymphadenitis.
- **Granuloma inguinale** is a tropical disease caused by *Calymmatobacterium granulomatis.* It appears as a raised ulcer with a copious chronic inflammatory exudate and granulation tissue. Such ulcers tend to enlarge and heal very slowly.
- **Lymphogranuloma venereum** is caused by *Chlamydia trachomatis.* It starts as a small, often innocuous, vesicle that ulcerates, typically accompanied by tender enlargement of inguinal lymph nodes that adhere to the skin and form sinuses draining pus and serosanguineous fluid.
- **Condyloma acuminatum** is caused by human papillomavirus type 6 or, less often, 11. It appears as flat-topped warts on the shaft (Fig. 23-20), small polyps on the glans and urethral meatus or larger cauliflower-like tumors that may be confused with verrucous carcinoma.

Balanitis Is Inflammation of the Glans Penis

In uncircumcised men, balanitis usually extends from the glans to the foreskin and is called **balanoposthitis**. Mostly it is caused by bacteria, but it may also be caused by fungi in diabetics or immunosuppressed people. Balanitis typically reflects poor hygiene. Significant complications of chronic balanoposthitis are meatal stricture, phimosis and paraphimosis.

BALANITIS XEROTICA OBLITERANS: This idiopathic chronic inflammatory condition is equivalent to lichen sclerosus of the vulva (see Chapter 24) and is characterized by fibrosis and sclerosis of subepithelial connective tissue. The affected portion of the glans is white and indurated. Fibrosis may constrict the urethral meatus or cause phimosis.

CIRCINATE BALANITIS: During oculo-urethro-synovial syndrome (OUS) (see below), the glans may show circular, linear or confluent plaque-like discolorations, occasionally associated with superficial ulcers.

PLASMA CELL BALANITIS: This chronic, innocuous disease of unknown origin (also called Zoon balanitis) causes macular discoloration or painless papules on the glans. Plasma cell and lymphocytic infiltrates are seen beneath a thickened overlying epithelium.

DERMATOSES: Many inflammatory skin diseases may involve the penis. Such conditions are discussed in Chapter 28.

Peyronie Disease Is an Idiopathic Fibrous Induration of the Penis

It is characterized by focal, asymmetric fibrosis of the penile shaft. During erections, the penis becomes curved and painful. Typically, it presents as an ill-defined induration of the penile shaft in a young or middle-aged man, with no change in the overlying skin. Microscopically, dense fibrosis is associated with sparse, nonspecific, chronic inflammatory infiltration. Collagen focally replaces muscle in the septum of the corpus cavernosum.

Peyronie disease affects 1% of men over age 40. In most instances, it is mild and does not interfere with sexual function. Severe cases may be so incapacitating as to require surgery, but the outcome is not always satisfactory.

URETHRITIS AND RELATED CONDITIONS

Urethritis is acute or chronic inflammation of the urethra.

SEXUALLY TRANSMITTED URETHRITIS: Urethritis presenting as urethral discharge is the most common sign

of STDs in men. Women rarely notice distinct urethral discharge and usually complain of vaginal discharge.

Gonococcal and nongonococcal urethritis have an acute onset, related to recent sexual intercourse. The discharge is typically purulent and greenish yellow. Symptoms include pain or tingling at the meatus of the urethra and pain on micturition **(dysuria)**. Meatal redness and swelling are common in both sexes. Acute gonococcal and nongonococcal urethritis can both become chronic.

The diagnosis is made by identifying the causative agent. In gonococcal urethritis, the discharge contains *Neisseria gonorrhoeae,* which can be identified microscopically in smears of urethral exudates. Nongonococcal urethritis is mostly caused by *C. trachomatis* or *Ureaplasma urealyticum* but may be related to a variety of other pathogens.

NONSPECIFIC INFECTIOUS URETHRITIS: Uropathogens such as* E. coli *and* P. aeruginosa *can cause urethritis. Typically infection is associated with cystitis but may be caused by other diseases (e.g., prostatic hyperplasia or urinary stones). In men, infectious urethritis may be the only sign of prostatitis; in women, it may be a complication of vaginitis and vulvitis. In hospitalized patients, it commonly follows cystoscopy and other urologic procedures and is almost inevitable in patients with indwelling urethral catheters.

Nonspecific infectious urethritis manifests clinically with urgency and a burning sensation during urination. Usually there is no discharge, but men may express some milky fluid by "stripping" or "milking" the urethra.

URETHRAL CARUNCLES: Polypoid inflammatory lesions near the female urethral meatus cause pain and bleeding. They are idiopathic and occur only in women, mostly after menopause. Urethral mucosal prolapse and attendant chronic inflammation may be implicated.

Urethral caruncles present as 1- to 2-cm exophytic, often ulcerated, polypoid masses, at or near the urethral meatus. They show acutely and chronically inflamed granulation tissue and ulceration and hyperplasia of transitional cell or squamous epithelium. Complex patterns of papillomatosis and occasional dysplastic epithelium may suggest a superficial resemblance to carcinoma, but this inflammatory lesion does not lead to cancer. Treatment is surgical excision.

REACTIVE ARTHRITIS (PREVIOUSLY REITER SYNDROME): Reactive arthritis is a triad of urethritis, conjunctivitis and arthritis of weight-bearing joints (e.g., knee, intervertebral joints). Other findings may include circinate balanitis, cervicitis and skin eruptions. It tends to affect young adults with the human leukocyte antigen (HLA)-B27 haplotype, usually a few weeks after chlamydial urethritis or enteric infection with (e.g.) *Shigella, Salmonella or Campylobacter.* The disease may thus be an aberrant immune reaction to unknown microbial antigen(s). Symptoms usually disappear spontaneously in 3–6 months, but arthritis recurs in half of patients.

TUMORS

Urethral Cancers May Arise from Squamous or Transitional Epithelia

These uncommon tumors usually occur in elderly women. Some penile cancers arise in the terminal part of the penile urethra.

PATHOLOGY: Most urethral cancers are squamous carcinomas originating in the distal urethra. Urothelial carcinoma, like that in the bladder, arises in the proximal urethra.

CLINICAL FEATURES: Urethral cancer develops most often in the sixth and seventh decades. Patients present with urethral bleeding and dysuria. Most tumors have spread to adjacent tissues or lymph nodes at the time of presentation. Radical surgery is the main therapy.

Cancer of the Penis Occurs Mostly in Uncircumcised Men

Cancer of the penis originates from the squamous mucosa of the glans and contiguous urethral meatus or the prepuce and skin covering the penile shaft.

EPIDEMIOLOGY: In the United States, invasive squamous cell carcinoma of the penis is uncommon, accounting for less than 0.5% of all cancers in men. The average age of patients is 60 years. Penile cancer is much more common in less developed countries: in some parts of Africa and Asia and South America, it constitutes 10% of cancers in men. It is virtually unknown in men circumcised at birth.

ETIOLOGIC FACTORS: No single agent has been identified as the cause of penile cancer. Current interest centers on the possible influence of smegma, the whitish material composed of accumulated keratin debris and secretion of the preputial (Tyson) glands that accumulates beneath the prepuce. Human papillomavirus (HPV) DNA has been found in 50% of all invasive carcinomas of the penis, suggesting that HPV types 16 and 18 play a role in some penile cancers. Cigarette smoking is also associated with a higher risk of penile cancer.

PATHOLOGY: Penile carcinoma may be preinvasive (in situ) or invasive.

SQUAMOUS CELL CARCINOMA IN SITU: Carcinoma in situ of the penis is similar to that in other sites (see Chapter 28). Grossly, it may present as Bowen disease or erythroplasia of Queyrat. **Bowen disease** is a sharply demarcated, erythematous or grayish white plaque on the shaft. **Erythroplasia of Queyrat** appears as solitary or multiple, shiny, soft, erythematous plaques on the glans and foreskin. Both of these resemble **squamous cell carcinoma in situ** elsewhere. They show cytologic atypia among keratinocytes of all layers of the epidermis, parakeratosis or hyperkeratosis; papillomatosis with broad epidermal papillae; and thinning of the granular layer. By definition, there is no invasion of the underlying dermis. Progression to invasive squamous cell carcinoma is estimated to occur in less than 10% of cases.

Bowenoid papulosis of the penis is caused by HPV and affects young, sexually active men. In contrast to the solitary lesion of Bowen disease, Bowenoid papulosis appears as multiple brownish or violaceous papules. Microscopically, it resembles other squamous carcinomas in situ, but there may be some differences. Most carcinoma in situ slowly merges at the margins with normal epithelium, but Bowenoid papulosis is sharply demarcated from normal epidermis, like HPV-induced warts. The altered epidermis

FIGURE 23-21. Carcinoma of the penis. This verrucous carcinoma arises on the glans and appears as an exophytic mass.

shows some superficial stratification and maturation and may contain giant keratinocytes with multinucleated atypical nuclei. HPV type 16 can be demonstrated in 80% of patients, and type 18 is occasionally implicated. Virtually all these lesions regress spontaneously and do not progress to invasive carcinoma.

INVASIVE SQUAMOUS CELL CARCINOMA: The tumor presents as (1) an ulcer; (2) an indurated crater; (3) a friable hemorrhagic mass; or (4) an exophytic, fungating, papillary tumor. It usually involves the glans or prepuce and less commonly the penile shaft. Extensive destruction of penile tissue, including the urethral meatus, is seen when the tumor has been neglected. Microscopically, these are typically well-differentiated, focally keratinizing, squamous cell carcinomas. Invasive tumors usually have underlying dense, chronic inflammation. The adjacent epidermis often shows dysplastic changes. The tumor may invade deeply along the shaft and spread to inguinal lymph nodes, then to iliac nodes and ultimately to distant organs.

VERRUCOUS CARCINOMA: This tumor is separated from other penile cancers because it is a cytologically benign but clinically malignant exophytic squamous cell carcinoma (Fig. 23-21). Grossly and cytologically, it resembles **condyloma acuminatum,** but it shows local invasion, unlike the latter. Verrucous carcinoma rarely metastasizes. Surgery is curative.

CLINICAL FEATURES: Most squamous cell cancers are confined to the penis at the time of presentation. Occult metastases to inguinal lymph nodes are not uncommon, but half of patients with enlarged regional lymph nodes do not have nodal metastases, only reactive changes due to tumor-associated inflammation.

Survival of patients with penile cancer is related to the clinical stage and, to a lesser degree, histologic grade of the tumor. Amputation of the penis is usually necessary. Patients with superficially invasive cancer have 90% 5-year survival; inguinal lymph node metastases reduce 5-year survival to 20%–50%, depending on the extent of spread. HPV infection is seen in at least half of cases.

Cancer of the Scrotum Is Quite Uncommon

In 1775, Sir Percival Pott introduced the idea of chemical carcinogenesis by reporting scrotal cancer as an occupational disease of chimney sweeps (see Chapter 8). Many industrial chemicals were found to be causative. Improved industrial hygiene has made this a rare tumor.

Squamous carcinoma of the scrotum typically affects men mostly in their 50s and 60s. At presentation, many show invasion of the scrotal contents and metastases to regional nodes. Therapy is surgical excision. As in penile cancer, HPV has been often implicated.

Testis, Epididymis and Vas Deferens

CRYPTORCHIDISM

Cryptorchidism, clinically known as undescended testis, ***is a congenital abnormality in which one or both testes are not in the scrotum.*** It is the most common urologic condition requiring surgical treatment in infants. The testes are not in the scrotum or are easily retracted in 5% of term male infants and 30% of those born prematurely. In the large majority of these, testes descend into the scrotum in the first year of life. Thus, the prevalence of cryptorchidism from the end of the first year of life into adulthood is about 1%. It is bilateral in 30% of affected men.

ETIOLOGIC FACTORS: Testicular maldescent is usually an idiopathic isolated developmental disorder. It may rarely be associated with other congenital anomalies.

PATHOLOGY: Testicular descent may be arrested at any point from the abdominal cavity to the upper scrotum (Fig. 23-22). Cryptorchid testes are classified by their location as **abdominal, inguinal or upper scrotal**. Rarely, the testes are located in unusual locations, such as the perineum or calf.

Cryptorchid testes are smaller than normal even at an early age, and differences between the affected and unaffected testes increase with age. The testes are firm and show fibrosis.

The histology of cryptorchid testes varies with age. In infancy and early childhood, the seminiferous tubules in

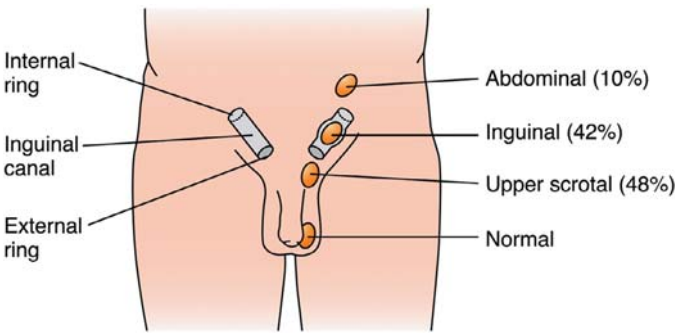

FIGURE 23-22. Cryptorchidism. In most instances, the testis has an upper scrotal location. It may also be retained in the inguinal canal and rarely in the abdominal cavity.

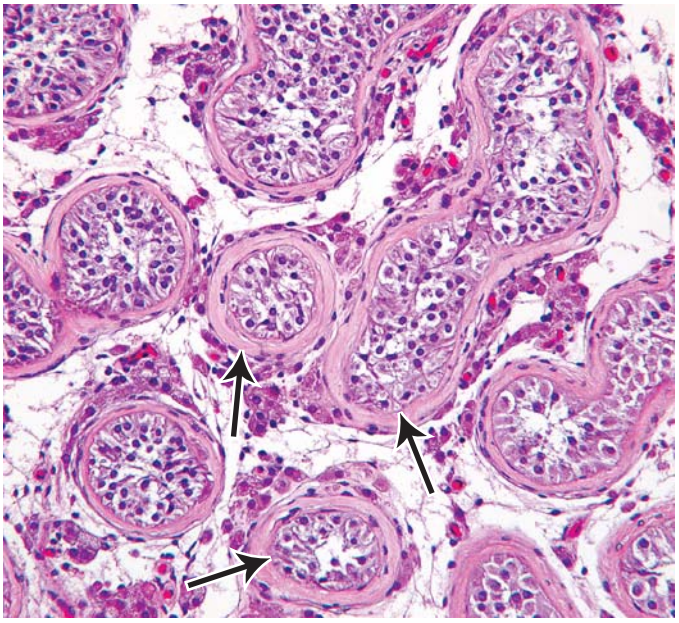

FIGURE 23-23. Cryptorchidism. This testis removed from a postpubertal man shows a markedly thickened hyalinized basement membrane (*arrows*) of seminiferous tubules, which show no signs of spermatogenesis.

affected testes are smaller, with fewer than normal germ cells. Postpubertal testes also show decreased germ cells, and spermatogenesis is limited to a minority of tubules. Hyaline thickening of tubular basement membranes and prominent stromal fibrosis are observed (Fig. 23-23). Eventually, tubules lose all spermatogenic cells and are entirely hyalinized. **Orchiopexy** (surgical placement of a testis into the scrotum) done either in childhood or after puberty does not prevent loss of seminiferous epithelium and tubules; both untreated and repositioned testes lack all spermatogenesis in half of the cases. A few adult cryptorchid testes (2%) contain atypical germ cells corresponding to carcinoma in situ.

CLINICAL FEATURES: The clinical significance of undescended testes is that they entail increased incidences of **infertility** and **germ cell neoplasia**. All men with bilateral cryptorchid testes have **azoospermia** and are infertile. Unilateral cryptorchidism is associated with **oligospermia,** defined as a sperm count below 20 million/mL, in 40% of cases. Although oligospermia is a cause of reduced fertility, most men with one normal testis can father children. Orchiopexy done in childhood or after puberty has no effect on the sperm count. Most urologists recommend orchiopexy between 6 months and 1 year of age, but it is not clear whether this treatment improves the eventual sperm count.

Cryptorchidism is associated with a 20- to 40-fold increased risk for testicular cancer. Conversely, 10% of patients with germ cell neoplasia have cryptorchid testes. Intra-abdominal testes are at higher risk than those retained in the inguinal canal; in turn, inguinal testes are at higher risk than those high in the scrotum. A contralateral, normally descended testis is also at risk, about 4 times that in normal men. Unfortunately, orchiopexy does not reduce cancer risk.

ABNORMALITIES OF SEXUAL DIFFERENTIATION

Disorders of gonadogenesis and formation of external genital organs, as well as development of secondary sex characteristics, can pertain to:

- Genetic sex; the presence or absence of X and Y chromosomes
- Gonadal sex; the presence or absence of testes or ovaries
- Genital sex; the appearance of external genital organs
- Psychosocial sexual orientation

Various conditions are listed in Table 23-5. Some of these, such as Klinefelter and Turner syndromes, are discussed in Chapter 6.

HERMAPHRODITISM: This rare developmental disorder is characterized by ambiguous genitalia in someone who has both male and female gonads. Gonads may become ovotestes (combination of ovary and testis) or one gonad may be testis and the other ovary. Half of these patients have a female karyotype (46,XX). The others are genetic males (46,XY) or mosaics or have a missing sex chromosome (45,X).

FEMALE PSEUDOHERMAPHRODITISM: Virilization of external genitalia may occur in genetic females (46,XX) who have normal ovaries and internal female genital organs. The vulva may fuse into scrotal folds and clitoromegaly is common. This phenotype is most often seen in the adrenogenital syndrome caused by 21-hydroxylase deficiency (see Chapter 27). Lack of this enzyme leads to excess androgen production in the adrenal gland during fetal life, and the ambiguous genitalia are seen at birth. Excess androgens in a pregnant woman can have the same effects on the external genitalia of the female baby in utero.

TABLE 23-5
DISORDERS OF SEXUAL DIFFERENTIATION

Sex Chromosomal Abnormalities
Klinefelter syndrome and its variants
Turner syndrome 46,XX males
Single-Gene Defects
Adrenogenital syndromes
Androgen insensitivity syndromes
Müllerian inhibitory substance deficiency
Prenatal Hormonal Effects
Exogenous hormones during pregnancy
Maternal hormone-producing tumors
Idiopathic Conditions
Hermaphroditism
Gonadal dysgenesis

A 46,XX karyotype is found in 1 of 25 patients with classical signs of Klinefelter syndrome. These 46,XX males carry the locus for the sex-determining region of chromosome Y (SRY) on one of their X chromosomes. It is not known how this translocation occurs.

MALE PSEUDOHERMAPHRODITISM: A spectrum of congenital disorders affects genetic males who have a normal 46,XY karyotype. The gonads are cryptorchid testes, but external genitalia appear feminine or ambiguously female with some virilization. Male pseudohermaphroditism occurs most often in **androgen insensitivity syndromes** due to deficiency of the androgen receptor, also known as **testicular feminization syndrome.**

MALE INFERTILITY

Infertility is empirically defined as inability to conceive after 1 year of coital activity with the same sexual partner without contraception. Some 15% of couples are childless in the United States, but the true prevalence of infertility is difficult to assess because it is confounded by cultural and social issues. The male is infertile in 20% of couples, the female in 40%, and both partners in 20%. In the remaining 20% of infertile couples, no cause can be identified. The causes of male infertility are listed in Table 23-6 and illustrated in Fig. 23-24.

TABLE 23-6
CAUSES OF MALE INFERTILITY

Supratesticular Causes
Disorders of the hypothalamic–pituitary–gonadal axis
Endocrine disease of the adrenal, thyroid; diabetes
Metabolic disorders
Major organ diseases (e.g., renal, hepatic, cardiopulmonary diseases)
Chronic infectious and debilitating diseases (e.g., tuberculosis, AIDS)
Drugs and substance abuse
Testicular Causes
Idiopathic: hypospermatogenesis or azoospermia
Developmental (cryptorchidism, gonadal dysgenesis)
Genetic disorders (e.g., Klinefelter syndrome)
Orchitis (immune and infectious)
Iatrogenic testicular injury (radiation, cytotoxic drugs)
Trauma of the testis and surgical injury
Environmental (? phytoestrogens)
Posttesticular Causes
Congenital anomalies of the excretory ducts
Inflammation and scarring of excretory ducts
Iatrogenic or posttraumatic lesions of excretory ducts

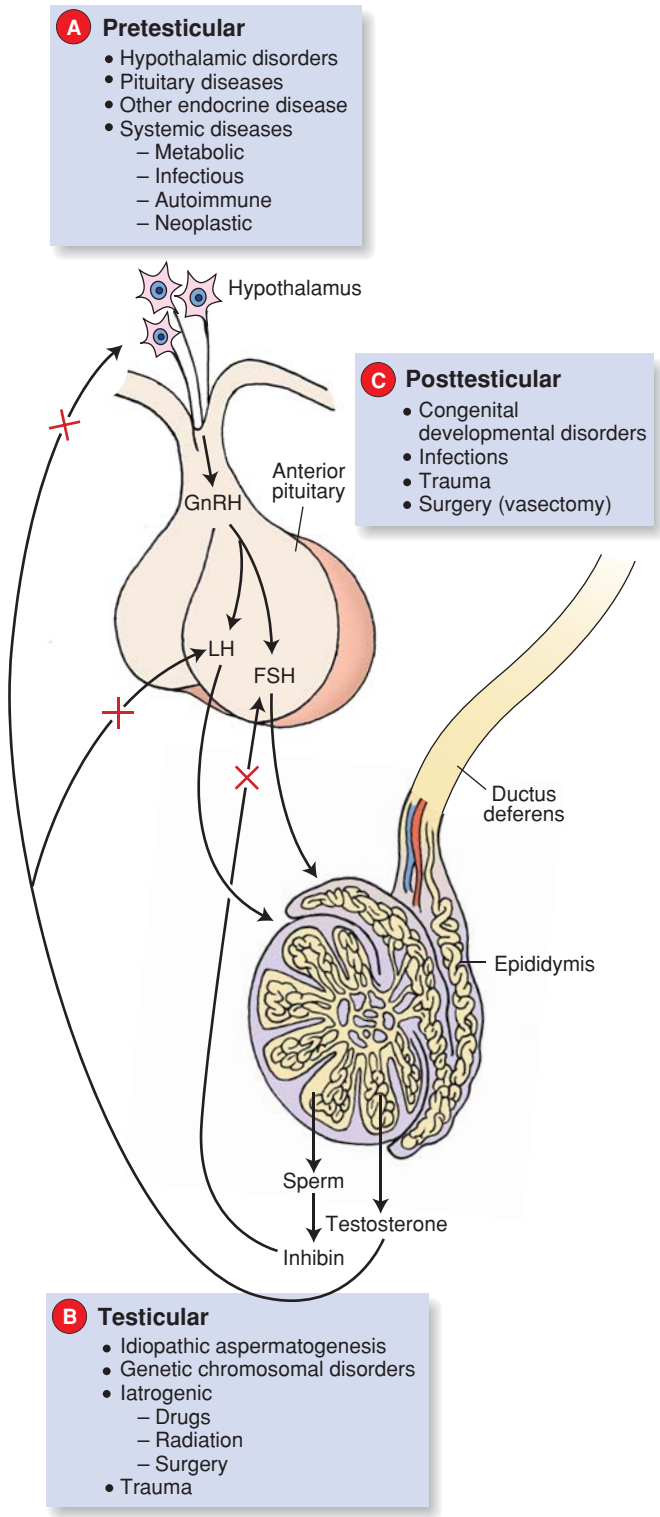

FIGURE 23-24. Causes of male infertility. A. Pretesticular infertility. *FSH* = follicle-stimulating hormone; *LH* = luteinizing hormone; *GnRH* = gonadotropin-releasing hormone. **B.** Testicular infertility. **C.** Posttesticular (obstructive) infertility.

Supratesticular causes of infertility affect hormonal and metabolic aspects of spermatogenesis. The best examples are injuries of the hypothalamic–pituitary area. Infertility

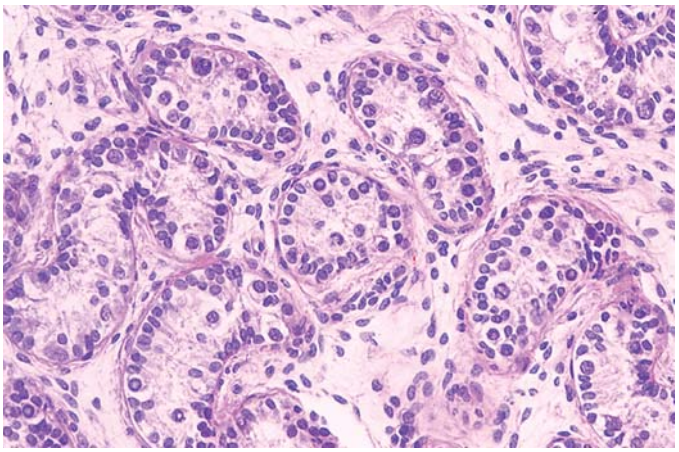

FIGURE 23-25. Hypogonadotropic hypogonadism. The testis of this 25-year-old man is composed of immature seminiferous tubules similar to those seen in prepubertal boys.

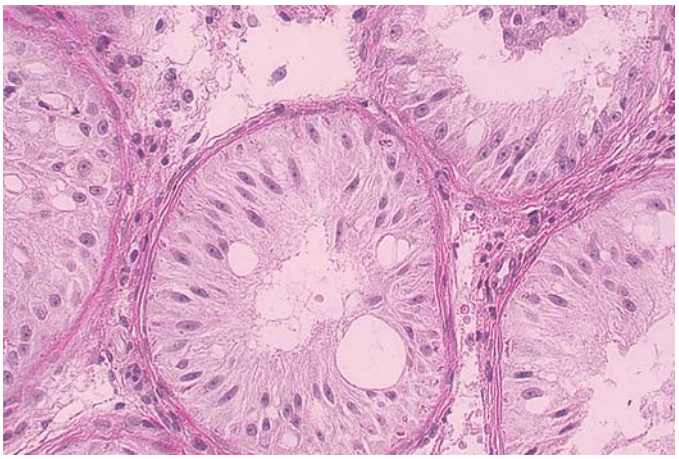

FIGURE 23-26. Germ cell aplasia–Sertoli cell only syndrome. The seminiferous tubules are lined by Sertoli cells and do not contain germ cells.

can result from transection of the pituitary stalk, destruction of the hypothalamus by a brain tumor or pressure on the pituitary by a craniopharyngioma. A pituitary tumor secreting prolactin (prolactinoma) may act as a mass lesion that destroys gonadotropin-secreting pituitary cells or compresses the pituitary stalk. It also secretes prolactin, which suppresses spermatogenesis.

Testicular infertility, the most common variety of male infertility, is related to pathologic changes in the testis. A male infertility (andrologic) workup includes urologic examination, sonography, semen analysis, hormonal studies and in some cases testicular biopsy.

Posttesticular infertility entails blockage of excretory ducts through which sperm reach the urethra. Chronic infections of the epididymis or vas deferens, previous trauma and congenital atresia are the causes.

PATHOLOGY: Testicular biopsy may identify causes of infertility, such as the following:

- **Immaturity of seminiferous tubules** is seen in hypogonadotropic hypogonadism caused by pituitary or hypothalamic diseases (Fig. 23-25). Seminiferous tubules show no spermatogenesis and resemble those of prepubertal testes.
- **Decreased spermatogenesis (hypospermatogenesis)** occurs in several systemic and endocrine diseases, including malnutrition and AIDS. Hypospermatogenesis is also found in cryptorchid testes and after vasectomy.
- **Germ cell maturation arrest** is usually idiopathic. It can occur at any stage of maturation.
- **Germ cell aplasia** ("Sertoli cells only" syndrome) is mostly idiopathic (Fig. 23-26). An underlying genetic mutation has been identified in some patients. It can be seen in drug-induced and toxic injury of the seminiferous epithelium.
- **Orchitis** is caused by viruses (e.g., mumps) or autoimmune diseases.
- **Peritubular and tubular fibrosis** may be related to congenital disorders such as cryptorchidism or to previous infection, ischemia or radiation (Fig. 23-27).

EPIDIDYMITIS

Epididymitis is acute or chronic inflammation of the epididymis, usually caused by bacteria.

Bacterial epididymitis in young men most often occurs in an acute form as a complication of gonorrhea or a sexually acquired *Chlamydia* infection. It is characterized by suppurative inflammation (Fig. 23-28). In older men, *E. coli* from associated urinary tract infections is a more common culprit. Patients present with intrascrotal pain and tenderness, with or without associated fever. Epididymitis of recent origin shows the hallmarks of acute inflammation. Persistent chronic epididymitis is associated with accumulation of plasma cells, macrophages and lymphocytes and, ultimately, with fibrotic obstruction of infected ducts. Gonorrheal epididymitis is a common cause of acquired male infertility.

Tuberculous epididymitis is now uncommon and is usually associated with established pulmonary and renal tuberculosis. It manifests as palpable enlargement of the epididymis and beading of the vas deferens, with confluent caseating granulomas.

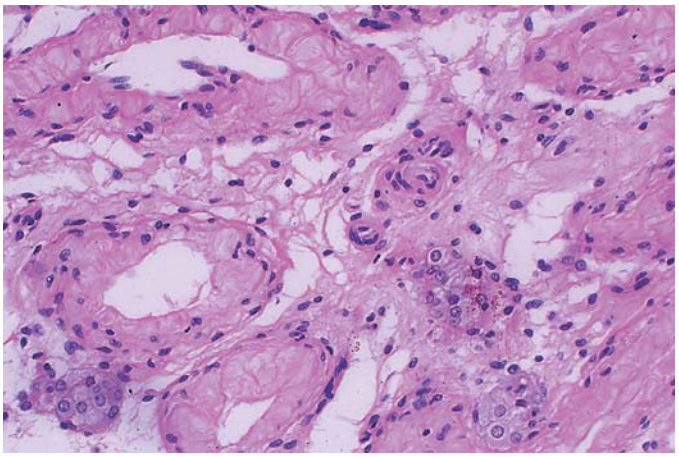

FIGURE 23-27. Postirradiation tubular atrophy of the testis. Seminiferous tubules are hyalinized, and there is no evidence of spermatogenesis.

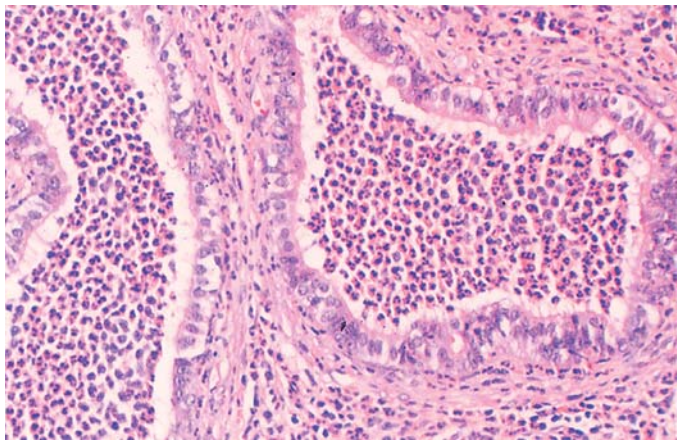

FIGURE 23-28. Bacterial epididymitis. The epididymal ducts contain numerous polymorphonuclear leukocytes.

Spermatic granulomas result from intense inflammatory responses to sperm outside of their usual channels. Traumatic rupture of epididymal ducts may play a role. Patients present with scrotal pain and swelling, frequently for weeks or months. The epididymis contains a mixed inflammatory cell infiltrate with many sperm fragments and macrophages phagocytosing sperm. Ultimately, inflammation results in interstitial fibrosis, ductal obstruction and infertility.

ORCHITIS

Orchitis is acute or chronic inflammation of the testis. It may occur as part of epididymo-orchitis, usually caused by ascending infection, or as isolated testicular inflammation. The latter is usually due to hematogenous spread of pathogens, but may be of autoimmune origin.

- **Gram-negative bacterial orchitis** is the most common form of the disease. It is often secondary to urinary tract infection and is typically associated with epididymitis. Infection may also manifest as intratesticular abscess or peritesticular suppuration and fibrosis.
- **Syphilitic orchitis** has two forms: (1) interstitial perivascular inflammation, with plasma cells, lymphocytes and macrophages; or (2) granulomatous inflammation (gummas).
- **Mumps orchitis** occurs in 20% of men who develop mumps but is uncommon because of widespread immunization against mumps. Viral infection is characterized by testicular pain and gonadal swelling, most often unilateral. Interstitial inflammation leads to destruction and loss of seminiferous epithelium (Fig. 23-29).
- **Granulomatous orchitis** of unknown cause is an uncommon disorder of middle-aged men that presents acutely as painful testicular enlargement or insidiously as induration. It shows noncaseating granulomas with neither organisms nor sperm remnants that might act as inciting agents. Variable numbers of seminiferous tubules are destroyed by the inflammatory process, which is considered to be a type IV (cell-mediated) hypersensitivity reaction.
- **Malakoplakia** of the testis has the same microscopic features and presumably the same histogenesis as malakoplakia elsewhere. It is typically related to *E. coli* infection.

TUMORS OF THE TESTIS

Tumors of the testis account for less than 1% of all cancers in men. More than 90% of these tumors are characterized by:

- Diagnosis between 25 and 45 years of age
- Germ cell origin
- Malignancy
- Curable by a combination of surgery and chemotherapy
- Cytogenetic marker, namely, isochromosome p12
- Metastasis first to periaortic abdominal lymph nodes

MOLECULAR PATHOGENESIS: The etiology of these tumors is not known. There is a geographic variation in the incidence of testicular cancer. The incidence is highest in Denmark, Sweden and Norway, but is low in Finland and southern European countries. The tumors are 5 times more common among Americans of European descent than in those of African heritage. Familial testicular cancers have been recorded but are rare. The only consistent cytogenetic abnormality is an additional fragment of chromosome 12 (isochromosome p12), found in 80% of germ cell tumors. As noted above, the only known risk factors are **cryptorchidism and gonadal dysgenesis**.

Malignant transformation of germ cells may occur during fetal development and involve (1) migrating primordial germ cells, (2) fetal germ cells interacting with stromal cells in the genital ridge or (3) early fetal spermatogonia. Since germ cell tumors rarely occur before puberty, some investigators believe that malignant transformation occurs in the peripubertal period and involves spermatogonia that are stimulated to proliferate and differentiate into spermatocytes. Although the initial events in testicular neoplasia are uncertain, a consensus holds that germ cell tumors progress through two pathways (Fig. 23-30). A carcinoma in situ stage, **intratubular testicular germ cell neoplasia** (ITGCN), precedes and progresses to invasive carcinoma (see below). This pathway accounts for most adult germ cell tumors. However, ITGCN is not found in testes harboring spermatocytic seminomas, teratomas of prepubertal testes or yolk sac tumors of infancy, which apparently develop directly from

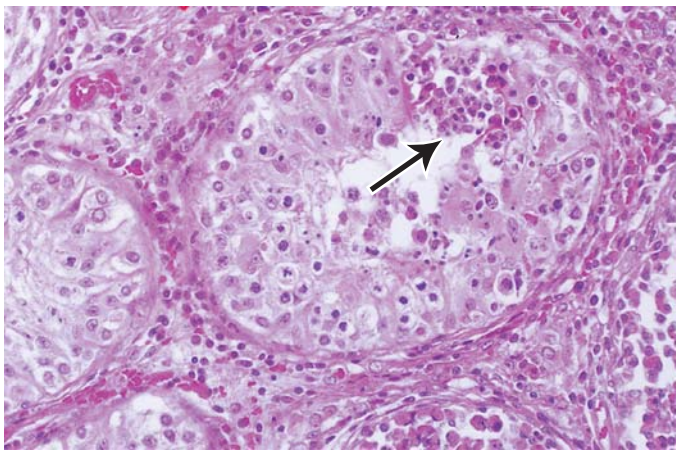

FIGURE 23-29. Viral orchitis. The interstitial spaces are infiltrated with mononuclear cells that spill focally into the lumen of seminiferous tubules (*arrow*). Note that the inflammation has interrupted normal spermatogenesis and that the seminiferous tubules do not contain sperm.

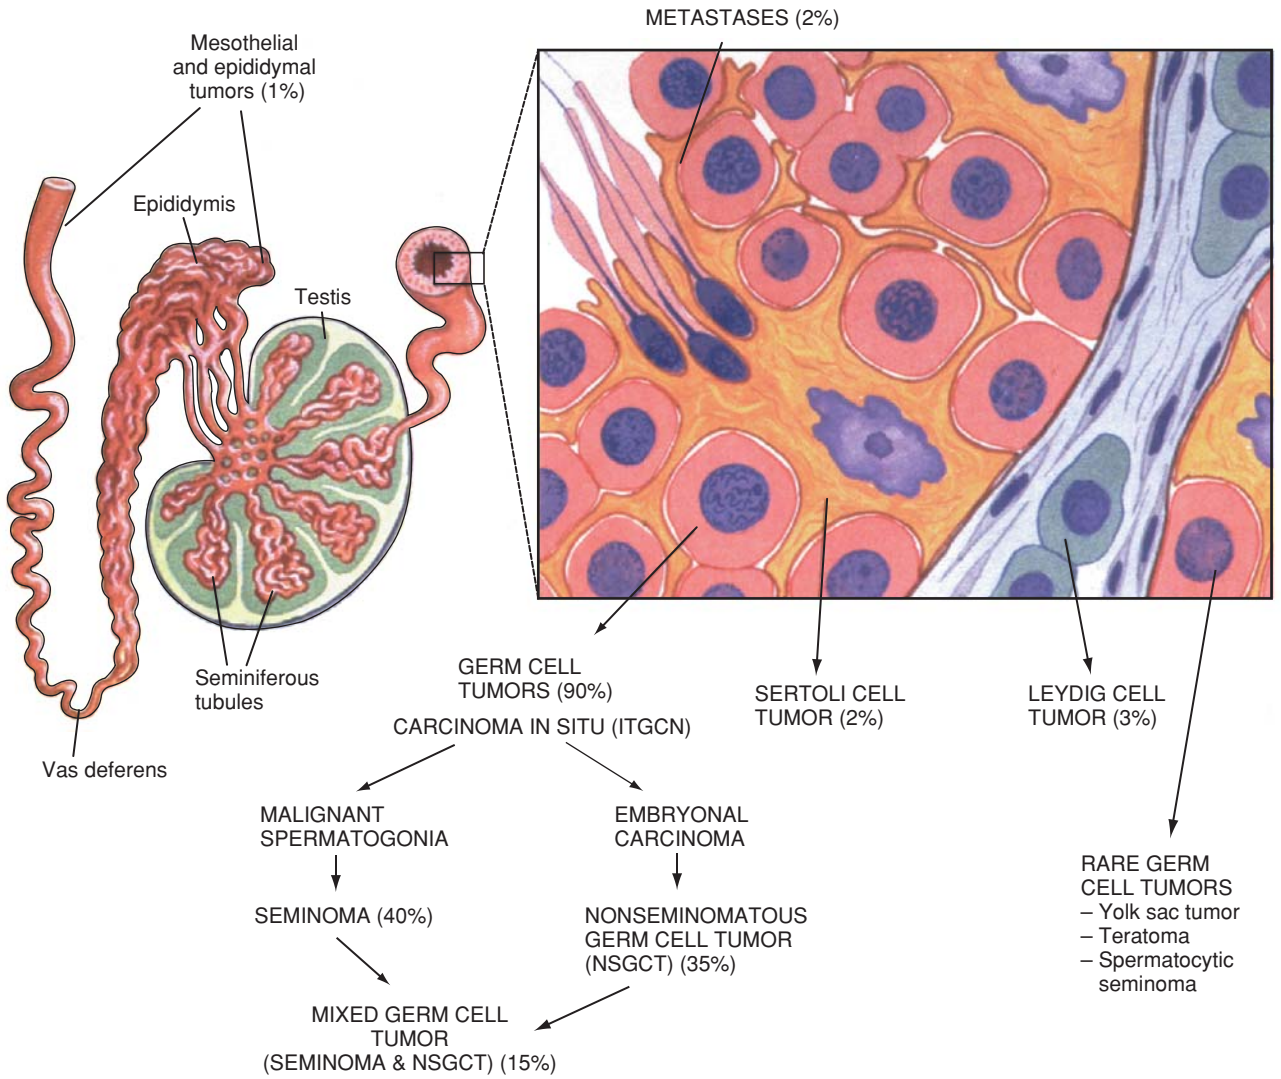

FIGURE 23-30. Tumors of the testis, epididymis and related structures. Most testicular tumors originate from germ cells and are preceded by a carcinoma in situ stage known as intratubular germ cell neoplasia (ITGCN). Germ cell tumors of adult testes can be classified as seminomas (40%) or nonseminomatous germ cell tumors (NSGCTs) (35%). In 15% of cases, seminomatous elements are intermixed with NSGCT, forming mixed germ cell tumors. Some germ cell tumors (yolk sac tumor of childhood, childhood teratomas and spermatocytic seminomas) develop without passing through a preinvasive ITGCN stage. Tumors originating from sex cord stromal cells (Leydig and Sertoli cell tumors) account for 5% of testicular tumors. Epididymal tumors, tumors of the mesothelial lining of the tunica vaginalis (adenomatoid tumors) and metastases are rare.

germ cells without an in situ phase. It is possible that some migratory primordial germ cells may not find their way into the seminiferous tubules during fetal testicular organogenesis and that such "misplaced" cells become progenitors of yolk sac tumors and teratomas. Such cells may also give rise to midline extragonadal germ cell tumors in the retroperitoneum, sacral region, anterior mediastinum and area of the pineal gland.

PATHOLOGY: Testicular tumors are classified histogenetically on the basis of their cell of origin into several groups (Table 23-7).

Tumor cells of ITGCN resemble spermatogonia or fetal germ cells but have much larger polyploid nuclei (Fig. 23-30). Like fetal germ cells, these cells express placental-like alkaline phosphatase (PlAP) on their surface. In infertile men with a history of cryptorchid testes, ITGCN can persist unchanged for 5–10 years, after which the neoplastic cells acquire invasive properties, penetrate tubular basement membranes and give rise to infiltrating malignant tumors.

Malignant cells that retain the phenotype of spermatogonia give rise to **seminomas**. Alternatively, neoplastic germ cells can resemble malignant embryonic cells **(embryonal carcinoma)** by a process like **parthenogenetic activation** of oocytes in the female gonads of amphibians and reptiles.

In some cases, embryonal carcinoma cells proliferate in an undifferentiated form. Thus, the term "embryonal carcinoma" is used to designate undifferentiated embryonic cells and for tumors composed of these cells. In other cases, embryonal carcinoma cells differentiate into the three embryonic germ layers (ectoderm, mesoderm, endoderm) or extraembryonic tissues that form the fetal membranes and

TABLE 23-7
TESTICULAR TUMORS

Germ cell tumors—90%

Leydig cell tumors (60%)
Sertoli cell tumors (40%)
Metastases—2%
Other Rare Tumors—3%

placenta. Further differentiation of germ layer cells leads to formation of various somatic tissues. Ectoderm differentiates into skin, central nervous system, retinal pigment and other related tissues. Mesoderm gives rise to smooth and striated muscle, cartilage and bone. Endoderm forms intestinal tissue, bronchial epithelium, salivary glands and so forth. The extraembryonic derivatives of embryonal carcinoma cells give rise to chorionic epithelium (cytotrophoblast and syncytiotrophoblast) and yolk sac–like epithelium. These complex tumors composed of malignant undifferentiated embryonal cells and their somatic and extraembryonic derivatives are **teratocarcinomas** or **malignant teratomas**. Rarely, extraembryonic components of teratocarcinomas overgrow and destroy all other components. Such tumors are composed of a single tumor type and are classified as **yolk sac carcinoma** or **choriocarcinoma**.

For clinical purposes, all germ cell tumors with embryonal carcinoma as their malignant stem cells are termed **nonseminomatous germ cell tumors (NSGCTs),** to distinguish them from seminomas. Pure yolk sac carcinomas of the adult testis and choriocarcinomas are also included in this group because it is assumed that these tumors originated from embryonal carcinoma cells and still may contain a few such cells that are not readily recognizable.

In 15% of cases, germ cell tumors have both seminoma and nonseminomatous elements. Such **mixed germ cell tumors** are treated clinically as nonseminomatous neoplasms.

Intratubular Germ Cell Neoplasia Is Testicular Carcinoma in Situ

ITGCN represents a preinvasive form of germ cell tumors.

EPIDEMIOLOGY: ITGCN can be seen as (1) an isolated focal histologic change in 2% of cryptorchid testes or testicular biopsies performed for infertility, (2) widespread carcinoma in situ adjacent to almost all invasive germ cell tumors and (3) lesions in 5% of contralateral testes in patients who had an orchiectomy for a testicular germ cell tumor.

PATHOLOGY: ITGCN involves testes patchily, usually affecting less than 10%–30% of tubules. Seminiferous tubules harboring this lesion have thick basement membranes and no sperm. The normal germ cells are replaced by neoplastic ones that are broadly attached to the basal lamina (Fig. 23-31). The tumor cells are larger than normal spermatogonia and have large central nuclei with finely dispersed chromatin and prominent nucleoli. Their cytoplasm is abundant and clear, with abundant glycogen. Nuclear DNA content is increased, suggesting that the cells are triploid. Plasma membranes are distinct and stain with antibodies to PlAP. The transcription factor OCT3/4 is a reliable marker for nuclei of ITGCN cells.

CLINICAL FEATURES: ITGCN is a precursor of invasive carcinoma, but the invasive tumor develops at an unpredictable pace. Half of men with ITGCN develop invasive cancer within 5 years and 70% in 7 years. Diagnosis of ITGCN on testicular biopsy is an indication for prophylactic orchiectomy.

Seminomas Contain Monomorphous Cells that Resemble Spermatogonia

EPIDEMIOLOGY: Seminomas are the most common testicular cancer, making up 40% of all germ cell tumors. Peak incidence is 30–40 years, and they are not found before prepuberty, except in those who have dysgenetic gonads.

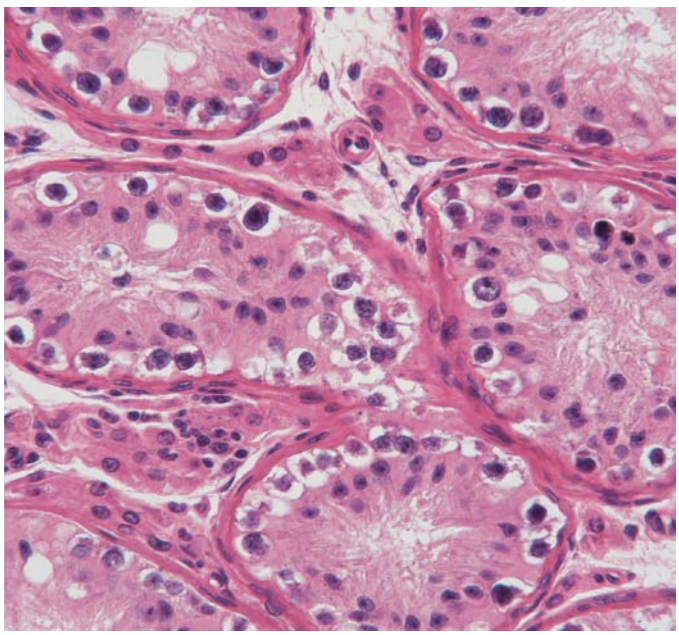

FIGURE 23-31. Intratubular germ cell neoplasia (ITGCN). The seminiferous tubules show no signs of spermatogenesis but instead contain large atypical cells corresponding to intratubular carcinoma in situ.

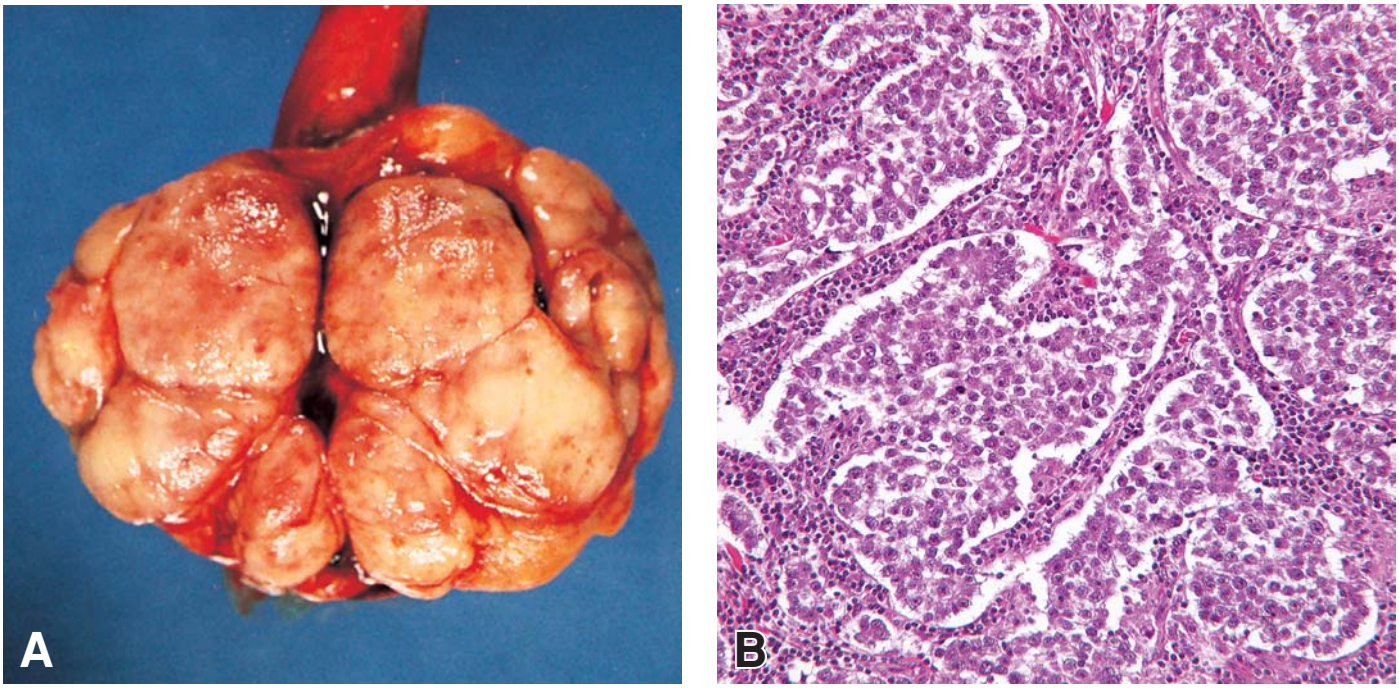

FIGURE 23-32. Seminoma. A. The cut surface of this nodular tumor is tan and bulging, suggesting that the tumor is firm and rubbery. **B.** Groups of tumor cells are surrounded by fibrous septa infiltrated with lymphocytes. Tumor cells have vesicular nuclei, which are much larger than the small round nuclei of the lymphocytes.

PATHOLOGY: Seminomas are solid, rubbery-firm, bosselated masses that are usually sharply demarcated from normal tissue, which may be compressed, atrophic and fibrotic. On cross-section the tumors look lobulated and homogeneous tan or grayish yellow (Fig. 23-32). Areas of necrosis or hemorrhage are infrequent but may be seen in larger tumors.

Seminomas resemble **ovarian dysgerminoma** (see Chapter 24) microscopically. They feature a single population of uniform polygonal cells with central vesicular nuclei. Their ample cytoplasm may be pale and eosinophilic or clear, since it has considerable glycogen and some lipid. Cells grow in nests or sheets separated by fibrous septa infiltrated with lymphocytes, plasma cells and macrophages. Septa may contain granulomas with giant cells. Tumor cells invade the testicular parenchyma and spread through seminiferous tubules into rete testis. The epididymis is involved later in the disease, usually before spread to abdominal lymph nodes.

Seminoma cells resemble immature spermatogonia. Like fetal spermatogonia and primordial germ cells in the fetus, they express PlAP on the plasma membrane. Seminoma cells also react with antibodies to c-Kit (CD117) and OCT3/4, which are reliable markers for this tumor.

Pathologists recognize two subtypes of seminoma: (1) **seminoma with syncytiotrophoblastic giant cells** and (2) **anaplastic seminoma**. The first subgroup includes the 20% of tumors that contain syncytiotrophoblastic cells. These multinucleated giant cells are best demonstrated with antibodies to human chorionic gonadotropin (hCG). Although they secrete hCG, blood hCG levels are usually below detectable limits. Some 5% of seminomas show brisk mitotic activity and nuclear pleomorphism and are classified as **anaplastic seminoma**. There are no clinical differences between classical seminomas and these two microscopic tumor variants.

CLINICAL FEATURES: Seminomas are usually progressively growing scrotal masses that are often diagnosed while still curable by orchiectomy, with or without abdominal lymph node dissection. They are highly radiosensitive, and radiotherapy is important in treating tumors that are cured by surgery alone. Even in advanced stages of dissemination, chemotherapy can be curative. ***The cure rate for all histologic subtypes of seminoma is now over 90%.***

Spermatocytic seminoma is a rare tumor, which, despite its name, is unrelated to classical seminoma. These are benign tumors of men over age 40. They are not associated with ITGCN and do not elicit lymphocytic reactions. Spermatocytic seminomas contain three cell types: large, small and intermediate cells. Immunohistochemically, the cells of these tumors do not express typical seminoma markers. Orchiectomy is curative.

Nonseminomatous Germ Cell Tumors Derive from Embryonal Cells

NSGCTs of the testis include several entities, two of which account for most of the cases: (1) pure embryonal carcinoma and (2) teratocarcinoma, also known as **malignant teratoma** or **mixed germ cell tumor**. **Pure choriocarcinoma, pure yolk sac carcinoma of the adult testis** and the so-called **growing benign teratoma** are rare NSGCTs. Mixed germ cell tumors are NSGCTs combined with seminomas.

EPIDEMIOLOGY: NSGCTs constitute 55% of all testicular germ cell tumors, of which 2/3 are teratocarcinomas, followed by mixed germ cell tumors and pure embryonal carcinomas. All other tumors of this group are extremely rare. Like seminomas, NSGCTs have a peak incidence in the third to fourth decades. At diagnosis, these patients are usually somewhat younger than those with seminomas.

FIGURE 23-33. Nonseminomatous germ cell tumor (NSGCT) of the testis. The cut surface of this small testicular tumor shows considerable heterogeneity, varying in color from white to dark red.

PATHOLOGY: NSGCTs vary in size and shape. They may be solid or partially cystic. Solid areas vary from white to yellow to red, indicating that they are composed of viable tumor cells, foci of necrosis and hemorrhage, respectively (Fig. 23-33).

The histology of NSGCTs is highly variable. Pure embryonal carcinomas exclusively contain undifferentiated embryonal carcinoma cells like cells from preimplantation-stage embryos (Fig. 23-34). Because the tumor cells have little cytoplasm, their hyperchromatic, disproportionately large nuclei seem to overlap. Embryonal carcinoma cells may grow as broad solid sheets, cords, gland-like tubules and acini, and sometimes even line papillary structures. Mitoses and apoptotic cells are common. Embryonal carcinomas invade the testis, epididymis and blood vessels and metastasize to abdominal lymph nodes, lungs and other organs.

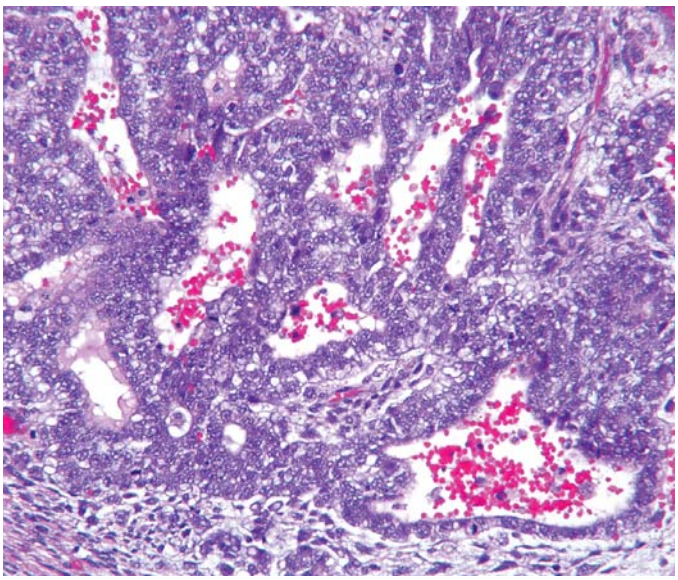

FIGURE 23-34. Embryonal carcinoma component of a nonseminomatous germ cell tumor (NSGCT). Because these undifferentiated cells have scant cytoplasm, their hyperchromatic nuclei impart a bluish color to the tumor. The nuclei appear crowded and seem to overlap each other. The cells form cords and sheets surrounding dilated vascular channels filled with red blood cells.

Embryonal carcinomas, like seminomas, react with antibodies to PlAP and OCT 3/4. Unlike seminomas and other tumors, they express cytokeratins and CD30, but not c-KIT (CD117).

Embryonal carcinoma cells are the stem cells of **teratocarcinomas (malignant teratomas),** which feature differentiated somatic elements (i.e., tissues normally found in various organs, and extraembryonic elements, including yolk sac cells and trophoblastic cells). Thus, such nonseminomatous tumors have foci of embryonal carcinoma and of other tissues (Fig. 23-35). Such a tumor might, for example, contain components of embryonal carcinoma, yolk sac and trophoblast. However, a similar tumor that also contains seminoma cells would be called a **mixed germ cell tumor**. In most tumors, the malignancy resides in the embryonal carcinoma cells. Interestingly, when these cells metastasize, they can differentiate into somatic or extraembryonic tissues, in which case the metastatic tumor can resemble the original one.

NSGCTs can give rise to clones of highly malignant cytotrophoblast and syncytiotrophoblast cells that overgrow other elements. Tumors composed exclusively of malignant chorionic epithelium are termed **choriocarcinomas**. Likewise, clones of malignant yolk sac epithelium produce **yolk sac carcinoma**.

Some histologically benign teratomas of postpubertal young men may have a malignant clinical course, even though they appear to be only mature, nonproliferating somatic tissues, without embryonal elements (Fig. 23-36). In some instances, it is assumed that the tumor was actually a teratocarcinoma in which almost all embryonal cells differentiated into mature somatic tissues but that a few remaining malignant cells were unnoticed, or had metastasized before resection. These tumors are clinically known as the **growing teratoma syndrome**. In other cases, teratoma tissues remain undifferentiated and resemble embryonic organs or embryonic tumors such as neuroblastoma. These **immature teratomas** are also potentially malignant.

CLINICAL FEATURES: Most NSGCTs present as testicular masses. They tend to grow faster than seminomas and metastasize more readily and more widely. Hence, for some NSGCTs, metastases may be the first sign of the neoplasm.

Unlike seminomas, NSGCTs often contain yolk sac and syncytiotrophoblastic components. Yolk sac cells secrete α-fetoprotein (AFP), a fetal protein not normally found in the blood. Syncytiotrophoblast cells release hCG, a hormone of pregnancy, that is also not found in males. ***Elevated serum AFP or hCG is found in 70% of patients with NSGCTs and is thus a useful tumor marker.*** Serum AFP, hCG and lactate dehydrogenase (a nonspecific tumor marker that reflects the extent of the total tumor mass) must be measured in all patients before orchiectomy and are included in the clinical staging of the tumor. These antigens are most useful to follow postoperative patients who have been treated for NSGCT. Persistently elevated AFP and/or hCG indicates that a patient is not tumor free. If initially high levels of AFP and hCG normalize after treatment but later rise again, metastatic spread is likely. AFP is a relatively insensitive marker of recurrence as elevated serum AFP is found only in 70% patients with recurrent cancer.

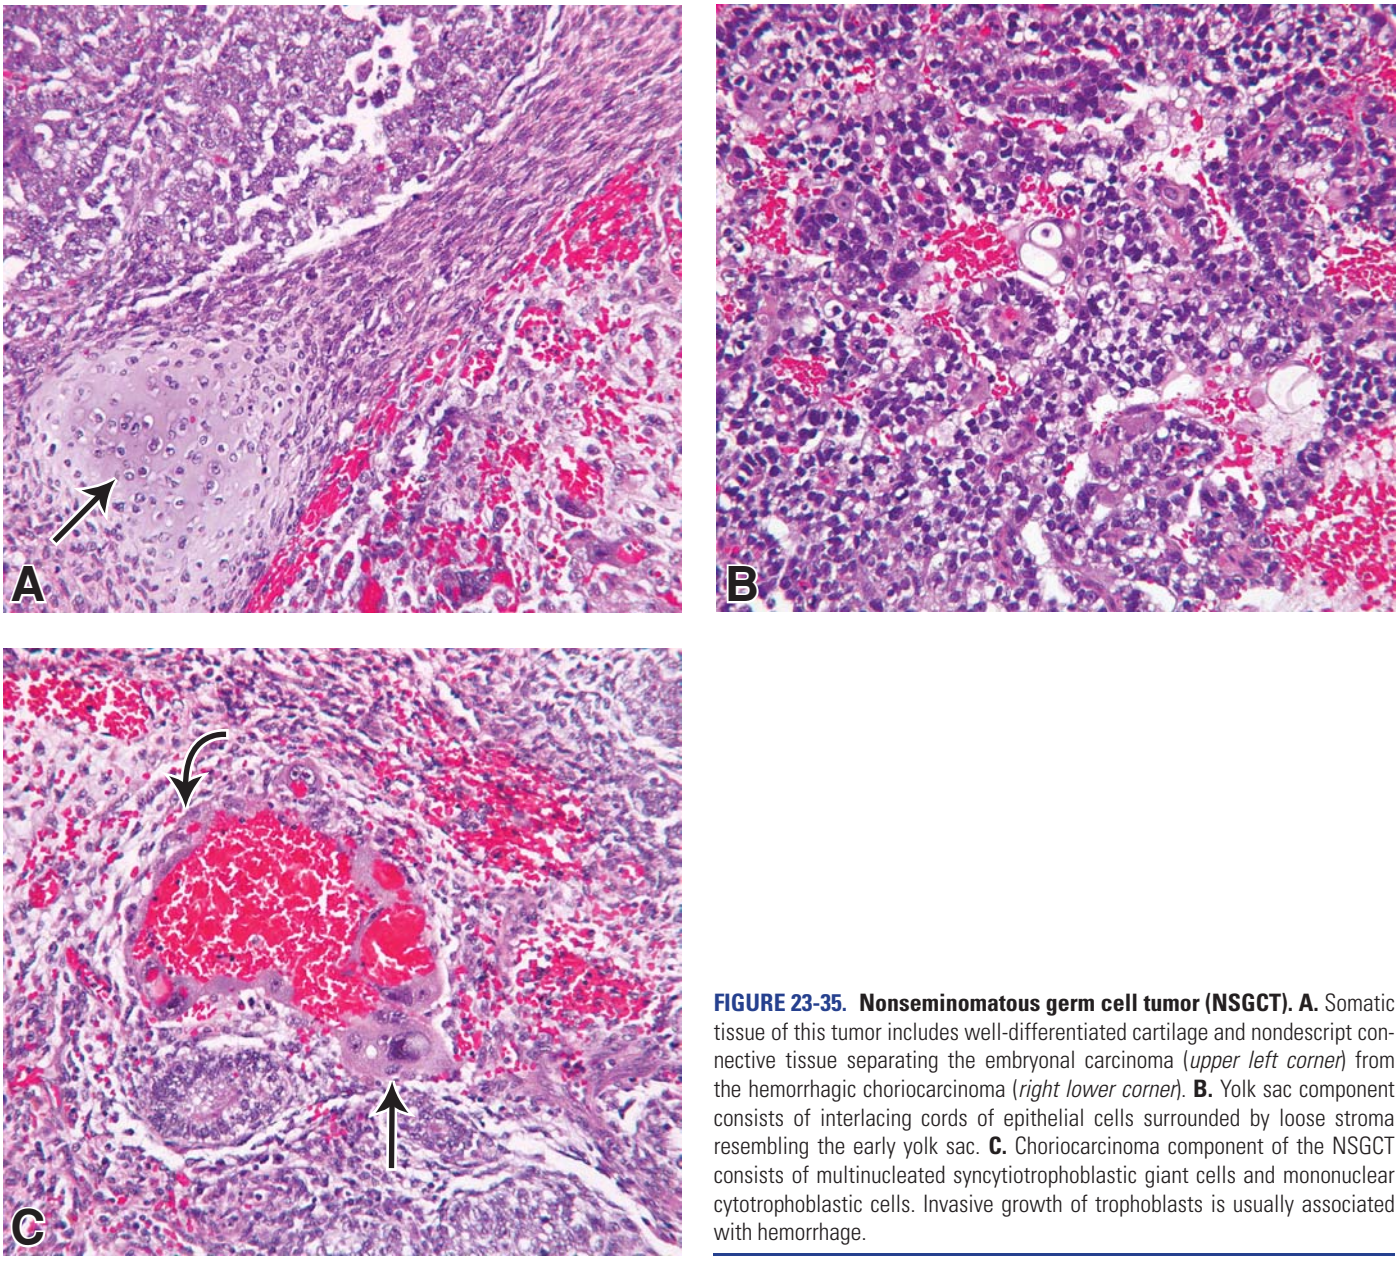

FIGURE 23-35. Nonseminomatous germ cell tumor (NSGCT). A. Somatic tissue of this tumor includes well-differentiated cartilage and nondescript connective tissue separating the embryonal carcinoma (*upper left corner*) from the hemorrhagic choriocarcinoma (*right lower corner*). **B.** Yolk sac component consists of interlacing cords of epithelial cells surrounded by loose stroma resembling the early yolk sac. **C.** Choriocarcinoma component of the NSGCT consists of multinucleated syncytiotrophoblastic giant cells and mononuclear cytotrophoblastic cells. Invasive growth of trophoblasts is usually associated with hemorrhage.

Treatment of NSGCT includes orchiectomy to remove the primary tumor, then platinum-based chemotherapy and, if indicated, surgical dissection of abdominal lymph nodes. Chemotherapy usually eliminates metastatic embryonal carcinoma cells, but differentiated tissues originating from them are resistant. Such tissues do not grow and are not likely to endanger the patient. Nevertheless, it is better to remove any residual tumor than to take a chance that a few malignant tumor cells might be lurking in residual tumors. ***Complete cures of NSGCTs are now common in over 90% of cases.***

Testicular Tumors Are Rare in Prepubertal Boys

In the first 4 years of life, most testicular neoplasms are yolk sac tumors. Benign teratomas are the most common testicular tumor between ages 4 and 12 years.

YOLK SAC TUMORS: These neoplasms are composed of cells arranged into structures reminiscent of parts of fetal yolk sac. Diagnosis is based on recognizing multiple microscopic tumor patterns and glomeruloid **Schiller-Duval bodies** (Fig. 23-37). These neonatal tumors resemble those of the yolk sac elements in NSGCTs. All such tumors secrete AFP into the serum. Yolk sac tumors of infancy and early childhood are considered malignant, but timely orchiectomy and removal of the tumor cure over 95% of patients.

TERATOMAS: These tumors of prepubertal testes are benign and are composed of mature somatic tissues. Orchiectomy and even testis-sparing surgery are curative.

Gonadal Stromal/Sex Cord Tumors Are Composed of Cells that Resemble Sertoli or Leydig Cells

Gonadal stromal/sex cord tumors make up 5% of testicular tumors.

LEYDIG CELL TUMORS: These are rare neoplasms composed of cells resembling interstitial (Leydig) cells of the testis. They can be hormonally active and secrete androgens, estrogens or both. Leydig cell tumors occur at any age, with

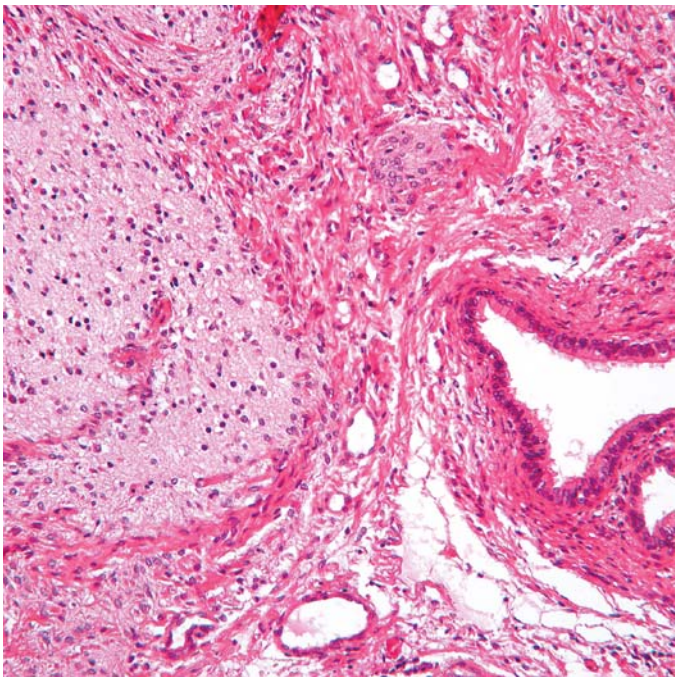

FIGURE 23-36. Teratoma. The tumor consists of neural tissue (*left*) connective tissue and smooth muscle cells (*midportion*) and glands lined by columnar epithelium (*right side of the picture*).

distinct peaks in childhood and then in adults from the third to the sixth decade.

PATHOLOGY: Leydig cell tumors vary from 1 to 10 cm and are circumscribed; some appear encapsulated. The cut surface is yellow to brown, and larger tumors have fibrous trabeculae, giving them a lobular appearance. Leydig tumor cells are uniform, with round nuclei and well-developed eosinophilic or vacuolated cytoplasm (Fig. 23-38). **Reinke crystals**—rectangular, eosinophilic, cytoplasmic inclusions—are characteristic of normal Leydig cells and are seen in 30% of tumors. Most (90%) Leydig cell tumors are benign, but it is difficult to predict their biological behavior on histologic grounds.

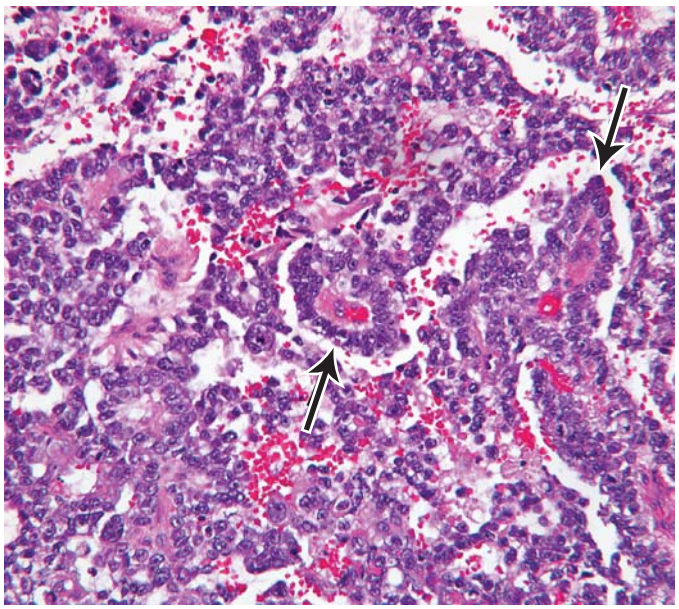

FIGURE 23-37. Yolk sac tumor. This childhood tumor is composed of interlacing strands of epithelial cells surrounded by loose connective stroma. The glomeruloid structures (Schiller-Duval bodies) are marked by arrows.

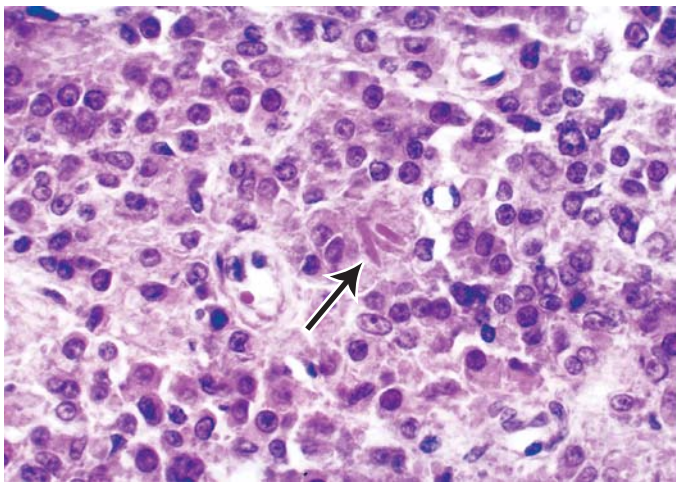

FIGURE 23-38. Leydig cell tumor. The tumor cells have uniform round nuclei and well-developed eosinophilic cytoplasm. Three cytoplasmic Reinke crystals are seen in the center of the field (*arrow*).

CLINICAL FEATURES: Androgenic effects of testicular Leydig cell tumors in prepubertal boys lead to precocious physical and sexual development. By contrast, feminization and gynecomastia are seen in some adults with this tumor. Either estrogen or testosterone levels may be elevated, but there is no characteristic pattern. All Leydig cell tumors in children and almost all tumors in adults are cured by orchiectomy.

SERTOLI CELL TUMORS: Some testicular sex cord stromal cell tumors contain neoplastic Sertoli cells. Most (90%) are benign and produce few if any hormonal symptoms.

PATHOLOGY: Sertoli cell tumors are small (1–3 cm), solid, yellow-gray, well-circumscribed nodules. They contain columnar tumor cells arranged into tubules or cords in a fibrous trabecular framework (Fig. 23-39). The rare malignant variant shows greater

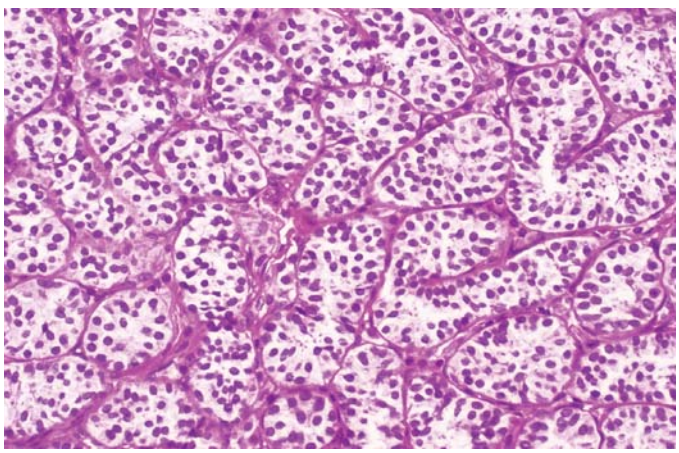

FIGURE 23-39. Sertoli cell tumor. The neoplastic cells are arranged in tubules surrounded by a basement membrane. These structures are reminiscent of seminiferous tubules devoid of germ cells.

cellular pleomorphism, focal necrosis and few cords and tubules. Most patients with Sertoli cell tumors are younger than age 40 and come to medical attention because of a scrotal mass. Endocrine effects are uncommon and, if present, are vague. Orchiectomy is curative.

All Other Germ Cell Tumors are Rare

Tumors may originate from the epithelium of the epididymis, connective tissue stroma, mesothelium and tunica vaginalis testis. All these tumors are rare. Metastatic tumors, including lymphomas, are also uncommon. All these tumors together account for less than 5% of all scrotal masses.

ADENOMATOID TUMOR: Adenomatoid tumor (benign mesothelioma) is a benign tumor that originates from the mesothelium of the testicular tunica vaginalis. These neoplasms usually occur in the upper pole of the epididymis, with fewer involving the tunica vaginalis or spermatic cord. They are well-demarcated nodules found by palpating the testis or epididymis. Microscopically, they contain mesothelial cells in cords or small duct-like structures embedded in dense fibrous stroma. Malignant mesotheliomas of tunica vaginalis testis are very rare.

METASTASES: Most of these spread from primary cancers of the prostate, large intestine or bladder (i.e., organs that are located in the pelvis and close to the testes).

MALIGNANT LYMPHOMA: This cancer is the most common neoplasm in the testes of men older than 60 years. It may be primary in the testis. More often, it reflects seeding of lymphoma from other sites or occurs in patients with leukemia. Diffuse large B-cell lymphoma is the most common form of lymphoma involving the testis. Most patients with lymphomatous involvement of the testis have a poor prognosis.

Prostate

The pathologic processes affecting the prostate can be simplified by considering just three processes: (1) inflammation, (2) hyperplasia and (3) neoplasia.

PROSTATITIS

Prostatitis is inflammation of the prostate. There are acute and chronic forms. Prostatitis is usually caused by coliform uropathogens, but often no etiology is found.

ACUTE PROSTATITIS: Typically a complication of other urinary tract infections, acute prostatitis results from reflux of infected urine into the prostate. An acute inflammatory infiltrate is seen in prostatic acini and stroma. It causes intense discomfort on urination and is often associated with fever, chills and perineal pain. Most patients respond well to antibiotics.

CHRONIC BACTERIAL PROSTATITIS: This infection is of longer duration that may or may not be preceded by an episode of acute prostatitis. Most patients complain of dysuria and burning at the urethral meatus. Suprapubic, perineal and low back pain or discomfort and nocturia may be also present. The urine usually contains bacteria. In addition to reflux of urine, prostatic calculi and local prostatic duct obstruction may contribute to development of chronic bacterial prostatitis. Infiltrates of lymphocytes, plasma cells and macrophages are the rule. Prolonged antibiotic therapy is often, but not always, curative.

NONBACTERIAL PROSTATITIS: Sometimes in chronic prostatitis, no causative organism is identified. It is the most common form of inflammation in prostatic biopsies, in prostatectomy specimens or at autopsy. Nonbacterial prostatitis typically affects men older than 50 years but can be seen at any age. Some cases may be due to *C. trachomatis, Mycoplasma* or *U. urealyticum.* However, in practice, nonbacterial prostatitis is a diagnosis of exclusion. The most common histology shows dilated glands filled with neutrophils and foamy macrophages surrounded by chronic inflammatory cells. The condition may be asymptomatic or it may cause symptoms like those of chronic bacterial prostatitis. Usually, no specific therapy is available.

GRANULOMATOUS PROSTATITIS: In most cases, the cause of granulomatous prostatitis cannot be established. Rarely, this disease can be traced to specific causative agents, including *M. tuberculosis,* BCG or fungi such as *Histoplasma capsulatum.* A granulomatous lesion resembling rheumatoid nodules has been related to previous transurethral resection of a portion of the prostate. The symptoms of chronic granulomatous prostatitis are vague and the diagnosis is made histologically. Caseating or noncaseating granulomas are associated with localized destruction of prostatic ducts and acini and, in later stages, with fibrosis.

CLINICAL FEATURES: As indicated above, symptoms of chronic prostatitis are highly variable and treatment may be ineffective. Most importantly, it may cause elevated serum prostate-specific antigen (PSA), a worrisome suggestion of prostatic malignancy (see below). Thus, the diagnosis is often made by biopsy done to exclude carcinoma.

NODULAR HYPERPLASIA OF THE PROSTATE

Nodular prostatic hyperplasia, also called benign prostatic hyperplasia ***(BPH), is a common disorder characterized clinically by obstruction of urinary outflow and pathologically by proliferation of glands and stroma.***

EPIDEMIOLOGY: BPH is most common in western Europe and the United States and least common in Asia. Its prevalence in the United States is higher among blacks than among whites. Clinical prostatism (i.e., BPH severe enough to interfere with urination) peaks in the seventh decade. However, prevalence of BPH is far greater at autopsy than is suggested by clinically apparent prostatism. In fact, 75% of men over age 80 have some degree of prostatic hyperplasia. The disorder is rare in men younger than 40 years of age.

MOLECULAR PATHOGENESIS: The earliest histogenetic events in BPH remain unclear. Testosterone is necessary for prostatic development and to maintain secretory function. The active androgen form is dihydrotestosterone (DHT), a product of the enzyme 5α-reductase. DHT binds nuclear receptors in glandular and stromal cells. In men, exogenous testosterone does not induce hyperplasia and does not even stimulate atrophic glands. With aging, circulating testosterone levels decline in men with and without BPH. As well, no change in serum

DHT is seen in men with BPH, although the ratio of circulating testosterone to DHT may be low. Conversely, drugs that block 5α-reductase (e.g., finasteride or dutasteride) reduce the size of the prostate in men with BPH. Prepubertal castration prevents the development of age-related BPH and completely protects against prostate cancer.

PATHOLOGY: Early nodular hyperplasia begins in the submucosa of the proximal urethra **(the transitional zone)**. Enlarging nodules compress the centrally located urethral lumen and the more peripherally located normal prostate (Fig. 23-40). In well-developed BPH, the normal gland is actually limited to an attenuated rim of tissue beneath the capsule. Individual nodules are demarcated by enveloping fibrous pseudocapsules (Fig. 23-41B). Larger nodules may show focal hemorrhage or infarction. Small stones may be seen as well.

In BPH, proliferation of epithelial cells of acini and ductules, smooth muscle cells and stromal fibroblasts are all

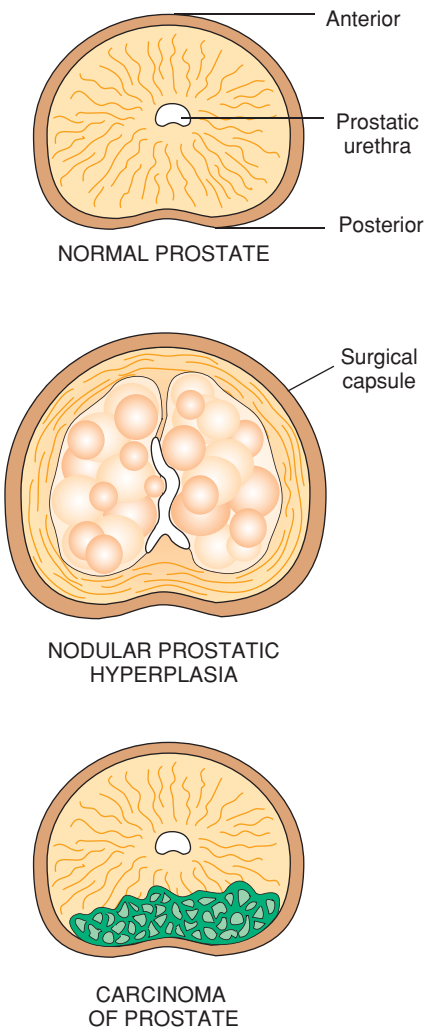

FIGURE 23-40. Normal prostate, nodular hyperplasia and adenocarcinoma. In prostatic hyperplasia, which involves predominantly the periurethral part of the gland, the nodules compress and distort the urethra. The expansion of the central prostatic glands leads to compression of the peripheral parts and fibrosis, resulting in the formation of a so-called surgical capsule. Prostatic carcinoma usually arises from the peripheral glands, and compression of the urethra is a late clinical event.

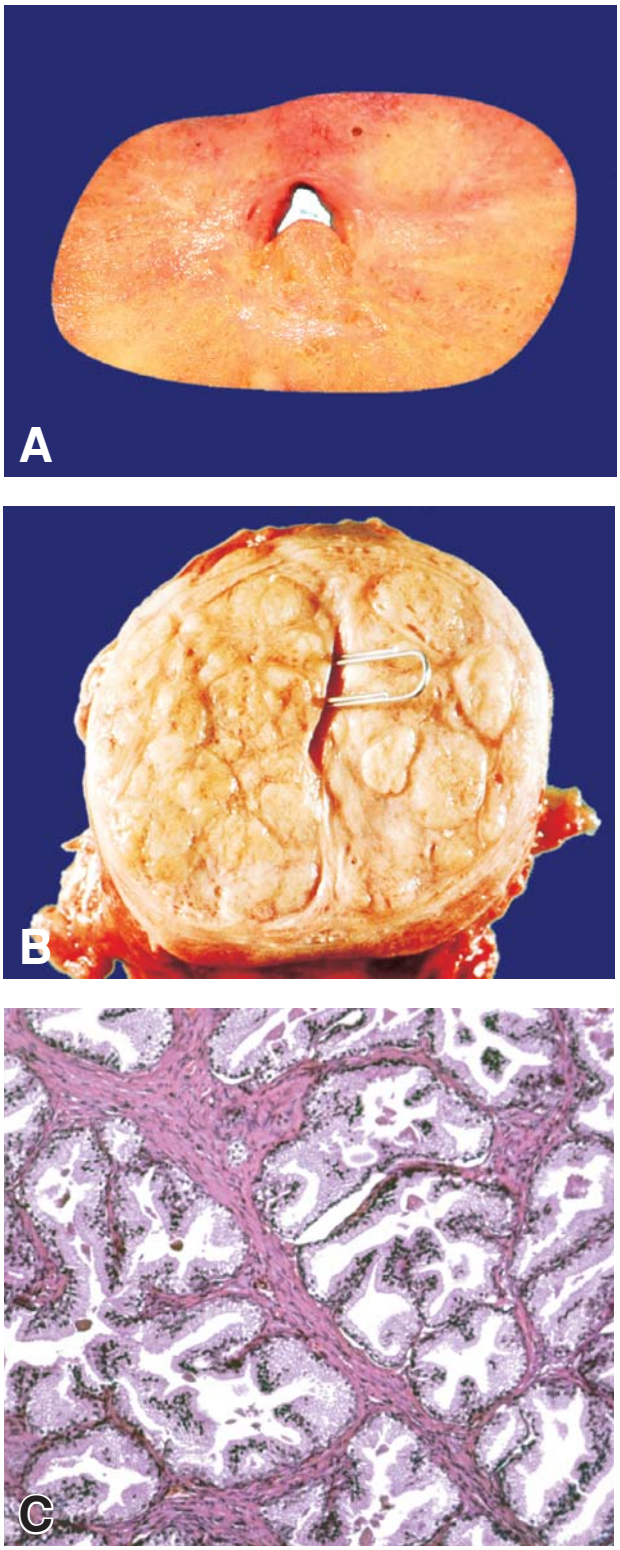

FIGURE 23-41. Nodular hyperplasia of the prostate. A. The cut surface of a prostate enlarged by nodular hyperplasia shows numerous well-circumscribed nodules of prostatic tissue surrounded by pseudocapsules. The prostatic urethra (*paper clip*) has been compressed to a narrow slit. **B.** Normal prostate. **C.** Hyperplastic prostate glands in nodular hyperplasia. The columnar epithelium lining the acini is composed of two cell layers: polarized clear cuboidal cells lining the acinar lumen and flattened basal cells interposed between the cuboidal acinar cells and the stroma. Hyperplastic cells line papillary projections protruding into the lumina of the acini.

seen in variable proportions. Typical fibromyoadenomatous nodules contain variably sized hyperplastic prostatic acini randomly scattered throughout their stroma. The epithelial (adenomatous) component contains a double layer of cells, with tall columnar cells overlying a basal layer (Fig. 23-41C) and often showing papillary hyperplasia. Chronic inflammation and corpora amylacea (eosinophilic laminated concretions) are frequently seen within the acini. In the uninvolved peripheral region of the prostate, glands are often atrophic and compressed by the expanding nodules.

Nonspecific prostatitis is common in nodular hyperplasia. There is a dense intraglandular and periglandular infiltrate of lymphocytes, plasma cells and macrophages, often with acute inflammatory cells and focal gland destruction. Focal infarcts of varying age are present in 20% of cases. Squamous metaplasia of ductal epithelium at the periphery of infarcts is typical.

CLINICAL FEATURES: The symptoms of nodular hyperplasia result from compression of the prostatic urethra and consequent bladder outlet obstruction (Fig. 23-42). A history of decreased vigor of the urinary stream and increasing urinary frequency is typical. Rectal examination reveals a firm, enlarged, nodular prostate. If severe obstruction is prolonged, back-pressure results in hydroureter, hydronephrosis and ultimately renal failure and death.

Treatment of BPH is either surgical or pharmacologic with drugs that block 5α-redutase. In addition, some patients receive α_1-adrenergic blockers to enhance urine flow. Transurethral radiofrequency ablation and cryotherapy are the surgical treatments of choice.

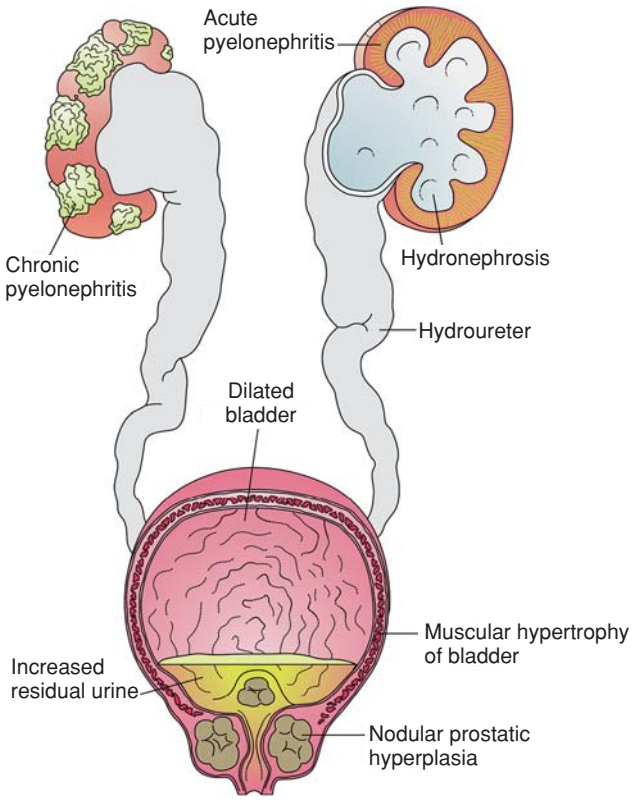

FIGURE 23-42. Complications of nodular prostatic hyperplasia.

IN SITU AND INVASIVE ADENOCARCINOMA OF THE PROSTATE

EPIDEMIOLOGY: ***In 1990, prostatic adenocarcinoma surpassed lung cancer to become the cancer most frequently diagnosed in American men.*** An estimated 220,000 new cases are diagnosed yearly in the United States. About 30,000 American men die annually from it, a figure equivalent to that of colorectal carcinoma. Prostate cancer is largely a disease of elderly men: 75% of patients are 60–80 years of age. Autopsy studies confirm that the tumor is more common with advancing age. Prostate cancer is diagnosed at autopsy in 20% of men in their 40s, and in 70% of men over age 70. The cumulative lifetime probability of being diagnosed with latent or symptomatic prostatic carcinoma is one in six for American men. There is considerable variation in age-related death rates for adenocarcinoma of the prostate throughout the world, the highest being in the United States and Scandinavian countries and the lowest in Mexico, Greece and Japan. Most western European countries have intermediate rates. American blacks, with a rate twice as high as that of white Americans, have the highest prostate carcinoma–related death rates in the world. In the United States, descendants of Polish and Japanese immigrants have a higher incidence of prostatic carcinoma than men in their original countries. Similarly, mortality from prostatic carcinoma among black American men exceeds that among blacks in Africa.

In addition to geography, racial and age differences, heredity and possibly diet influence prostate cancer risk. One tenth of cases have familial tendencies, so risk is significantly increased in persons with first-degree relatives with prostate cancer. Dietary fat content may increase risk of prostate cancer, but neither environment nor dietary factors have been found to be causative.

Unfortunately, the clinical course of prostate cancer is often capricious. Some tumors are amenable to therapy, while others are not. Further, many prostate cancers are so indolent (or latent) that they may never be clinically significant during the patient's lifetime. For this reason, the utility of screening for prostate cancer using blood PSA levels is controversial.

MOLECULAR PATHOGENESIS: Androgenic control of normal prostatic growth and the responsiveness of prostate cancer to castration and exogenous estrogens indicate a role for male hormones. However, patients with prostate cancer do not typically have higher levels of circulating androgens. Elevated urinary estrone-to-testosterone ratios have been reported. The androgen (AR) gene shows considerable variation in CAG repeats in exon 1. Men with fewer AR CAG repeats are at greater risk for developing prostate cancer. Some tumors show somatic mutations that place the transcription factor gene ETV1 under the control of the androgen-regulated TMPRSS2 promoter. Other cases show hypermethylation of the gene for the antioxidant enzyme glutathione S-transferase. Altered regulation of STAT transcription factors and dysregulation of the PTEN tumor suppressor are also documented.

There is consensus that intraductal dysplastic epithelial proliferation, termed **prostatic intraepithelial neoplasia (PIN),** is a precursor lesion of prostatic adenocarcinoma. ***PIN describes prostatic ducts lined by cytologically atypical luminal cells and a concomitant decrease in basal cells.***

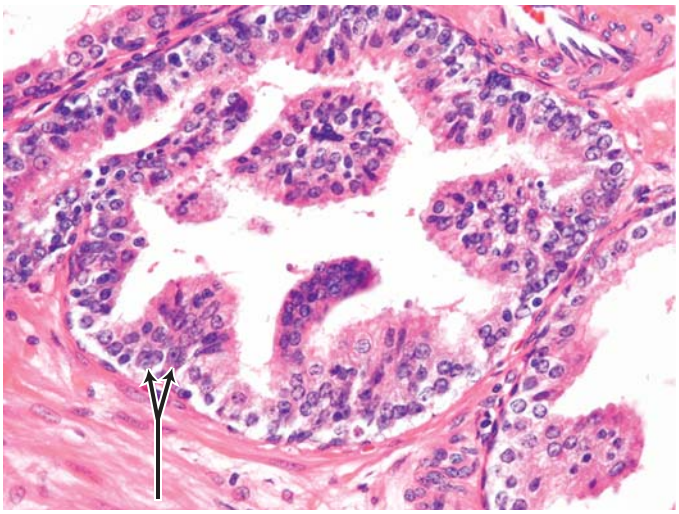

FIGURE 23-43. High-grade prostatic intraepithelial neoplasia (PIN). The large duct in the center is lined by atypical cells with enlarged nuclei and prominent nucleoli (*arrows*).

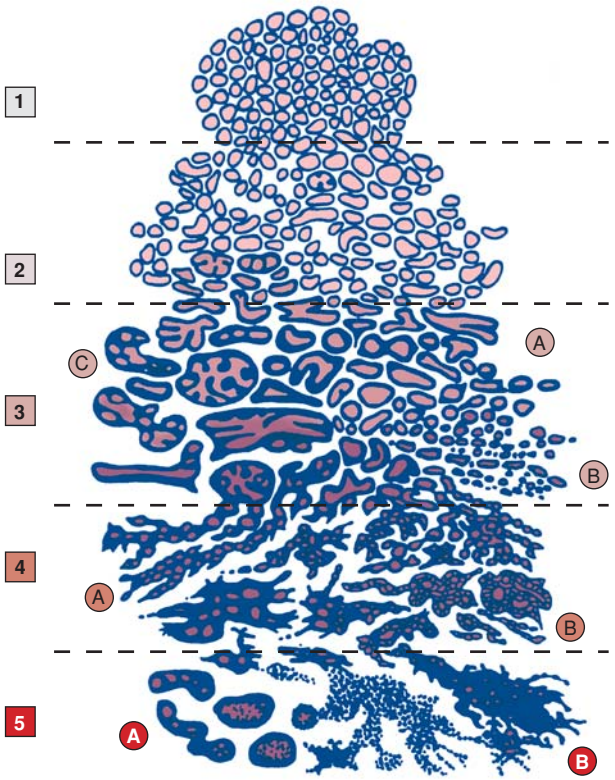
Nuclei of high-grade PIN are enlarged and show nucleoli and marked crowding (Fig. 23-43). Substantial data indicate that PIN lesions are premalignant and progress to adenocarcinoma. High-grade PIN may precede invasive cancer by up to two decades, and their severity increases with increasing age.

Morphologic evidence linking PIN to invasive prostate cancer includes (1) both lesions are mainly peripheral, (2) cytologic similarity of high-grade PIN to invasive cancer and (3) close topographic proximity of high-grade PIN to invasive cancer. Finally, PIN lesions are more frequent in prostates with cancer than in those without tumors. Certain indicators in high-grade PIN resemble those of invasive cancer (e.g., aneuploidy, transforming growth factor [TGF]-α, type IV collagenase, expression of *bcl-2* and *c-erb-2* oncogenes). Recognition of high-grade PIN on needle biopsy is important because many patients with high-grade PIN on initial biopsy have invasive carcinoma on follow-up biopsy.

PATHOLOGY: Adenocarcinomas account for the vast majority of all primary prostatic tumors. They are commonly multicentric and located in the peripheral zones in over 70% of cases. The cut surface of a carcinomatous prostate shows irregular, yellow-white, indurated subcapsular nodules.

HISTOLOGIC FEATURES OF INVASIVE CARCINOMA: Most prostatic adenocarcinomas are of acinar origin and feature small to medium-sized glands that lack organization and infiltrate the stroma. Well-differentiated tumors show uniform medium-sized or small glands (Fig. 23-44) lined by



GLANDS

Differentiation	Distribution
1 'Round,' lined by single layer of cuboidal cells	Close packed in rounded masses; definite edge
2 More variable in size and shape	Separated up to one gland diameter; 'loose' edge
3a Irregular shape; medium to large size 3b Small to minute glands, not fused or 'chained' 3c Masses of cribriform or papillary epithelium with smooth outer surfaces	Irregularly spaced apart; poorly defined 'edge'; surround normal strucutres Very irregular spacing and distribution; no 'edge'; surround normal structures
4a Ragged masses of fused glandular epithelium; bare tumor cells in stroma 4b Same as 4a; large clear cells	Ragged infiltrating masses that overrun normal structures; No smooth surfaces against stroma
5a Smooth, cribriform to solid masses; often central necrosis 'comedocarcinoma' 5b Anaplastic carcinoma with vacuoles and glands that suggest adenocarcinoma	Ragged infiltrating masses that infiltrate stromal fibers

FIGURE 23-44. Prostatic carcinoma. Gleason grading system.

a single layer of neoplastic epithelial cells. Malignant acini have no basal cells and no longer grow in lobular patterns. Progressive loss of differentiation of prostatic adenocarcinomas is characterized by:

- Increasing variability of gland size and configuration.
- Papillary and cribriform patterns.
- Rudimentary (or no) gland formation, with only solid cords of infiltrating tumor cells. Uncommonly, a prostate cancer is composed of small undifferentiated cells growing individually or in sheets, without evidence of any structural organization.

CYTOLOGIC FEATURES: The prominence of pleomorphic and hyperchromatic nuclei is highly variable. One or two conspicuous nucleoli in a background of chromatin clumped near the nuclear membrane is the most frequent nuclear feature. The cytoplasm stains slightly eosinophilic or may be so vacuolated that it simulates clear cells of renal cell carcinoma. Cell borders are distinct in better-differentiated tumors but are not well demarcated in poorly differentiated ones.

GRADING: Prostatic adenocarcinoma is most commonly classified according to the **Gleason grading system** (Figs. 23-44 and 23-45), which is based on five histologic patterns of tumor gland formation and infiltration. Recognizing the high frequency of mixed tumor patterns, the Gleason score is the sum of the grades (1 through 5) attributed to the most prominent pattern and that of the minority pattern. The best-differentiated tumors have Gleason scores of 2 (1 + 1), while the most poorly differentiated cancers score 10 (5 + 5). Gleason patterns 1 and 2 are rare. The most commonly diagnosed Gleason pattern is 3. Combined with tumor stage, Gleason grading has prognostic value: lower scores correlate with better prognoses.

INVASION AND METASTASIS: The high frequency of invasion of the prostatic capsule by adenocarcinoma reflects the tumor's subcapsular site of origin. Perineural tumor invasion within the prostate and in adjacent tissues is usual. Since peripheral nerves are devoid of perineural lymphatic channels, this mode of invasion represents contiguous spread of the tumor along a tissue space that offers a plane of low resistance.

The seminal vesicles are almost always involved by direct extension of prostate cancer. Invasion of the urinary bladder tends to occur later in the clinical course. The earliest metastases occur in the obturator lymph nodes, and then to iliac and periaortic lymph nodes. Metastases to the lung reflect further lymphatic spread through the thoracic duct and dissemination from the prostatic venous plexus to the inferior vena cava. Bony metastases, particularly to the vertebral column (Fig. 23-46), ribs and pelvic bones, are painful and difficult to manage.

CLINICAL FEATURES: Current screening programs for prostate cancer use digital rectal examination in combination with serum PSA levels. PSA is a glycoprotein produced by the prostate. It is a serine protease involved in liquifying seminal ejaculate. It maintains a baseline serum level in men. Serum levels are increased by prostate inflammation, hypertrophy and neoplasia. Patients with elevated serum PSA levels are typically evaluated further by needle biopsies. ***Preoperative PSA levels correlate with cancer volume.*** Since most prostate cancers are asymptomatic, PSA screening is the most common detection method. Uncommonly, patients with prostate cancer present with bladder outlet obstruction or symptoms referable to metastatic tumor.

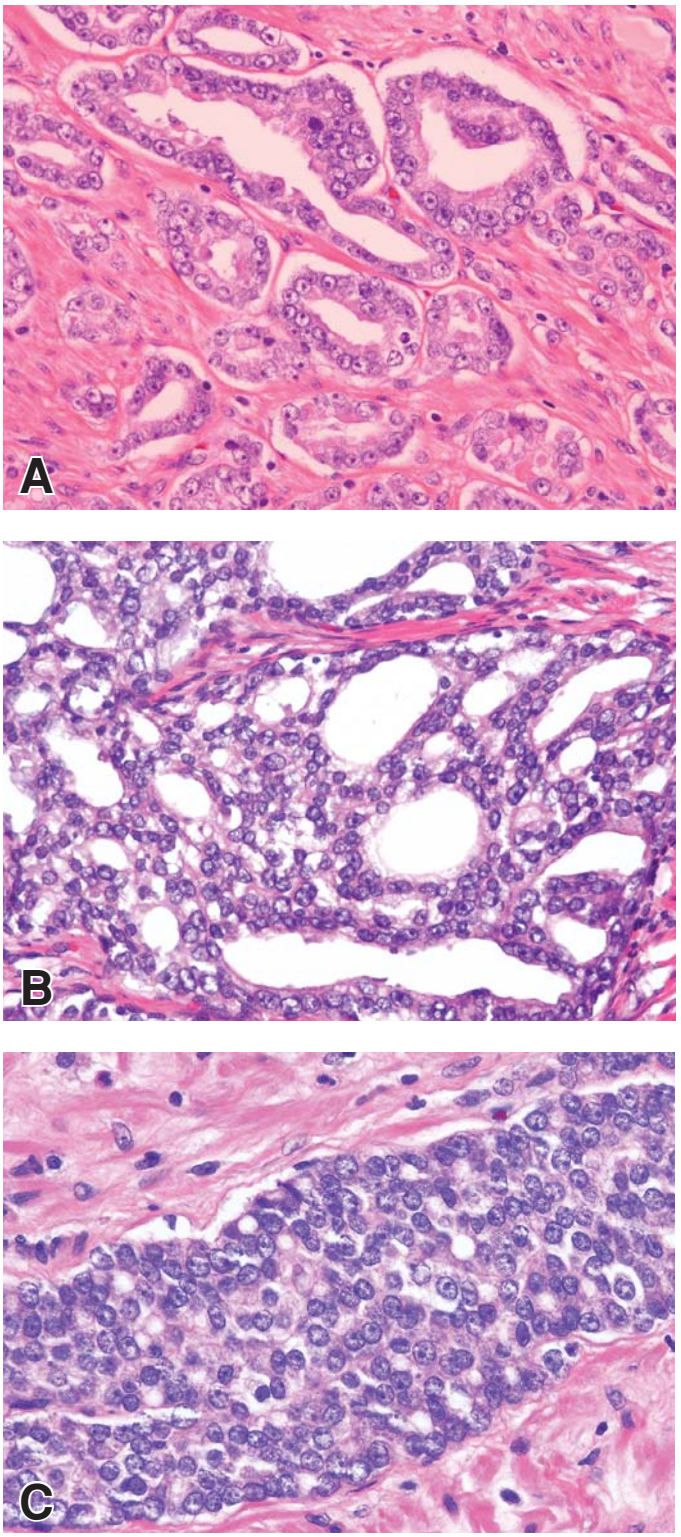


FIGURE 23-45. Gleason grading system. A. Gleason grade 1. **B.** Gleason grade 3. **C.** Gleason grade 5.

At present, guidelines for prostate cancer screening are in flux. Widespread screening leads to more cancer diagnoses and treatment. With treatment come side effects and quality-of-life issues. Given that several large epidemiologic

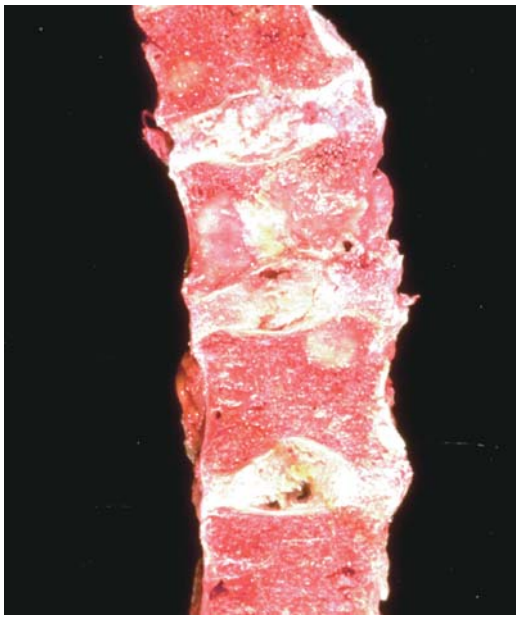

FIGURE 23-46. Prostatic carcinoma metastatic to the spine. The vertebral bodies contain several osteoblastic metastases.

studies report conflicting results with regard to the benefit of active prostate cancer therapy, the high frequency of side effects that occur with aggressive screening and treatment (e.g., incontinence, impotence) cannot be ignored. To this end, the U.S. Preventive Service Task Force (USPSTF) was convened to examine the relevant published literature. It concluded that there was insufficient evidence to recommend routine prostate cancer screening (and, by default, therapy). This position remains controversial. Other national organizations such as the American College of Physicians and the American Urological Association have adopted less extreme guidelines, recommending individualized patient evaluation and selective screening.

TABLE 23-8
TNM STAGING OF PROSTATIC CARCINOMA

T—Primary Tumor
T1 No clinically detectable tumor
T1a Histologic tumor found in 5% or less of tissue examined
T1b Histologic tumor found in more than 5% of tissue examined
T2 Tumor confined to the prostate
T2a Tumor in one lobe only
T2b Tumor in both lobes
T3 Tumor extends through the capsule
T3a Extracapsular extension only
T3b Tumor extends into seminal vesicles
T4 Tumor invades adjacent structures other than seminal vesicles
N—Regional Lymph Nodes
N0 No regional lymph node involvement
N1 Regional lymph node metastases present
M—Distant Metastases
M0 No distant metastases
M1 Distant metastases present

The principles of clinical staging (TNM) of prostate cancer are shown in Fig. 23-47 and Table 23-8. At initial presentation, 10% of prostate cancers are stage T1. In patients with

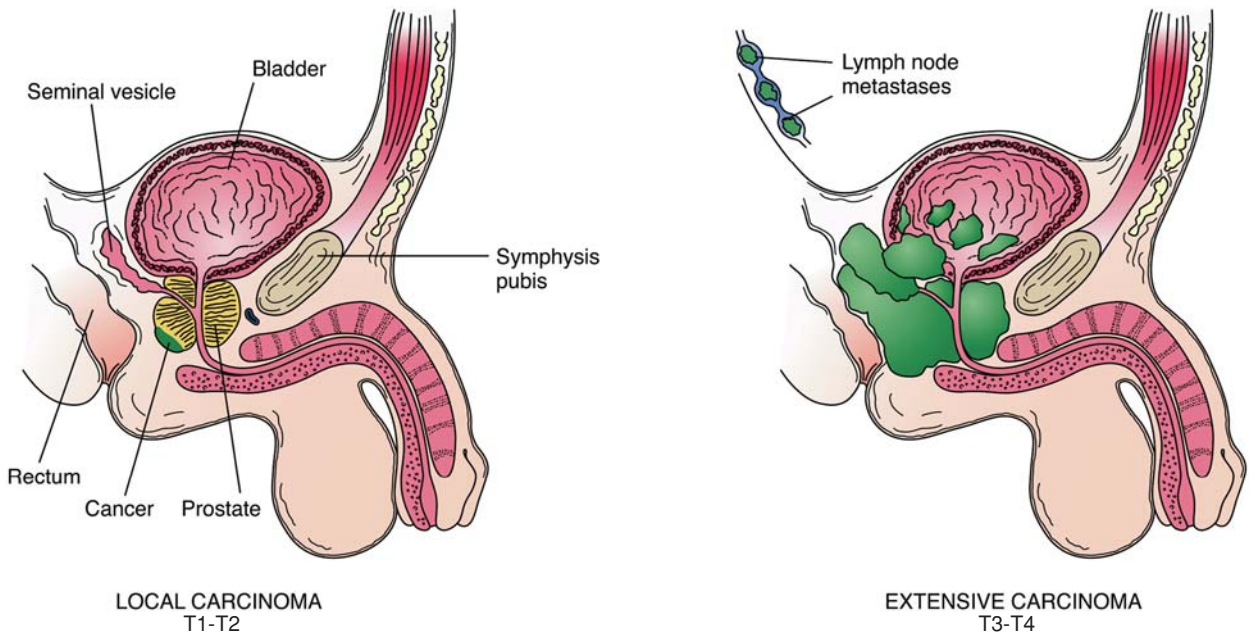

FIGURE 23-47. Staging of prostatic carcinoma. Tumor–node–metastasis (TNM) system is most widely used for staging of prostate carcinoma. Stage T1 and T2 tumors are localized to the prostate, whereas stage T3 and T4 tumors have spread outside the prostate.

tumors clinically judged to be localized to the prostate (stage T2), 60% show microscopic evidence of capsular penetration or seminal vesicle invasion (stage T3). Metastases are found in lymph nodes, bones, lung and liver, in order of decreasing frequency. Widespread tumor dissemination (carcinomatosis), with pneumonia or sepsis, is the most common cause of death.

The immunohistochemical demonstration of **PSA** in metastatic tumors is useful in identifying the prostate as the primary site of a tumor. PSA is also detectable in the serum of patients with prostate cancer. A rising serum PSA level is an indicator of recurrent disease after therapy. A new marker for prostate carcinoma, **α-methylacyl-CoA racemase** (AMCAR), is also useful for identifying prostatic adenocarcinoma inside the gland as well as in metastatic sites. **Serum alkaline phosphatase** levels are elevated in patients with osteoblastic bony metastases, because this enzyme is released from osteoblasts that are forming new bone at a site of metastasis.

Therapy for prostate cancer is highly controversial, owing to recent studies that suggest that many tumors may best be left alone and considerable difficulty in distinguishing between the tumors that are likely to benefit from treatment and those that are not. However, treatment generally depends on tumor stage. Patients with stage T1 and T2 cancers are treated by radical prostatectomy, radiofrequency ablation, cryogenic procedures or radiation therapy. Radiation therapy may be either external beam or implanted radioactive seeds (brachytherapy). In stage T3 tumors, radiation therapy, combined with androgen deprivation therapy, is the treatment of choice, acknowledging that half of these patients have occult pelvic lymph node metastases (and possibly further systemic dissemination), which cannot be cured by surgical means. Patients with low-grade, low-volume tumors may opt to be managed by active surveillance only.

For patients with metastatic disease or whose tumors progress clinically, traditional chemotherapy combined with androgen deprivation is the main strategy. Bone metastases can be treated using local radiation, bisphosphonates and supplements of calcium and vitamin D.

The 5-year survival rates depend on stage and Gleason grade (Fig. 23-44). Using staging data, survival is as follows: stages T1 and T2, 90%; stage T3, 40%; and stage T4, 10%.

EMBRYOLOGY

The gonadal anlage forms as a swelling of the embryonic urogenital ridge, initially in an indifferent state. The gonad is derived from mesoderm except for the germ cells, which are of extraembryonic (yolk sac) origin. Both sex chromosomes and autosomal chromosomes determine whether gonadal stromal cells will differentiate into testis or ovary. If the gonadal stroma is male, a gene on the Y chromosome (sex-determining region Y [SRY]) interacts with the primitive gonad to initiate development of a testis. An ovary develops if gonadal stroma is female and there is no stimulus to form a testis. Ovaries and testes become histologically distinct by about day 40.

Wolffian (mesonephric) ducts begin to develop at about day 25, regardless of the embryo's sex. If stimulated by testosterone (secreted by Leydig cells starting about day 70), the ducts differentiate into vas deferens, epididymis and seminal vesicle. If not stimulated by day 84, the ducts regress and remain as vestigial rests in the female. They may form cysts in the cervix or vagina **(mesonephric cyst)**.

Müllerian (paramesonephric) ducts, the anlage of the fallopian tubes, uterus and vaginal wall, appear at about day 37 as funnel-shaped openings of celomic epithelium. They develop into paired, undifferentiated tubes, using the wolffian ducts as "guide wires" to reach the area of the future hymen. If a wolffian duct is absent, as in renal agenesis, the vagina and cervix are almost always abnormal or absent. At day 54, müllerian ducts fuse into a straight uterovaginal canal.

A central tenet of genital tract development in both sexes is that müllerian tubes develop along female lines unless specifically impeded by embryonic testicular factors. In males, Sertoli cells in developing testes produce **antimüllerian hormone,** also called **müllerian-inhibiting substance,** which causes müllerian ducts to regress.

External genitalia assume masculine form if testosterone is converted locally to dihydrotestosterone. Otherwise (i.e., relative estrogen excess), female external genitalia persist. The genital tubercle develops into the clitoris, genital folds into the labia minora and genital swellings into the labia majora. The basic layout of the female genital tract is established by day 120.

GENITAL INFECTIONS

Genital Infections Are Commonly Sexually Transmitted

Infectious diseases of the female genital tract are common and are caused by many organisms (Table 24-1; also see Chapter 9). Most of the important infectious diseases of the female genital tract are sexually transmitted.

Bacterial Infections

Gonorrhea

Gonorrhea is caused by *Neisseria gonorrhoeae,* a fastidious, gram-negative diplococcus. A million cases of gonorrhea occur yearly in the United States. The infection is a frequent cause of acute salpingitis and pelvic inflammatory disease (PID) (Fig. 24-1).

ETIOLOGIC FACTORS AND PATHOLOGY: The organisms ascend through the cervix and endometrial cavity, where they cause **acute endometritis**. They then attach to mucosal cells in the fallopian tube and elicit acute inflammation, which is confined to the mucosal surface **(acute salpingitis)**. Infection may then spread to the ovary, sometimes causing a **tuboovarian abscess**. Pelvic and abdominal cavities may be affected, leading to subdiaphragmatic and pelvic abscesses.

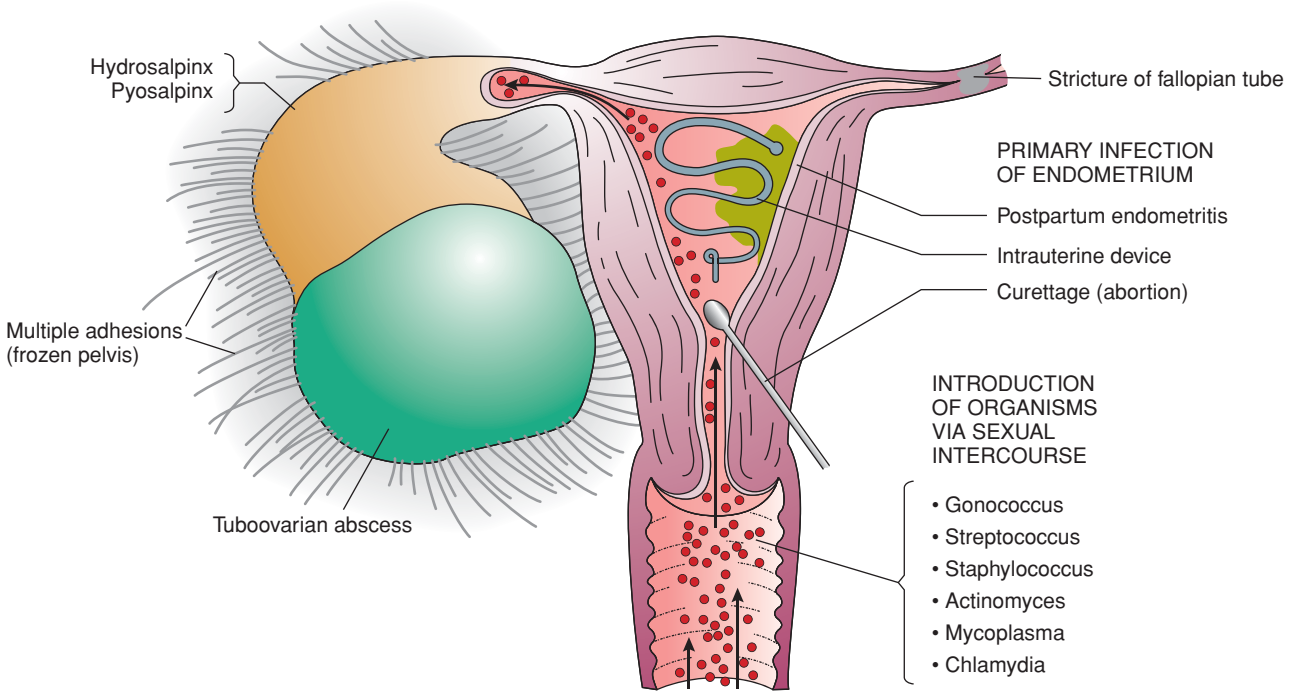

FIGURE 24-1. Pelvic inflammatory disease.

TABLE 24-1
INFECTIOUS DISEASES OF THE FEMALE GENITAL TRACT

Organism	Disease	Diagnostic Feature
Sexually Transmitted Diseases		
Gram-negative rods and cocci		
Calymmatobacterium granulomatis	*Granuloma inguinale*	Donovan body
Gardnerella vaginalis	*Gardnerella infection*	Clue cell
Haemophilus ducreyi	Chancroid (soft chancre)	
Neisseria gonorrhoeae	Gonorrhea	Gram-negative diplococcus
Spirochetes		
Treponema pallidum	Syphilis	Spirochete
Mycoplasmas		
Mycoplasma hominis	Nonspecific vaginitis	
Ureaplasma urealyticum	Nonspecific vaginitis	
Rickettsiae		
Chlamydia trachomatis types D–K	Various forms of pelvic inflammatory disease (PID)	
Chlamydia trachomatis type $L_{1–3}$	Lymphogranuloma venereum	
Viruses		
Human papillomavirus (HPV)	Condyloma acuminatum/planum Neoplastic potential	Koilocyte
Types 6, 11, 40, 42, 43, 44, 57	Low risk	Low-grade squamous intraepithelial lesion (LSIL)
Types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 66	High risk	High-grade squamous intraepithelial lesion (HSIL)
Herpes simplex type 2	Herpes genitalis	Multinucleated giant cell with intranuclear homogenization and inclusion bodies
Cytomegalovirus (CMV)	Cytomegalic inclusion disease	Bulbous intranuclear inclusion body
Molluscum contagiosum	Molluscum infection	Molluscum body
Protozoa		
Trichomonas vaginalis	Trichomoniasis	Trichomonad
Selected Nonsexually Transmitted Diseases		
Actinomyces and related organisms		
Actinomyces israelii	PID (one of many organisms)	Sulphur granules
Mycobacterium tuberculosis	Tuberculosis	Necrotizing granulomas
Fungi		
Candida albicans	Candidiasis	*Candida* sp.

Systemic complications of gonorrhea include septicemia and septic arthritis. At all sites of infection, the organisms induce purulent inflammatory reactions that rarely resolve completely. Dense fibrous adhesions often remain, distorting and destroying the plicae of the fallopian tube and frequently leading to sterility.

Syphilis

Syphilis (see Chapter 9) is caused by *Treponema pallidum*, a thin, motile spirochete. Spread is via sexual contact with an infected person or transplacental spread (congenital syphilis). *T. pallidum* penetrates small cuts in the skin or normal mucosal surfaces. Untreated, syphilis persists, often waxing and waning, through three stages.

- In the **primary stage,** a **chancre** usually appears after about 3 weeks at the portal of bacterial entry. It is a painless, indurated papule, 1 cm to several centimeters in diameter, surrounded by an inflammatory cuff that breaks down to form an ulcer. The lesion may persist for 2–6 weeks. It then heals spontaneously.
- **Secondary syphilis** appears after a latent period of several weeks to months and features low-grade fever, headache, malaise, lymphadenopathy and highly infectious lesions called **condylomata lata** (syphilitic warts). These secondary lesions heal after 2–6 weeks and symptoms disappear spontaneously.
- The **tertiary stage** develops any time thereafter and may entail severe damage to the cardiovascular and nervous systems.

PATHOLOGY: The hallmark of syphilis in biopsy specimens is a dense inflammatory infiltrate with lymphocytes and plasma cells, particularly adjacent to blood vessels. Silver impregnation techniques (Warthin-Starry stain or its modifications) help demonstrate the spirochetes. The more advanced stages of disease show greater obliterative endarteritis and subsequent tissue destruction.

Granuloma Inguinale

Granuloma inguinale is caused by *Calymmatobacterium granulomatis*, a sexually transmitted, gram-negative, encapsulated rod. The disease occurs with equal frequency in women and men.

PATHOLOGY: The primary lesion begins as a painless, ulcerated nodule involving genital, inguinal or perianal skin. The organisms invade through skin abrasions and spread initially by direct extension, destroying skin and underlying tissues. Extensive local spread and lymphatic permeation occur later. Vacuolated macrophages teem with characteristic intracellular bacteria **(Donovan bodies)**. The organism, best seen with the Wright stain, resembles a closed safety pin. Hyperplasia of overlying squamous epithelium may be exuberant enough to be misinterpreted as a squamous cell carcinoma. Relapses after antibiotic therapy are common.

Chancroid

Chancroid, also called **soft chancre,** is caused by *Haemophilus ducreyi*, a gram-negative bacillus. It is rare in the United States but is common in underdeveloped countries.

PATHOLOGY: Single or sometimes multiple small, vesiculopustular lesions appear on the cervix, vagina, vulva or perianal region 3–5 days after sexual contact with an infected partner. At this stage examination shows granulomatous inflammation. The lesion may rupture to form a painful, purulent ulcer that bleeds easily. Inguinal lymphadenopathy, fever, chills and malaise may occur. A major complication is scarring during the healing phase, which may cause urethral stenosis.

Gardnerella

Sexual transmission of *Gardnerella vaginalis*, a gram-negative coccobacillus, causes many cases of "nonspecific vaginitis." Since the organism does not penetrate the mucosa, it causes no inflammation and biopsies appear normal. A wet mount specimen of a vaginal discharge or a Papanicolaou-stained smear (Pap smear) can identify the bacteria. **Clue cells,** squamous cells covered by coccobacilli, are pathognomonic.

Mycoplasma

Mycoplasmas (see Chapter 9) are minute pleomorphic organisms that resemble the so-called L bacterial forms but differ by having no cell wall. They are common oropharyngeal and urogenital tract commensals and colonize the lower genital tract through sexual contact. *Ureaplasma urealyticum* can be isolated from the lower genital tract in 40% of healthy women. It may cause infertility and lead to adverse effects on pregnancy and perinatal infections. *Mycoplasma hominis* is found in the lower genital tract of 5% of healthy women and causes a small proportion of cases of symptomatic cervicitis and vaginitis. *M. hominis* is often isolated in association with *G. vaginalis* or *Trichomonas vaginalis* infection. Although the role of mycoplasma in genital tract infections is not completely understood, the organisms are encountered in PID, acute salpingitis, spontaneous abortion and puerperal fever. Affected tissue is usually unremarkable histologically.

Chlamydia Infections

Chlamydia trachomatis is a common, venereally transmitted gram-negative obligate intracellular rickettsia. Fifteen serotypes are known. *C. trachomatis* causes several disorders in women, men and infants. It has been found in the genital tracts of about 8% of asymptomatic women and 20% of women with symptoms of lower genital tract infection. Chlamydial disease is easily confused with gonorrhea, as the symptoms of both diseases are similar.

PATHOLOGY: Serotypes D through K cause the more common genital infections. Cervical mucosa is severely inflamed, and endocervical and metaplastic squamous cells contain small inclusion bodies. Cytologically, perinuclear intracytoplasmic inclusions with distinct borders and intracytoplasmic **coccoid bodies** are seen. Complications include ascending infection of the endometrium, fallopian tube and ovary, which may result in tubal occlusion and infertility. Chlamydia may also infect Bartholin glands and cause acute urethritis. Infants delivered vaginally to infected mothers may develop conjunctivitis, otitis media and pneumonia.

Lymphogranuloma Venereum

Lymphogranuloma venereum is a venereal infection of men and women, endemic in tropical countries. It is caused by the L form of *C. trachomatis*, serotypes L1 through L3.

PATHOLOGY: After a few days to a month, a small painless vesicle forms at the site of inoculation. It heals rapidly and often is not even noticed. In the second stage, inguinal lymph nodes become enlarged and may rupture to form suppurative fistulas. Perirectal lymph nodes in women become matted and painful. In untreated patients, a third stage may appear after latency lasting several years. In this phase, scarring causes lymphatic obstruction, resulting in genital elephantiasis and rectal strictures. Infected tissues in the second and third stages show necrotizing granulomas and neutrophil infiltrates. Inclusion bodies within macrophages may also be seen.

Viral Infections

Human Papillomavirus

Human papillomavirus (HPV) is a DNA virus that infects genital skin and mucosal surfaces to produce wart-like lesions referred to as **condylomata acuminatum** or flat lesions known as **squamous intraepithelial lesions (SILs)**. Over 100 HPV serotypes are known, one third of which cause genital tract lesions. The median time from infection to first detection of HPV is 3 months. In the United States, as many as 2/3 of women graduating college have genital HPV infections, which result from sexual contact with an infected person. Even in women who have had only one sexual partner, the risk of cervical HPV by 3 years after first intercourse is 50%. HPV prevalence among women 14–59 years old exceeds 25%. About 20 million people are currently infected with HPV in this country; serotypes 6 and 11 account for over 80% of visible condylomata.

Several strains of HPV are the major etiologic factors for squamous cell cancer in the female lower genital tract, as well as anal and oropharyngeal cancers in both sexes. Types 16, 18, 31 and 45 are most often linked to squamous intraepithelial neoplasia and invasive cancer (see below). Vaccines to prevent infection with high-risk HPV serotypes 6, 11, 16 and 18 have been available since 2006 and are the reason for the lower infection rates in teenage girls.

Most cases of HPV are diagnosed by cervical Pap smear. Recent tests directly detect HPV DNA. Treatment is based on the histology of lesions (low vs. high grade), which predicts those at greatest risk for progression to carcinoma.

PATHOLOGY: Lesions in the vulva, perianal region, perineum, vagina and cervix caused by HPV infection are separated into low and high grades based on the appearance of the affected epithelium, which may be flat or exophytic. The warty form of low-grade squamous intraepithelial lesion (LSIL) is known as condylomata acuminatum. Acuminate warts are generally caused by low-cancer-risk viral subtypes and may present as papules, plaques or nodules, which eventually become spiked or cauliflower-like excrescences (Fig. 24-2A). LSIL is characterized by koilocytes (from the Greek *koilos*, "hollow"), epithelial cells with a perinuclear halo and a wrinkled nucleus bearing HPV particles (Fig. 24-2B). Viral DNA typically remains episomal. Extensive virus replication causes cytoplasmic injury, creating koilocytes (Fig. 24-2C). High-grade squamous intraepithelial lesions (HSILs) are discussed below.

Herpesvirus

Herpes simplex type 2 is a very large double-stranded DNA virus that commonly causes sexually transmitted genital infections. After an incubation period of 1–3 weeks, small vesicles develop on the vulva and erode into painful ulcers. Similar lesions occur in the vagina and cervix. Epithelial cells adjacent to intraepithelial vesicles show ballooning degeneration and many contain large nuclei with eosinophilic viral inclusions.

Herpesvirus infections follow relapsing, remitting courses. While latent, the virus resides in spinal (sacral) ganglia. If it reactivates during pregnancy, passage through the birth canal may transmit the virus to the newborn infant, often with fatal consequences. Active vaginal herpetic lesions at the time of delivery are therefore an indication for Cesarean section.

Cytomegalovirus

Cytomegalovirus (CMV) is a ubiquitous double-stranded DNA virus of the *Herpesvirus* family. More than 80% of people over the age of 35 have antibodies to CMV. Several lines of evidence suggest that many cases are sexually transmitted: (1) seroprevalence of CMV has risen in young adults, (2) the virus is recovered more often from cervical secretions and semen than from any other body sites and (3) viral titers in semen are 100,000 times higher than in urine. Still, CMV only rarely causes genital infections in women. Infection in the endometrium may result in spontaneous abortion or infection of the newborn. Infected cells exhibit characteristic large, eosinophilic, intranuclear inclusions and, occasionally, cytoplasmic inclusions.

Molluscum Contagiosum

Molluscum contagiosum (see Chapter 28) is a highly contagious double-stranded DNA poxvirus. Infection leads to multiple smooth, gray-white nodules that are centrally umbilicated and exude a cheesy material. Lesions occur predominantly in the genital region but may be found elsewhere as well. Large, cytoplasmic viral inclusions **(molluscum bodies)** are seen in infected epithelial cells. Most lesions regress spontaneously, but untreated ones may persist for years.

Trichomoniasis

T. vaginalis is a large, pear-shaped, flagellated protozoan that often causes vaginitis. It is transmitted sexually, and 25% of infected women are asymptomatic carriers. Infection causes a heavy, yellow-gray, thick, foamy discharge with severe itching, dyspareunia (painful intercourse) and dysuria (painful urination). The motile trichomonads are identified on wet mount preparations and may also be demonstrated in Pap smears.

Pelvic Inflammatory Disease

PID is infection of pelvic organs due to extension of one of several microorganisms above the uterine corpus (Fig. 24-1). Ascending infection results in bilateral acute salpingitis, pyosalpinx and tuboovarian abscesses. **N. gonorrhoeae *and* Chlamydia *are the main organisms responsible for PID, but most infections are polymicrobial.*** PID is less common in monogamous women than in others. Occasionally, it occurs after postpartum endometritis or as a complication of endometrial curettage.

CLINICAL FEATURES: Patients with PID typically present with lower abdominal pain. Physical examination reveals bilateral adnexal tenderness

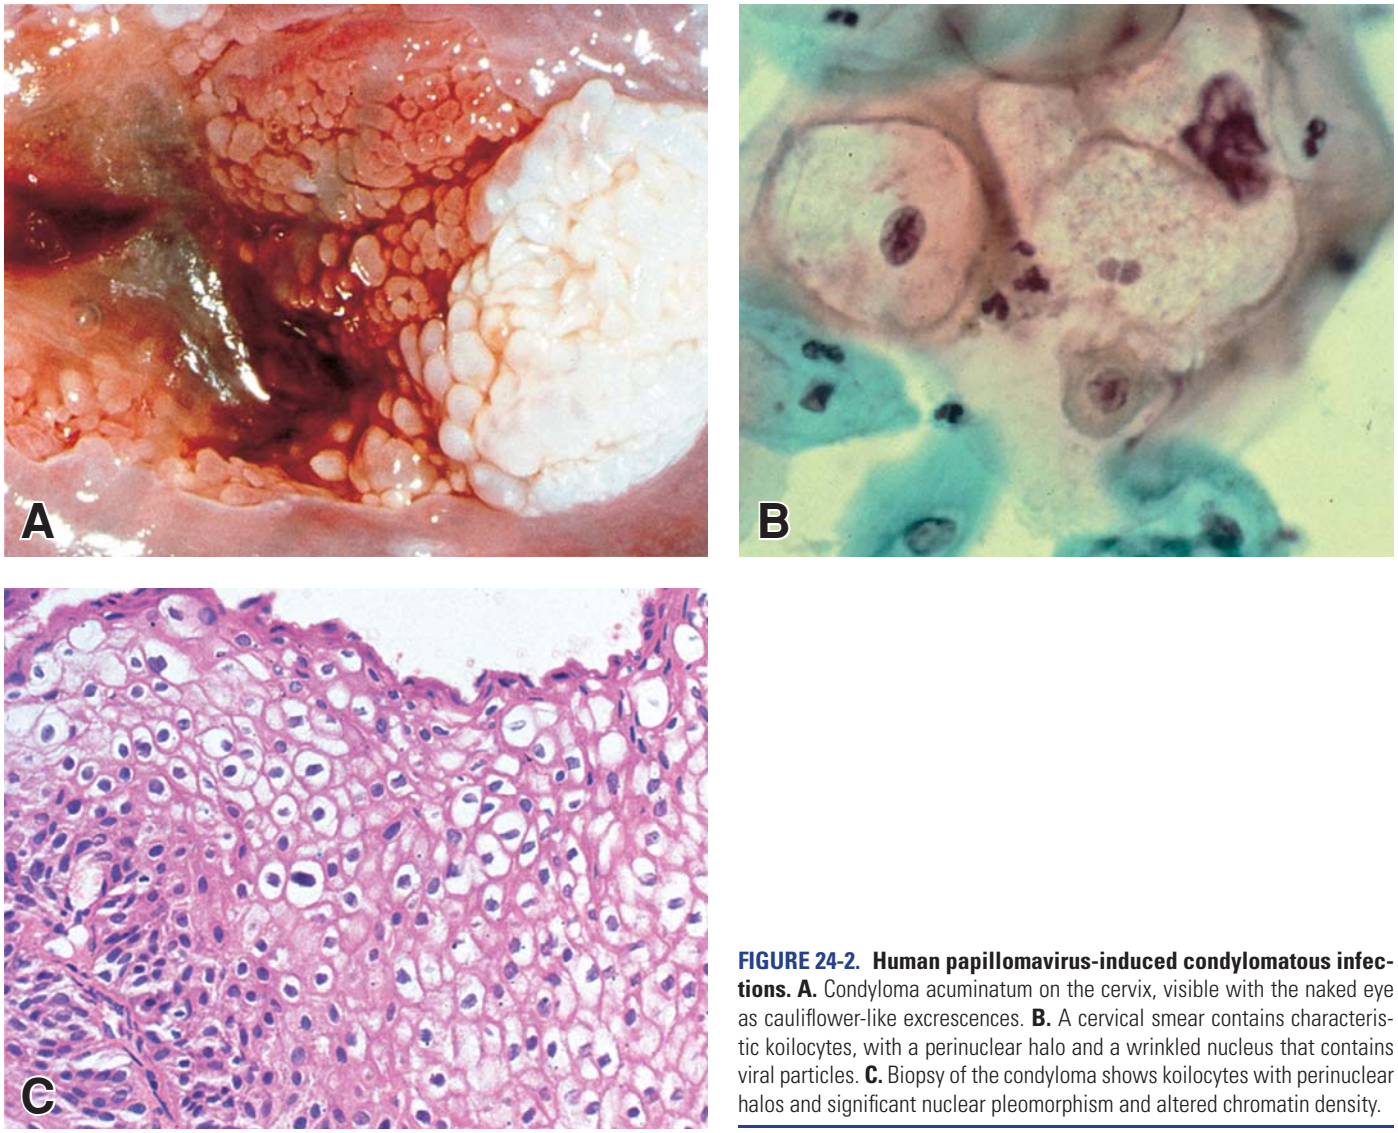

FIGURE 24-2. Human papillomavirus-induced condylomatous infections. A. Condyloma acuminatum on the cervix, visible with the naked eye as cauliflower-like excrescences. **B.** A cervical smear contains characteristic koilocytes, with a perinuclear halo and a wrinkled nucleus that contains viral particles. **C.** Biopsy of the condyloma shows koilocytes with perinuclear halos and significant nuclear pleomorphism and altered chromatin density.

and marked discomfort when the cervix is manipulated (chandelier sign). Complications of PID include (1) rupture of a tuboovarian abscess, which may result in life-threatening peritonitis; (2) infertility from scarring of the healed tubal plicae; (3) increased rates of ectopic pregnancy; and (4) intestinal obstruction from fibrous bands and adhesions.

Some Genital Infections Are Not Transmitted Sexually

Tuberculosis

Mycobacterium tuberculosis may infect any part of the female genital tract. Genital tuberculosis occurs in 1% of infertile women in the United States and in over 10% of such women in less developed countries. Detecting acid-fast bacilli (AFB) confirms the diagnosis.

PATHOLOGY:

TUBERCULOUS SALPINGITIS: Salpingitis is usually the initial lesion of tuberculous genital infection, due to hematogenous dissemination from the respiratory tract. Tuberculous salpingitis results in fibrinous adhesions and scarring of the fallopian tube. These complications lead to multiple functional abnormalities (e.g., infertility, ectopic gestation, pelvic pain). The tubes may become nodular. **Pyosalpinx** (fallopian tube distended with pus) and **hydrosalpinx** (fluid-filled tube) are late sequelae, and the adjacent ovary may become infected.

TUBERCULOUS ENDOMETRITIS: Endometritis complicates half the cases of tuberculous salpingitis. Noncaseating, poorly formed granulomas with rare giant cells are typical. Although the endometrium may show well-formed granulomas with caseous necrosis and characteristic Langhans giant cells, menstrual shedding limits the time during which such mature granulomas may develop.

Candidiasis

Ten percent of women are asymptomatic carriers of fungi in the vulva and vagina, *Candida albicans* being the most common offender. Only 2% present with clinically apparent candidal vulvovaginitis, although the risk is greatly

increased by diabetes mellitus, oral contraceptive use and pregnancy. Infection causes vulvar itching and a white discharge. Clinical examination reveals firmly adherent, small white plaques on mucous membranes ("thrush"). Biopsy shows submucosal edema and chronic inflammation. The fungi do not penetrate epithelium; the white patches are foci of desquamated, necrotic epithelial cells containing cellular debris; bacterial flora; candidal spores; and pseudohyphae. Characteristic spores and pseudohyphae in a wet mount preparation or with a Pap stain are diagnostic. Untreated infections wax and wane and often disappear after delivery.

Actinomycosis

Genital tract actinomycosis is uncommon but is increasingly reported in association with use of intrauterine devices (IUDs). *Actinomyces israelii*, the causative organism, is a gram-positive rod found in 4% of normal genital tracts. It enters the uterine cavity via the tail of the IUD; ascends to the fallopian tube, ovary and broad ligaments; and forms a tuboovarian abscess. Suppurating lesions display drainage tracts that contain dense microcolonies of organisms ("sulfur granules"). Actinomycosis results in extensive fibrosis and scarring of the female genital tract.

Toxic Shock Syndrome Is Due to Vaginal Staphylococcal Infection

Toxic shock syndrome is an acute, sometimes fatal disorder characterized by fever, shock and a desquamative erythematous rash. In addition, vomiting, diarrhea, myalgias, neurologic signs and thrombocytopenia are common. Certain strains of *Staphylococcus aureus* release an exotoxin called **toxic shock syndrome toxin-1,** which impairs the ability of mononuclear phagocytes to clear other potentially toxic substances, such as endotoxin. Pathologic alterations are characteristic of shock, and lesions of disseminated intravascular coagulation are usually prominent. Toxic shock syndrome was first recognized when long-acting tampons were introduced, allowing sufficient time for the staphylococci to proliferate. Contraceptive "sponges" were also associated. The incidence of toxic shock syndrome has decreased markedly since recognition of the role of tampons in promoting colonization of the vagina by *S. aureus.*

Vulva

ANATOMY

The vulva is composed of the mons pubis, labia majora and minora, clitoris and vestibule. At puberty, the mons pubis and lateral borders of the labia majora acquire increased subcutaneous fat and grow coarse hair. Sebaceous and apocrine glands in these regions develop concomitantly. The paired external openings of the paraurethral glands **(Skene glands)** flank the urethral meatus. **Bartholin glands,** just posterolateral to the introitus, are branching, mucus-secreting, tubuloalveolar glands drained by a short duct lined by transitional epithelium. In addition, microscopic mucous glands are scattered throughout the area bounded by the labia minora. Inguinal and femoral lymph nodes provide primary lymph drainage routes, except for the clitoris (the homolog of the penis), which shares the lymphatic drainage of the urethra.

DEVELOPMENTAL ANOMALIES AND CYSTS

ECTOPIC BREAST TISSUE: Small, isolated nodules of ectopic breast tissue may extend in the "milk line" to the vulva and enlarge during pregnancy.

BARTHOLIN DUCT CYST: The paired Bartholin glands produce a clear mucoid secretion that continuously lubricates the vestibular surface. The ducts are prone to obstruction and consequent cyst formation (Fig. 24-3). Cyst infection may lead to **abscess formation**. Bartholin gland abscess was formerly associated with gonorrhea, but staphylococci, chlamydia and anaerobes are now more frequently the cause. Treatment consists of incision, drainage, marsupialization and appropriate antibiotics.

FOLLICULAR CYSTS: Follicular cysts recapitulate the most distal portion of the hair follicle. Also called **epithelial inclusion cysts** or **keratinous cysts,** follicular cysts frequently appear on the vulva, especially the labia majora. They contain a white cheesy material and typically are lined by stratified squamous epithelium.

MUCINOUS CYSTS: Vulvar mucinous glands occasionally become obstructed and develop cysts. Mucinous columnar cells line the cyst and may become infected.

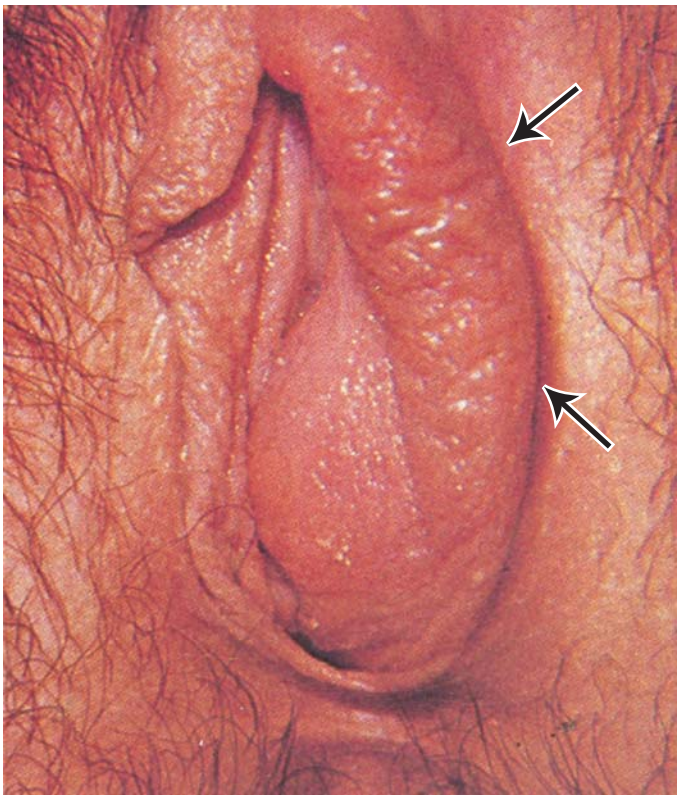

FIGURE 24-3. Bartholin gland cyst. The 4-cm lesion (*arrows*) is posterior to the vaginal introitus.

FIGURE 24-4. Vulvar acute dermatitis (eczema). Erythema, edema and weeping vesicles (*arrow*) are present.

DERMATOSES

Vulvar Acute Dermatitis Appears as Reddened Vesiculated Skin

PATHOLOGY: As vesicles rupture (Fig. 24-4), the fluid forms a crust on the skin surface. The epidermis contains various inflammatory cells, and spongiotic areas form vesicles that rupture to produce the exudative lesions. The dermis shows a perivascular lymphocytic infiltrate and edema, with separation of collagen fibers. Dilated lymphatics and capillaries are typical.

The most common endogenous types of acute dermatitis are **atopic (hypersensitivity) dermatitis** and **seborrheic dermatitis,** seen as a scaly macular eruption. Dermatitides with exogenous causes include irritant dermatitis (e.g., urine on the vulvar skin) and contact allergic dermatitis (type 4 delayed hypersensitivity reaction) and are manifest as either acute or chronic dermatitis.

Chronic Dermatitis, or Lichen Simplex Chronicus, Is the End Stage of Many Vulvar Inflammatory Diseases

Vulvar chronic dermatitis (Fig. 24-5) follows many diseases that are clinically pruritic and thus subject to repeated scratching in their active phase. These include lichen planus, psoriasis and lichen sclerosus (see Chapter 28). The skin is thickened and white with exaggerated markings ("lichenification") as a result of marked hyperkeratosis. Scaling is generally present, and excoriations due to recent scratching are often seen.

LICHEN SCLEROSUS: Lichen sclerosus is an inflammatory disease associated with autoimmune disorders such as vitiligo, pernicious anemia and thyroiditis. Autoimmune etiology of lichen sclerosus is further suggested by the presence of activated T cells in the dermis.

PATHOLOGY AND CLINICAL FEATURES: The condition is characterized by white plaques and atrophic skin with a parchment-like or crinkled appearance and, occasionally, marked contracture of vulvar tissues (Fig. 24-6A). Hyperkeratosis, loss of rete ridges, epithelial thinning with flattening of rete pegs, cytoplasmic vacuolation of the basal layer and a homogeneous, acellular zone in the upper dermis are seen (Fig. 24-6B). A band of lymphocytes with few plasma cells typically underlies this layer. The disease develops insidiously and is progressive, often causing itching and dyspareunia. Women with symptomatic lichen sclerosus have a 15% chance of developing squamous cell carcinoma.

BENIGN TUMORS

HIDRADENOMA: This benign apocrine sweat gland tumor appears chiefly in the labia majora as a well-circumscribed nodule, rarely larger than 1 cm. Microscopically, it is composed of papillary tubules and acini lined by two layers of cells: an inner layer of apocrine columnar cells and an outer one of myoepithelial cells.

SYRINGOMA: An adenoma of eccrine glands, syringoma manifests as a flesh-colored papule within the dermis of labia majora. This asymptomatic tumor is composed of a proliferation of small ducts embedded in a dense

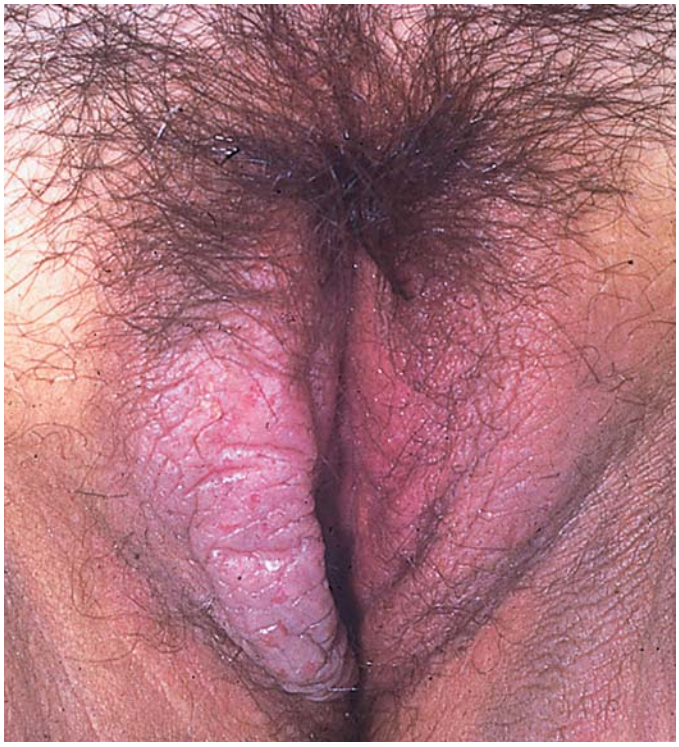

FIGURE 24-5. Lichen simplex chronicus of the right labium majus. There is thickening and accentuation of skin markings, with surface excoriation due to recent scratching.

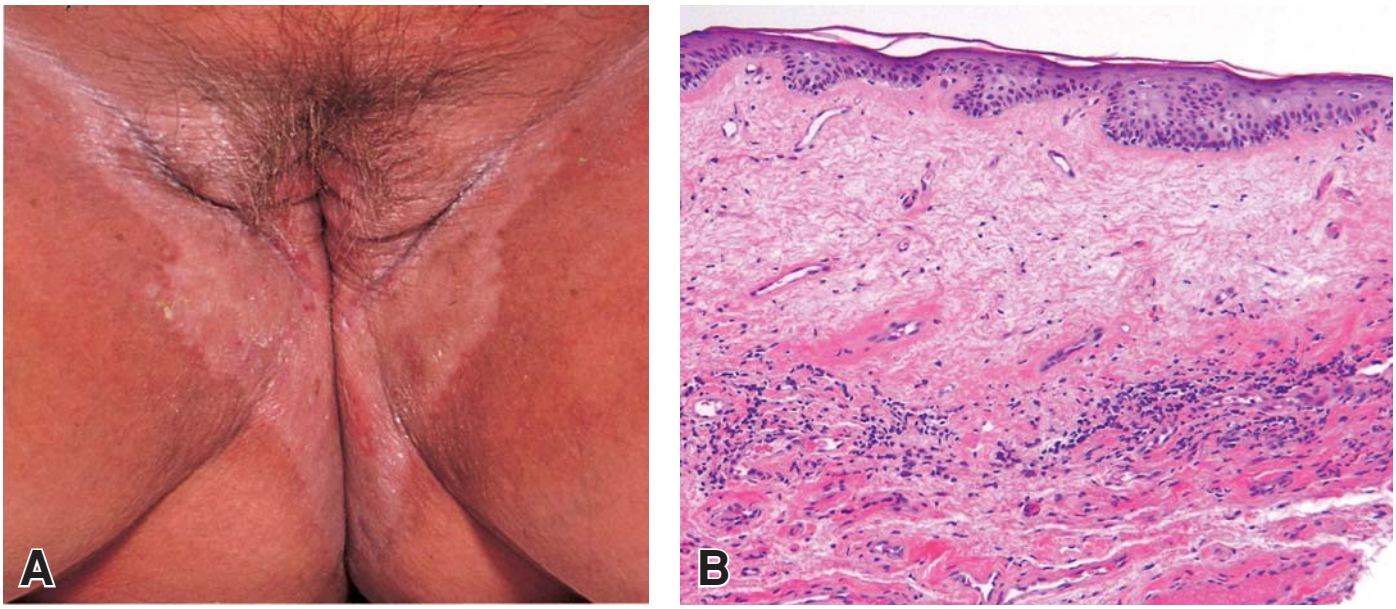

FIGURE 24-6. Lichen sclerosus of vulva. A. The sharply demarcated white lesion affects the vulva and perineum. **B.** The epidermis is thin and exhibits hyperkeratosis and a lack of the normal rete pattern. The dermis displays an acellular, homogeneous zone overlying a mild chronic inflammatory infiltrate.

fibrous stroma (see Chapter 28). Duct walls have two layers of cells: an inner layer of serous cells and an outer one of myoepithelial cells. The lumen contains amorphous eosinophilic material.

CONNECTIVE TISSUE TUMORS: **Senile hemangiomas** (cherry hemangiomas) are small, purple skin papules, which may bleed following surface trauma. **Lobular capillary hemangioma** (formerly called pyogenic granuloma), previously thought to be a reaction to superficial wound infection, is a variant of hemangioma. Secondary infection occurs, as the surface of the lesion is fragile and easily disrupted. Soft tissue tumors found elsewhere in the body also occur in the vulva, including granular cell tumor, leiomyoma, fibroma, lipoma and histiocytoma.

PIGMENTED VULVAR LESIONS: **Lentigo** occurs in about 10% of women and presents as small macules. **Nevi** and **seborrheic keratosis** also occur in this area (Chapter 28).

MALIGNANT TUMORS AND PREMALIGNANT CONDITIONS

Vulvar Intraepithelial Neoplasia Is a Precursor of Invasive Squamous Cell Carcinoma

Vulvar carcinoma, mostly squamous cell carcinoma, accounts for 3% of all female genital cancers and occurs mainly in women over age 60. These tumors are divided into keratinizing squamous cell carcinomas unrelated to HPV (>70% of cases) and warty basaloid carcinomas associated with high-risk HPV (<25% of cases). Classic vulvar intraepithelial neoplasia (VIN) lesions are also known as high-grade vulvar squamous intraepithelial lesions (vulvar HSILs).

ETIOLOGIC FACTORS AND CLINICAL FEATURES: Keratinizing squamous carcinomas frequently develop in older women (mean age, 76 years), sometimes in the context of long-standing lichen sclerosus. The precursor lesion is called **differentiated vulvar intraepithelial neoplasia (dVIN)** (Fig. 24-7A), which carries a high risk of cancer development. Carcinomas develop as nodules or masses in a background of **"leukoplakia"** (*white plaques,* a nonspecific, descriptive term). Cases of lichen sclerosus, differentiated VIN and invasive squamous cell carcinoma with identical p53 gene mutations have been reported. p53 gene mutation, however, is an uncommon late event in vulvar carcinogenesis.

By contrast, the less common HPV-associated warty and basaloid carcinomas develop from a precursor lesion called **classic VIN** (Fig. 24-7B). Since 1980, there has been a 5–10-fold increase in classic VIN in women under age 40, typically related to **HPV 16**. HPV-associated VIN lesions have a low risk of progression to invasive carcinomas (6%), except in older or immunosuppressed women. Lesions associated with oncogenic HPV types generally demonstrate activated p16. Women with VIN may have squamous neoplasms similar to VIN elsewhere in the lower genital tract.

PATHOLOGY: VIN reflects a spectrum of neoplastic changes from minimal to severe cellular atypia with differing pathogenesis as described above. These lesions may be single or multiple, and macular, papular or plaque-like. Histologic grades of VIN I, II and III correspond to mild, moderate and severe dysplasia, respectively. However, grade III (which includes squamous cell carcinoma in situ [CIS]) is by far the most common. Differentiated VIN shows severe nuclear atypia of the basal layer with striking epithelial maturation in the superficial layers (Fig. 24-7A). Keratinocytes of the latter contain rounded nuclei with enlarged nucleoli and ample eosinophilic cytoplasm with prominent intercellular bridges. Rete pegs often contain keratin pearls.

Terminology for HPV-related lesions has recently been standardized throughout the anogenital tract along the lines

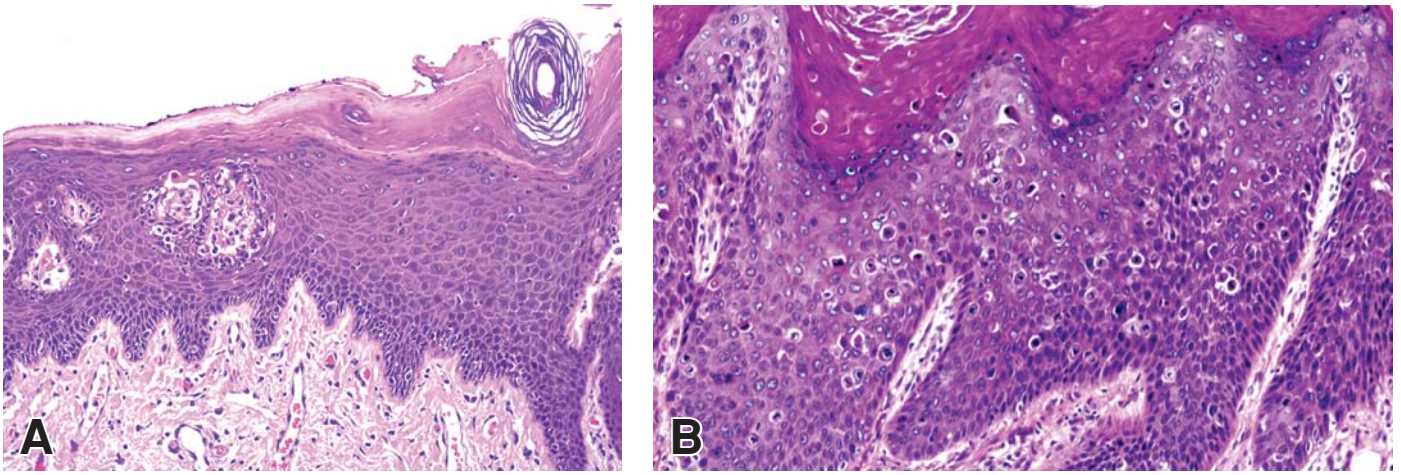

FIGURE 24-7. Vulvar intraepithelial neoplasia (VIN). A. Differentiated VIN is not associated with human papillomavirus (HPV) and demonstrates atypia accentuated in the basal and parabasal layers. There is striking epithelial maturation in the superficial layers. **B.** Classic VIN is caused by HPV and includes features of full-thickness atypia, numerous mitoses and often, as in this example, hyperkeratosis.

of what has been applied to the cervix: LSIL and HSIL. This has not been adopted universally, and there is the additional complication that most vulvar squamous precancerous lesions are not HPV related (differentiated VIN). In the vulva, LSILs include acuminate warts and bland flat lesions that may only have rare diagnostic koilocytes. As in comparable lesions in the cervix (see below), criteria used in establishing the grade of classic VIN include (1) nuclear size and atypia, (2) number and severity of atypical mitoses and (3) loss of cytoplasmic differentiation toward the epithelial surface. In the undifferentiated form seen in younger women, the entire epithelium consists of cells with highly atypical nuclei and negligible cytoplasm. Mitoses, often atypical, are common (Fig. 24-7B). **Bowen disease,** a term still used in the dermatologic literature, is a synonym for VIN III.

Keratinizing squamous cell carcinomas usually follow differentiated VIN. Two thirds of larger tumors are exophytic (Fig. 24-8A); the remainder are ulcerative and endophytic. The tumor is composed of invasive nests of malignant squamous epithelium with central keratin pearls (Fig. 24-8B). The

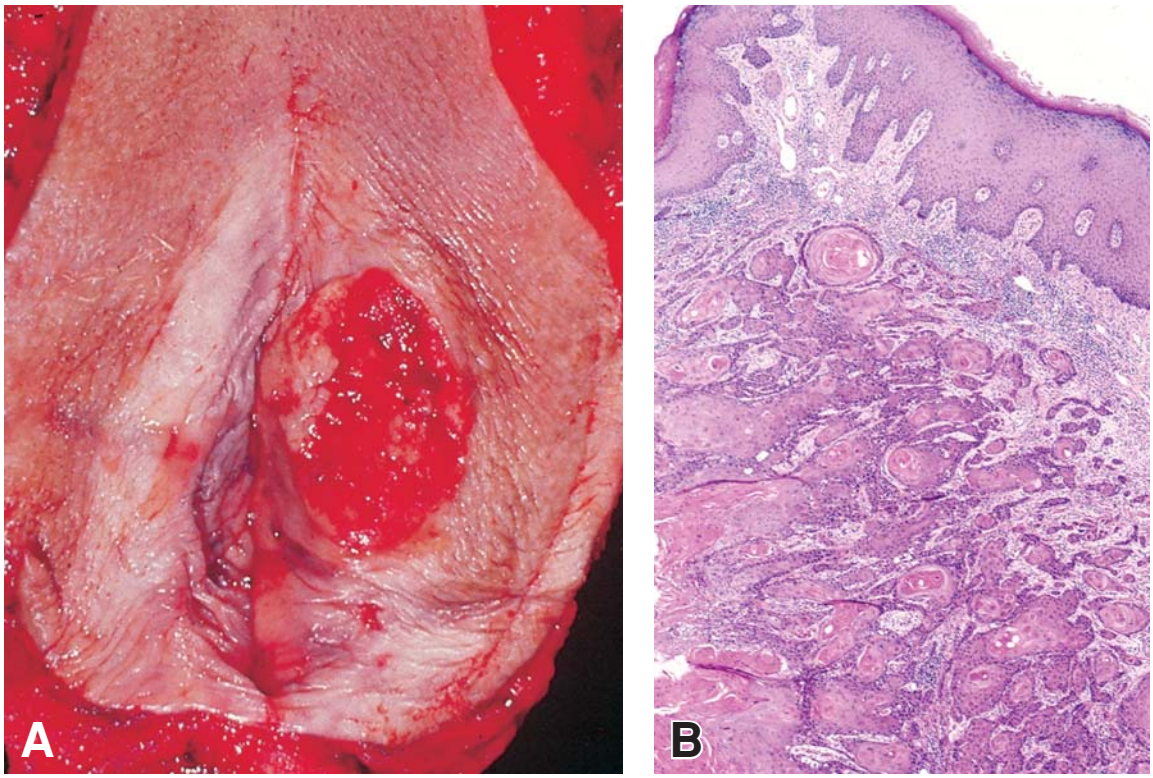

FIGURE 24-8. Squamous cell carcinoma of vulva. A. The tumor is situated in an extensive area of lichen sclerosus (*white*). **B.** Nests of neoplastic squamous cells, some with keratin pearls, are evident in this well-differentiated tumor.

tumors grow slowly, extending to contiguous skin, vagina and rectum. They metastasize initially to superficial inguinal lymph nodes and then to deep inguinal, femoral and pelvic lymph nodes.

CLINICAL FEATURES: Most patients with VIN present with vulvar itching and burning with raised, well-defined skin lesions of variable sizes, which may be pink, red, brown or white. Carcinomas, but not VIN, may develop ulceration, bleeding and secondary infection. Spontaneous regression of VIN has been reported, most often in younger women.

Prognosis for patients with vulvar cancer is generally good, with 70% overall 5-year survival. Tumor grade, size, location and, most importantly, the number of lymph node metastases predict survival. Two thirds of women with inguinal node metastases survive 5 years, but only 1/4 of those with pelvic node metastases live that long. Better-differentiated tumors have a better mean survival, approaching 90% if nodes are negative.

Verrucous Carcinoma Is a Well-Differentiated Squamous Cancer

Vulvar verrucous carcinoma is a distinct variety of squamous cell carcinoma that grows as a large fungating mass resembling a giant condyloma acuminatum. HPV, usually type 6 or 11, is commonly involved. The tumor is very well differentiated, with large nests of squamous cells with abundant cytoplasm and small, bland nuclei. Squamous pearls are common and mitoses are rare. The tumor invades along broad fronts, and lymphocytes and plasma cells often heavily infiltrate the stromal interface. Verrucous carcinomas rarely metastasize. Wide local surgical excision is the treatment of choice, but other forms of therapy (cryosurgery and retinoids) have been used successfully.

Basal Cell Carcinoma

Basal cell carcinomas of the vulva are identical to those in the skin. They are not associated with HPV, rarely metastasize and are usually cured by surgical excision.

Malignant Melanoma

Although uncommon, malignant melanoma is the second most frequent cancer of the vulva (5%). It occurs in the sixth and seventh decades but is occasionally found in younger women. It has biological and microscopic characteristics of melanoma occurring elsewhere in the body. It is highly aggressive, and the prognosis is poor.

Extramammary Paget Disease Resembles Similar Tumors of the Breast and Elsewhere

The disorder usually occurs on the labia majora in older women. Women with Paget disease of the vulva complain of pruritus or a burning sensation for many years.

PATHOLOGY: The lesion is large, red, moist and sharply demarcated. Diagnostic cells (Paget cells) may arise in the epidermis or epidermally derived adnexa. They have pale, vacuolated cytoplasm (Fig. 24-9) with abundant glycosaminoglycans; they stain with periodic acid–Schiff (PAS) and mucicarmine and expresses carcinoembryonic antigen (CEA). They appear as large single cells or, less often, as clusters of cells that lack intercellular bridges and are usually confined to the epidermis.

Intraepidermal Paget disease may be present for many years and is often far more extensive throughout the epidermis than preoperative biopsies indicate. Unlike Paget disease of the breast, which is almost always associated

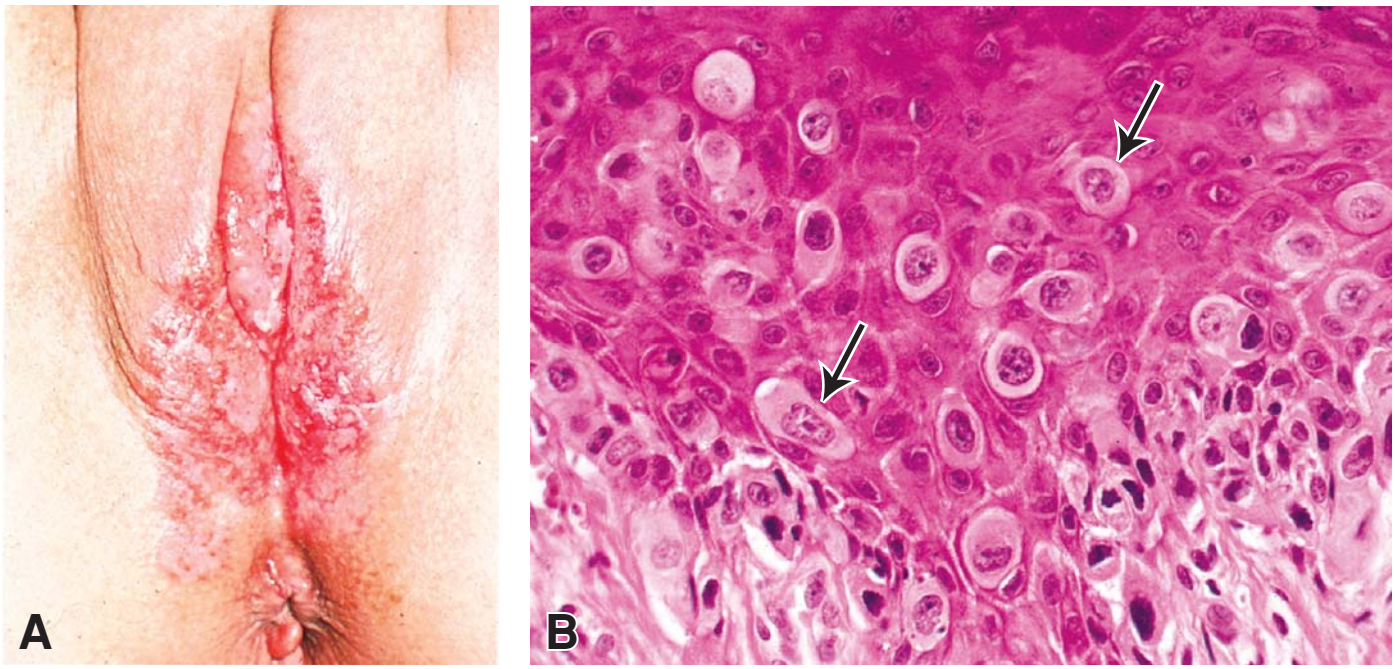

FIGURE 24-9. Paget disease of the vulva. A. The lesion is red, moist and sharply demarcated. **B.** Individual Paget cells (*arrows*), characterized by an abundant pale cytoplasm, infiltrate the epithelium and are interspersed among normal keratinocytes.

with underlying duct carcinoma, extramammary Paget disease is only rarely associated with carcinoma of the skin adnexa. Metastases occur rarely, so treatment requires only wide local excision or simple vulvectomy.

Vagina

ANATOMY

The vagina extends from the uterus to the vestibule of the vulva and is lined by hormone-responsive squamous epithelium. Estrogens stimulate, and progestogens inhibit, vaginal epithelial proliferation and maturation. Thus, in the secretory phase of the menstrual cycle or during pregnancy, when progesterone levels are high, intermediate cells, rather than superficial ones, predominate in vaginal smears. Maturing epithelial cells accumulate glycogen, giving their cytoplasm a clear appearance.

Lymph drains through the lateral perivaginal plexus. Lymphatics from the vaginal vault and upper vagina join branches from the cervix, to drain into pelvic and then paraaortic nodes. The lower vagina also drains to inguinal and femoral nodes.

NONNEOPLASTIC CONDITIONS AND BENIGN TUMORS

Congenital Anomalies of the Vagina Are Rare

Congenital absence of the vagina is generally associated with anomalies of the uterus and urinary tract. If there is a functional uterus, absence of a vagina may lead to accumulation of menstrual blood in the uterus.

Septate vagina results from failure of embryonic müllerian ducts to fuse properly, and the resulting median wall does not resorb.

Vaginal atresia and imperforate hymen prevent the vaginal embryonic lining from maturing from müllerian to squamous epithelium, which can cause vaginal adenosis.

Diminished Estrogen Stimulation Causes Atrophic Vaginitis

Atrophic vaginitis is thinning and atrophy of the vaginal epithelium. The thinned epithelium is a poor barrier to infections or abrasions. This occurs most commonly in postmenopausal women with low estrogen levels. Dyspareunia and vaginal spotting are common symptoms.

Vaginal Adenosis Occurred in Females Exposed to Diethylstilbestrol in Utero

In vaginal adenosis, the glandular epithelium that normally lines the embryonic vagina fails to be replaced during fetal life by squamous epithelium. Use of diethylstilbestrol (DES) to prevent miscarriages in women who were prone to repetitive abortions led, in the 1970s, to a substantial increase in this disorder in daughters of those women. Between the 10th and 18th weeks of gestation, upgrowth of squamous epithelium from the urogenital sinus replaces the glandular (müllerian) linings of the vagina and exocervix. DES exposure during this critical time arrests this process and some glandular tissue (i.e., adenosis) remains.

Adenosis manifests as red, granular patches on the vaginal mucosa, which microscopically are composed of mucinous columnar cells (resembling those lining the endocervix) and ciliated cells (like those lining the endometrium and fallopian tubes). Many of these lesions disappear as young women grow older. Rare cases of **clear cell adenocarcinoma** of the vagina (Fig. 24-10) have also occurred in the daughters of women treated with DES, typically in the upper third of the vagina. Clear cell adenocarcinomas are almost invariably curable when small and asymptomatic, but in more advanced stages, may spread by hematogenous or lymphatic routes.

Fibroepithelial Polyp

Vaginal polyps are uncommon benign growths with a connective tissue core and an outer lining of vaginal squamous epithelium. They are usually single, gray-white and smaller than 1 cm in diameter. Simple excision is usually curative.

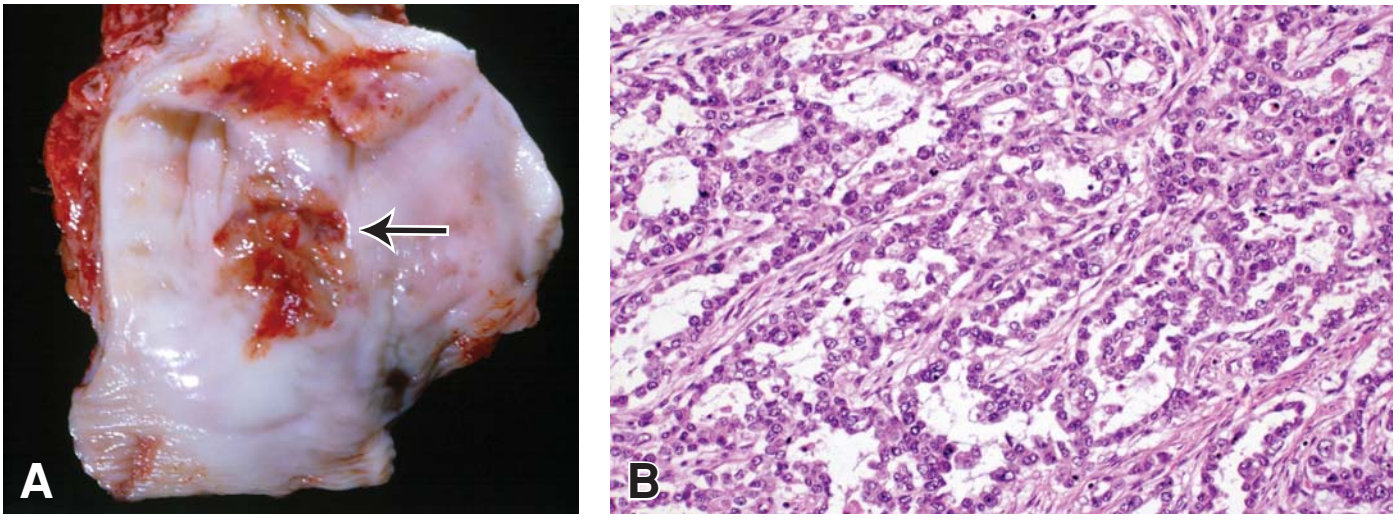

FIGURE 24-10. Clear cell adenocarcinoma of the vagina (in utero exposure to diethylstilbestrol [DES]). A. The tumor has arisen on the upper third of the anterior wall (*arrow*), corresponding to the most frequent site of adenosis. **B.** Microscopically, tubular glands are lined by hobnail cells.

Benign Mesenchymal Tumors

Most benign vaginal tumors resemble those elsewhere in the female genital tract (e.g., leiomyomas, rhabdomyomas and neurofibromas). These are solid submucosal tumors usually less than 2 cm in diameter.

MALIGNANT TUMORS OF THE VAGINA

Primary malignant tumors of the vagina are uncommon, constituting about 2% of all genital tract tumors. **Most (80%) vaginal malignancies represent metastatic spread.** The most common symptoms are vaginal discharge and bleeding during coitus, but advanced tumors may cause pelvic or abdominal pain and edema of the legs. Tumors confined to the vagina are usually treated by radical hysterectomy and vaginectomy.

Over 90% of Primary Vaginal Cancers Are Squamous Carcinomas

It is generally a disease of older women, with peak incidence between the ages of 60 and 70. It is most common in the anterior wall of the upper third of the vagina, where it usually grows as an exophytic mass. High-grade **vaginal intraepithelial lesion** (vaginal HSIL), a term replacing both "vaginal dysplasia" and "carcinoma in situ," frequently precedes invasive carcinoma. Vaginal squamous cell carcinoma may develop some years after cervical or vulvar carcinoma, suggesting a carcinogenic field effect in the lower genital tract, related to HPV infection.

Since most preinvasive and early invasive cancers are clinically silent, routine use of vaginal cytology is the most effective method to detect squamous carcinoma of the vagina. Prognosis is related to the extent of tumor spread at the time of discovery. Five-year survival in patients with tumors confined to the vagina (stage I) is 80%, whereas it is only 20% for those with extensive spread (stages III/IV).

Rhabdomyosarcoma Is a Rare Vaginal Tumor in Children

This tumor typically consists of confluent polypoid masses resembling a bunch of grapes, and hence may be called sarcoma botryoides (from the Greek *botrys*, "grapes") (Fig. 24-11). It occurs almost exclusively in girls under 4 years old. It arises in the lamina propria of the vagina and

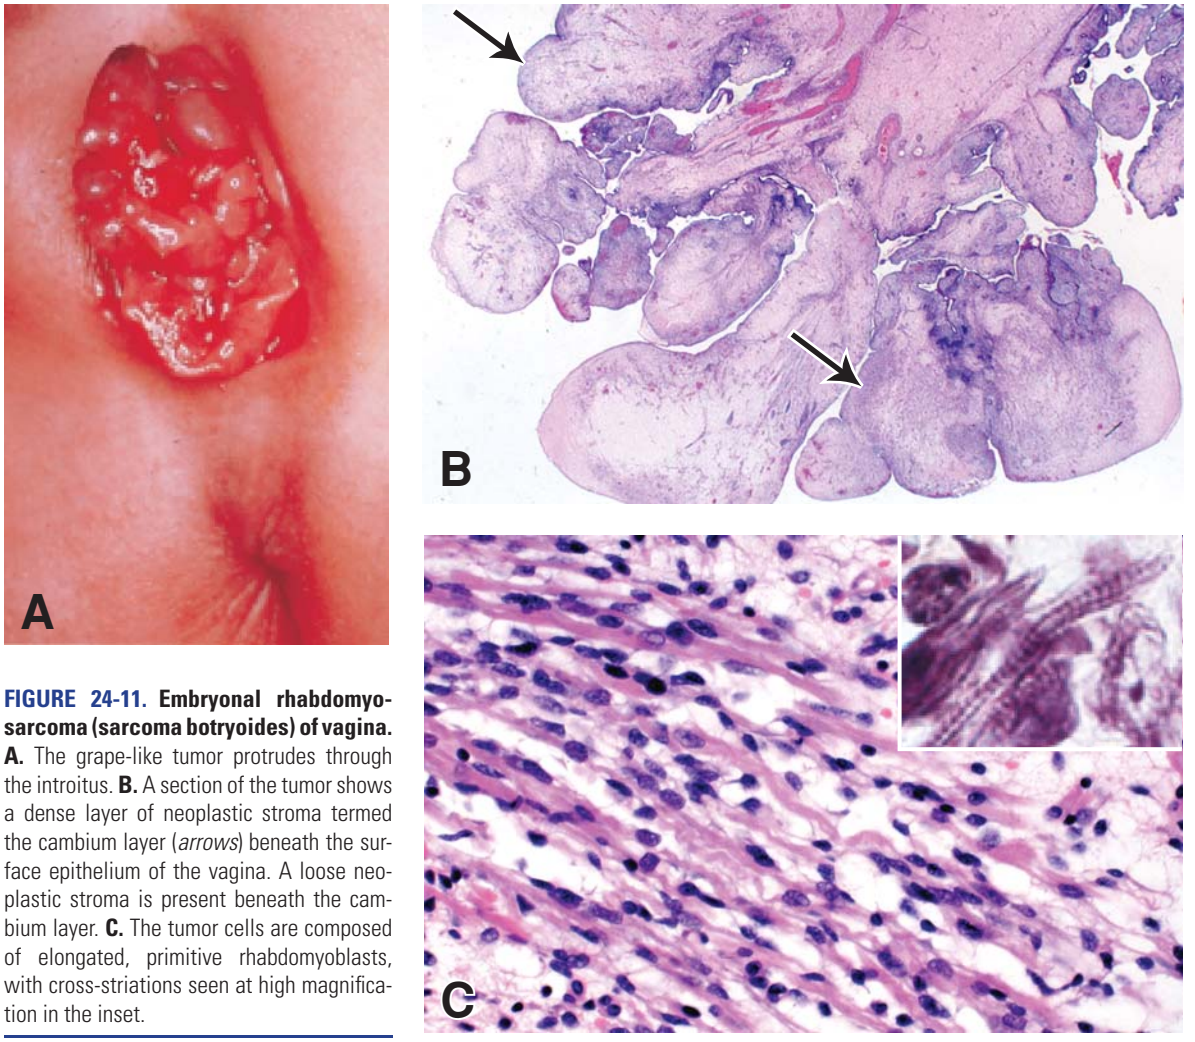

FIGURE 24-11. Embryonal rhabdomyosarcoma (sarcoma botryoides) of vagina. **A.** The grape-like tumor protrudes through the introitus. **B.** A section of the tumor shows a dense layer of neoplastic stroma termed the cambium layer (*arrows*) beneath the surface epithelium of the vagina. A loose neoplastic stroma is present beneath the cambium layer. **C.** The tumor cells are composed of elongated, primitive rhabdomyoblasts, with cross-striations seen at high magnification in the inset.

consists of primitive spindle rhabdomyoblasts (Fig. 24-11C), some of which show cross-striations. Myosin and actin myofibrils are often demonstrable. A dense zone of round rhabdomyoblasts (the cambium layer) is present beneath the vaginal epithelium (Fig. 24-11B). Deep to this layer, the stroma is myxomatous and shows fewer neoplastic rhabdomyoblasts. The tumor is usually detected because of spotting on the child's diaper. Tumors under 3 cm in greatest dimension tend to be localized and may be cured by wide excision and chemotherapy. Larger tumors often spread to adjacent structures, regional lymph nodes or distant sites. Even in advanced cases, half of patients survive with radical surgery and chemotherapy.

Cervix

ANATOMY

The cervix (from the Latin *collare,* "neck") is the inferior part of the uterus that connects the corpus to the vagina (Fig. 24-12). Its exposed portion (the **exocervix, ectocervix** or **portio vaginalis**) protrudes into the upper vagina and is covered by glycogen-rich squamous epithelium. The **endocervix** is the canal that leads to the endometrial cavity. It is lined by longitudinal mucosal ridges made of fibrovascular cores lined by a single layer of mucinous columnar cells. Occasionally, the outlet of an endocervical gland becomes blocked and mucin is retained, which produces cystic dilations of these glands, termed **nabothian cysts**. The **external os** is the *macroscopic* junction between the exocervix and endocervix. The **squamocolumnar junction** is the *microscopic* junction of the squamous and mucinous columnar epithelia. The area between the endocervix and endometrial cavity is called the **isthmus** or **lower uterine segment**.

The exocervix remodels continuously throughout life. During embryonic development, upward migration of squamous cells meets columnar epithelium of the endocervix to form the initial squamocolumnar junction (Fig. 24-13). In some young women, this "original" squamocolumnar junction is located at the internal os. In most, however, the columnar epithelium extends onto the exocervix, in which case, the areas of the exocervix lined by columnar epithelium are termed **endocervical ectropion** and appear by colposcopic examination as reddish discolorations. With age, the columnar epithelium of the ectropion undergoes squamous metaplasia and a new squamocolumnar junction is formed at the internal os.

The area between the distalmost squamocolumnar junction and the external os is called the **transformation zone**. Immature squamous epithelium of this zone displays progressive nuclear maturation and increasing amounts of glycogen-free cytoplasm toward the surface. Colposcopy shows a thin white membrane, which eventually becomes thicker and whiter as the squamous epithelium matures (Figs. 24-13 and 24-14). As cells accumulate glycogen, they become indistinguishable from normal squamous epithelium lining the exocervix. The transformation zone is the site of cervical squamous carcinoma (see below).

Examination of the transformation zone by iodine staining is the basis of the **Schiller iodine test**. Normal mature (glycogen-rich) squamous cells lining the exocervix stain with iodine and the exocervix appears mahogany brown. If they are immature (glycogen poor), no iodine staining occurs and the exocervix is pale.

CERVICITIS

Inflammation of the cervix is common and is related to constant exposure to bacterial flora in the vagina. Acute and chronic cervicitis are caused by many organisms, particularly

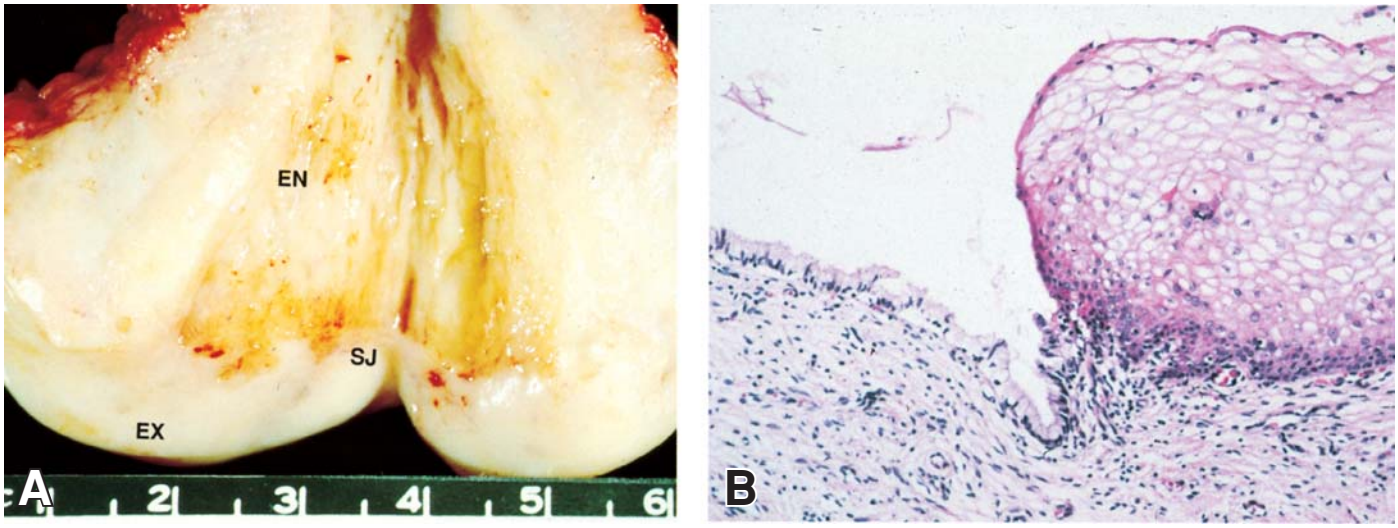

FIGURE 24-12. Anatomy of the cervix. A. The cervix has been opened to show the endocervix (EN), squamocolumnar junction (SJ) and exocervix (EX). The thick layer of squamous cells covering the exocervix accounts for its white color. **B.** A microscopic view of the squamocolumnar junction. The endocervix is lined by a single layer of columnar mucus-producing cells that abruptly meets the exocervix lined by mature squamous cells. *Note:* In specimens in which the squamocolumnar junction is on the ectocervix or in the endocervical canal, the region between it and the external os is called the *transformation zone* (Fig. 24-13).

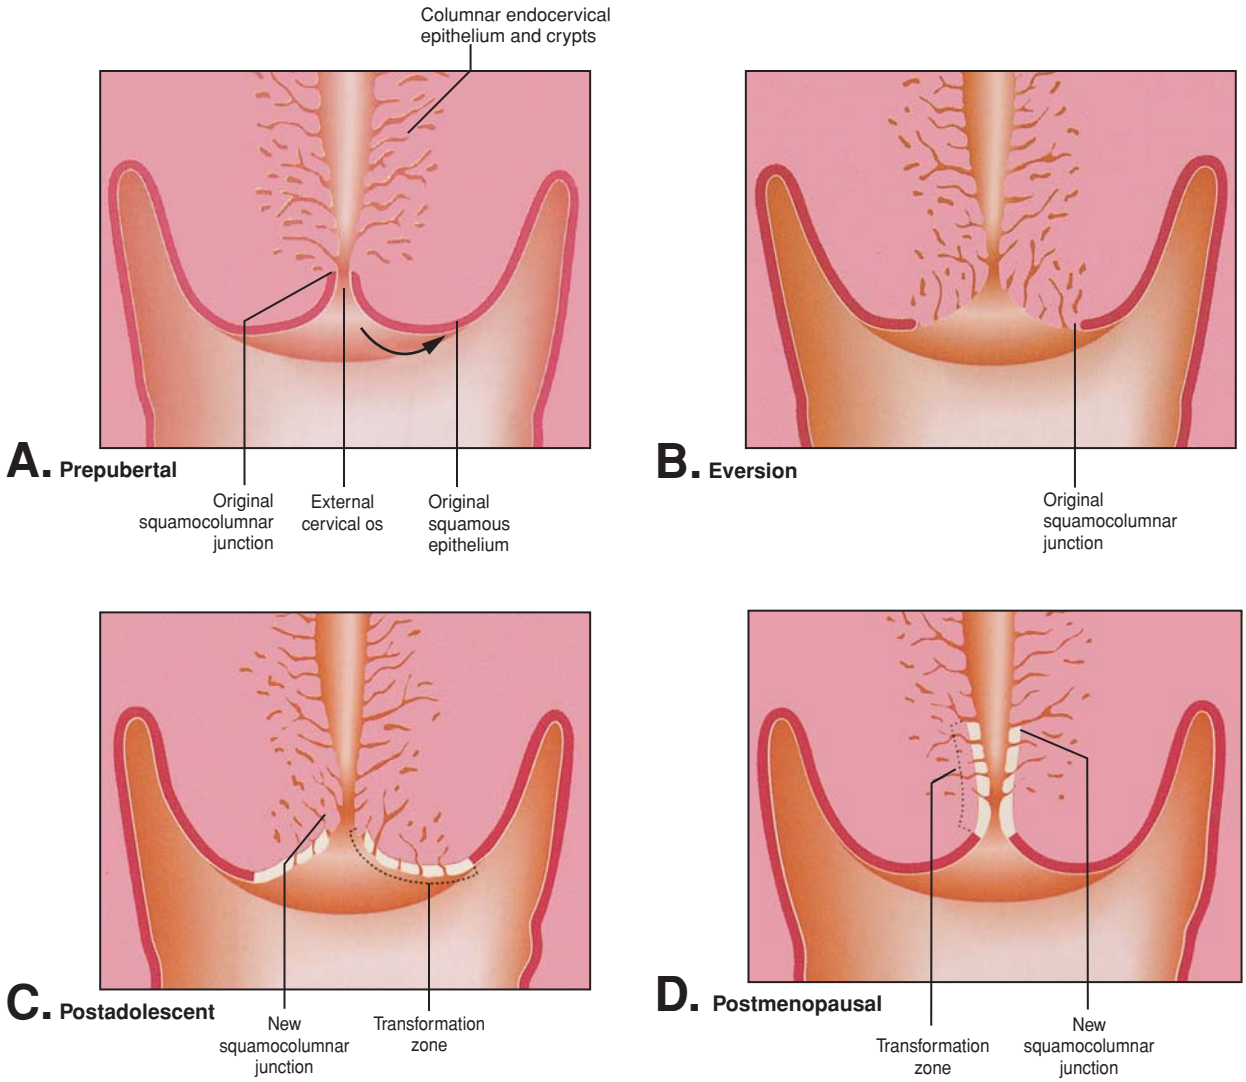

FIGURE 24-13. The transformation zone of the cervix. A. Prepubertal cervix. The squamocolumnar junction is situated at the external cervical os. The arrow shows the direction of the movement that takes place as a result of the increase in bulk of the cervix during adolescence. **B. The process of eversion.** On completion, endocervical columnar tissue lies on the vaginal surface of the cervix and is exposed to the vaginal environment. **C. Postadolescent cervix.** The acidity of the vaginal environment is one of the factors that encourages squamous metaplastic change, replacing the exposed columnar epithelium with squamous epithelium. **D. Postmenopausal cervix.** At this time, cervical inversion occurs. This phenomenon is the reverse of eversion, which was so important in adolescence. The transformation zone is now drawn into the cervical canal, often making it inaccessible to colposcopic examination.

endogenous vaginal aerobes and anaerobes, *Streptococcus, Staphylococcus* and *Enterococcus*. Other specific organisms include *C. trachomatis, N. gonorrhoeae* and occasionally herpes simplex type 2. Some agents are sexually transmitted; others may be introduced by foreign bodies, such as residual fragments of tampons and pessaries.

PATHOLOGY: In **acute cervicitis,** the cervix is grossly red, swollen and edematous, with copious pus "dripping" from the external os. Microscopically, the tissues exhibit extensive polymorphonuclear leukocyte infiltration and stromal edema.

Chronic cervicitis is more common. The cervical mucosa is hyperemic (Fig. 24-15) and may show true epithelial erosions. The stroma is infiltrated, principally by lymphocytes and plasma cells. Metaplastic squamous epithelium of the transformation zone may extend into endocervical glands, forming clusters of squamous epithelium, which must be differentiated from carcinoma.

BENIGN TUMORS AND TUMOR-LIKE CONDITIONS OF THE CERVIX

Endocervical Polyps Are Usually Benign

Endocervical polyps are the most common cervical growths (Fig. 24-16). They appear as single smooth or lobulated masses, usually under 3 cm in greatest dimension. They typically manifest as vaginal bleeding or discharge. The lining epithelium is mucinous, with variable squamous metaplasia, but may feature erosions and granulation tissue if women are symptomatic. Simple excision or curettage is curative. Cancer rarely arises in an endocervical polyp (0.2% of cases).

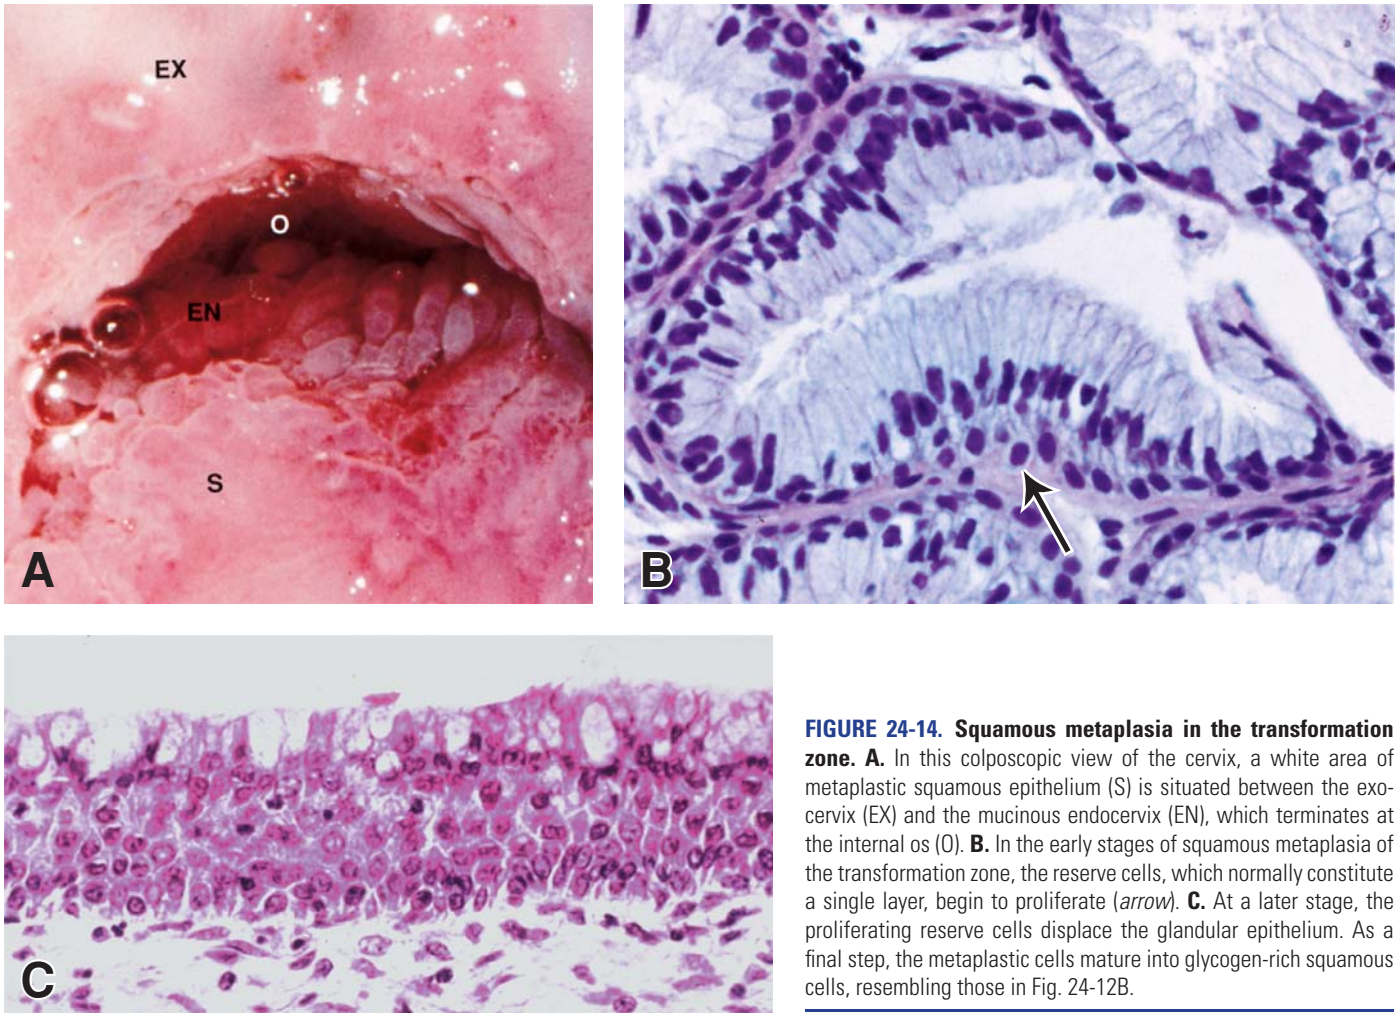

FIGURE 24-14. Squamous metaplasia in the transformation zone. A. In this colposcopic view of the cervix, a white area of metaplastic squamous epithelium (S) is situated between the exocervix (EX) and the mucinous endocervix (EN), which terminates at the internal os (O). **B.** In the early stages of squamous metaplasia of the transformation zone, the reserve cells, which normally constitute a single layer, begin to proliferate (*arrow*). **C.** At a later stage, the proliferating reserve cells displace the glandular epithelium. As a final step, the metaplastic cells mature into glycogen-rich squamous cells, resembling those in Fig. 24-12B.

Microglandular Hyperplasia Reflects Progestational Stimulation

Cervical microglandular hyperplasia is a benign condition showing closely packed vacuolated glands lacking intervening stroma and mixed with a neutrophilic infiltrate. The glands vary in size and are lined by a flattened-to-cuboidal epithelium (Fig. 24-17). Nuclei are uniform, and mitoses are rare. Squamous metaplasia and reserve cell hyperplasia are common. It should not be confused with well-differentiated adenocarcinoma. Microglandular hyperplasia is usually asymptomatic and, because it is typically associated with progestin stimulation, it usually occurs during pregnancy, in the postpartum period and in women taking oral contraceptives.

Leiomyomas Can Cause Cervical Bleeding

Cervical leiomyomas can prolapse into the endocervical canal and cause uterine contractions and pain resembling the early phases of labor. The appearance is similar to that of uterine leiomyomas (see below).

SQUAMOUS CELL NEOPLASIA

Fifty years ago, cervical cancer was the leading cause of cancer death in American women. The introduction and widespread use of cytologic screening decreased cervical carcinoma by 50%–85% in Western countries. It is now the sixth most common female cancer in the United States, and mortality has fallen by 70%. Worldwide, however, cervical cancer remains the second most common cancer in women.

Squamous Intraepithelial Lesions Are Precursors of Invasive Cancer

SILs of the cervix are the effects of human papilloma virus and are designated as low grade (LSILs) or high grade (HSILs) based on the corresponding infecting viral subtype and risk of progression to invasive squamous cell carcinoma (Fig. 24-18). Squamous precancer terminology was standardized across all anogenital sites in 2012 by the Lower Anogenital Squamous Terminology (LAST) group under the sponsorship of the College of American Pathologists, although legacy terms of cervical intraepithelial neoplasia (CIN), dysplasia and CIS are commonly used interchangeably.

Cervical SIL carries a risk for ***malignant transformation*** that varies between low- and high-grade subtypes (Figs. 24-18 and 24-19). The disease spectrum is primarily driven by the nature of the infecting virus, with each class demonstrating its own disease spectrum. The grades of SIL are:

- LSIL: CIN-1: mild dysplasia
- HSIL: CIN-2, moderate dysplasia; CIN-3, severe dysplasia, carcinoma in situ

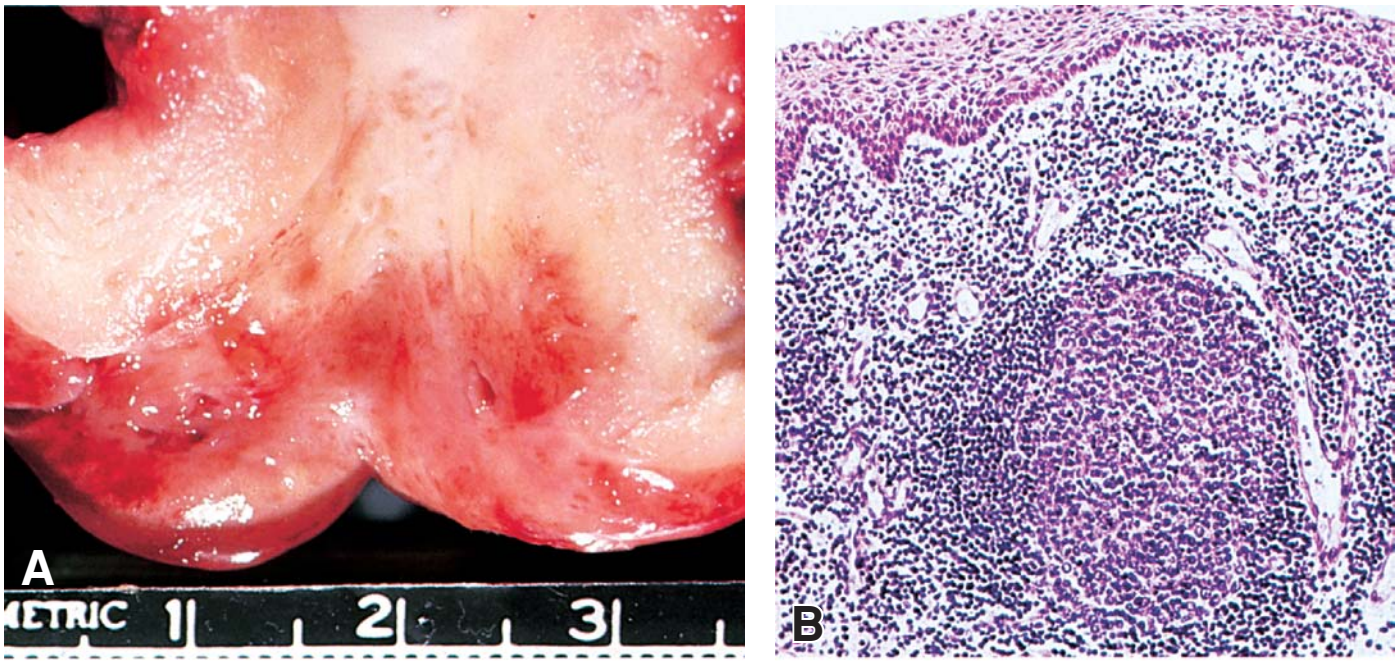

FIGURE 24-15. Chronic cervicitis. A. The cervix has been opened to reveal the reddened exocervix. **B.** Microscopic examination discloses chronic inflammation and the formation of a lymphoid follicle.

LSIL rarely progresses in severity and commonly disappears (CIN-1, mild dysplasia). HSIL describes more severe histologic lesions (CIN-2 and CIN-3), which tend to progress and require treatment. Early phases of infection with all HPV types likely involve episomal viral propagation throughout a polyclonal epithelial field, with an LSIL cytology. Oncogenic types of HPV are prone to subsequent genomic integration of virus and promote monoclonal outgrowth of cells driven by transforming viral proteins (E6/E7) with progression to HSIL.

EPIDEMIOLOGY AND MOLECULAR PATHOGENESIS: Epidemiologic features of SIL and invasive cancer are similar. Cervical cancer usually manifests in women 40–60 years old (mean 54), but SIL generally occurs before age 40. ***The critical factor is HPV infection, which correlates with multiple sexual partners and early age at first coitus.*** Thus, SIL is essentially a **sexually transmitted disease**. Smoking increases the incidence of cancer of the cervix, but the mechanism is obscure.

HPV infection leads to SIL and cervical cancer (Fig. 24-19). In LSIL, HPV is episomal and replicates freely to cause cell death. Huge numbers of virus must accumulate in the cytoplasm before being visible as a koilocyte. In most cases of HSIL, viral DNA integrates into the cell genome. Proteins encoded by HPV-16 E6 and E7 genes bind and inactivate p53 and Rb proteins, respectively, and mitigate their tumor suppressor functions (see Chapter 5). Once HPV integrates into host DNA, copies of intact virus do not accumulate and koilocytes are absent in many cases of high-grade dysplasia and all invasive cancers.

Roughly 85% of LSIL lesions have low-risk HPV. Genital warts (condylomata acuminata) of the cervix often contain

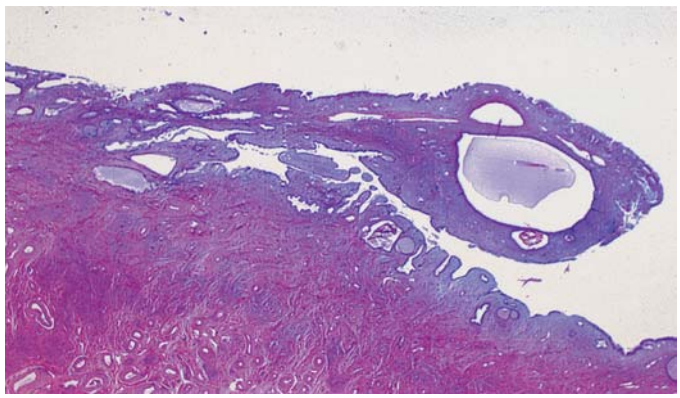

FIGURE 24-16. Endocervical polyp. An epithelial lining covers a fibrovascular core.

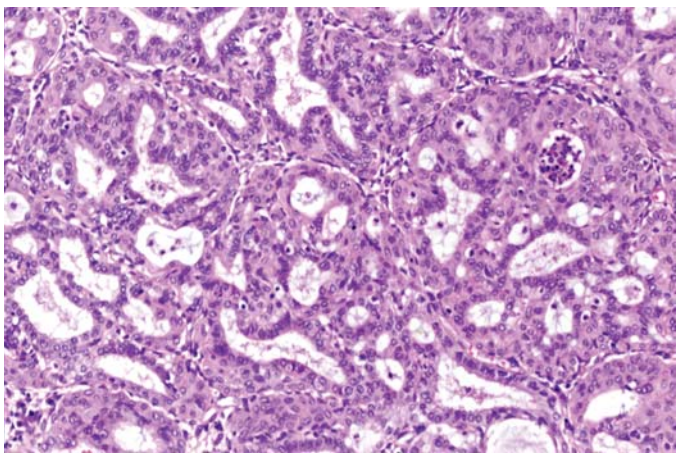

FIGURE 24-17. Microglandular hyperplasia. Small proliferated glands are admixed with a neutrophilic infiltrate.

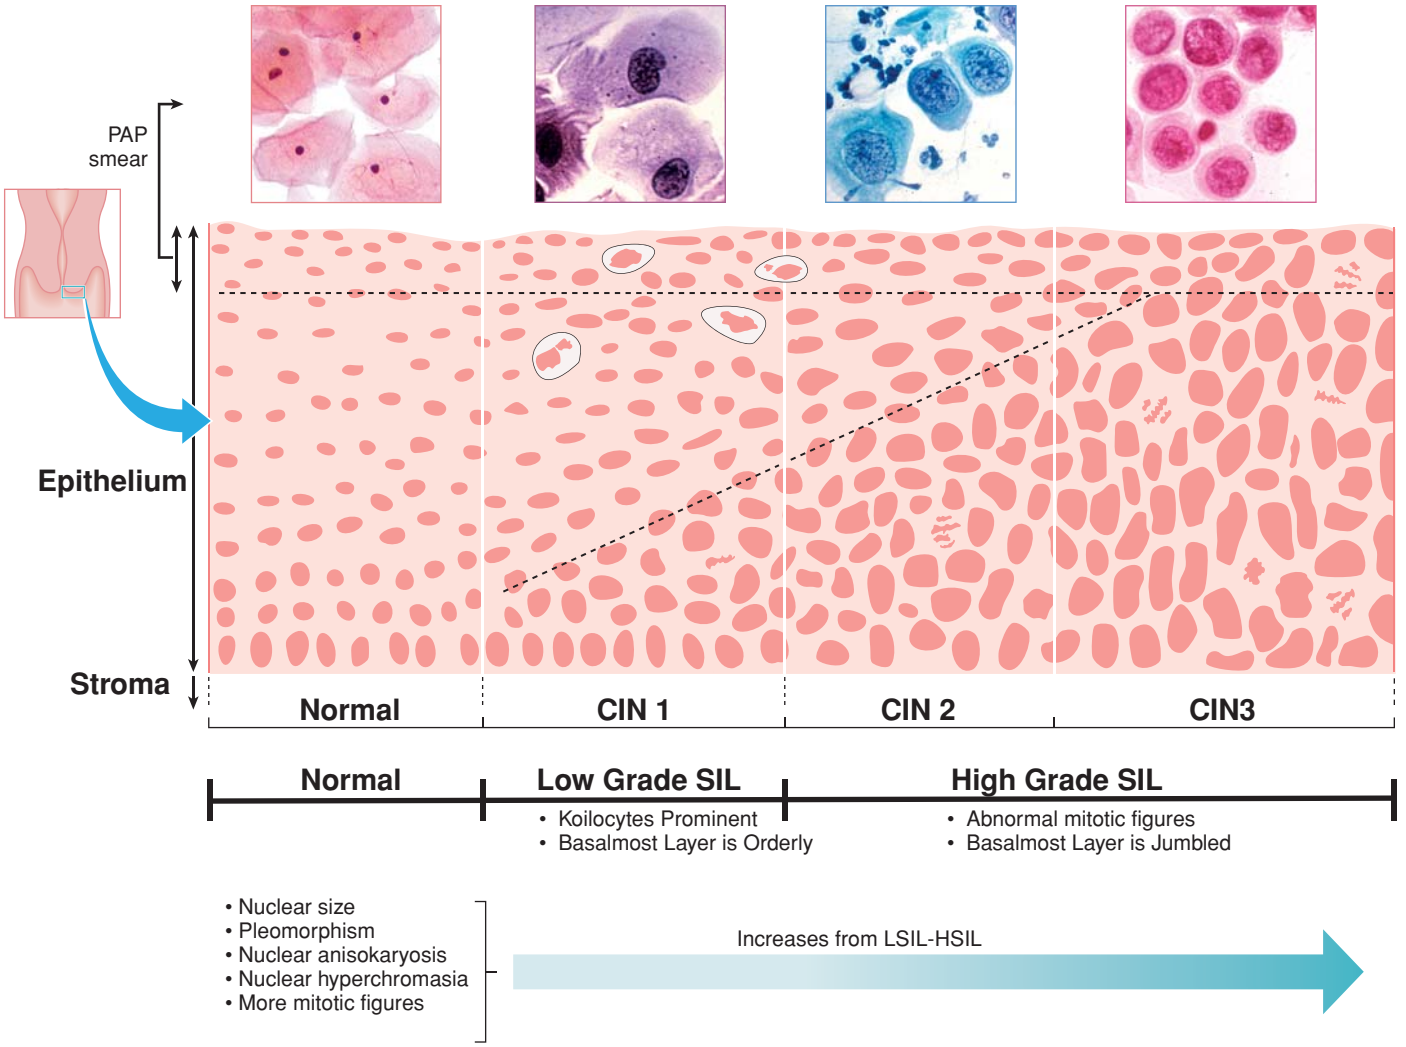

FIGURE 24-18. The Bethesda system for designation of premalignant cervical disease as squamous intraepithelial lesions (SILs). This chart integrates multiple aspects across the normal–LSIL (low-grade squamous intraepithelial lesion), and LSIL–HSIL (high-grade squamous intraepithelial lesion) interfaces, which correspond to therapeutic thresholds. It lists the qualitative and quantitative features that distinguish low-cancer-risk (LSIL) from high-cancer-risk (HSIL) lesions, which are generally caused by different subtypes of human papillomavirus. It also illustrates approximate counterparts for the legacy cervical intraepithelial neoplasia (CIN) system, which was based on a model of continuous progression rather than dichotomous viral subtypes. Finally, the scheme illustrates the corresponding cytologic smear resulting from exfoliation of the most superficial cells, indicating that even in the mildest disease state, abnormal cells reach the surface and are shed.

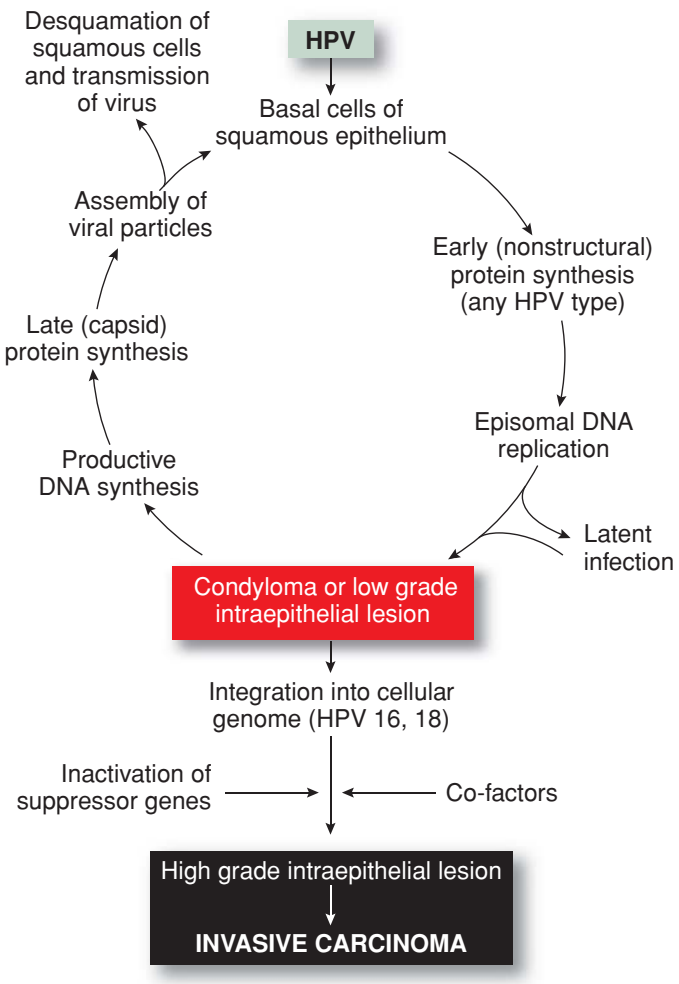
HPV-6 or -11, both considered low-risk HPV types. By contrast, cells in HSIL usually contain HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59 and 68. **HPV types 16 and 18** are found in 70% of invasive cancers; other high-risk types account for another 25%.

Hormonally induced eversion of the cervix and an acidic vaginal environment encourage development of the transformation zone. Without HPV, benign squamous metaplasia is the eventual outcome. But in the presence of HPV or other carcinogenic agents, transformation zone stem cells are diverted into SIL and may progress to invasive carcinoma, depending on the subtype and unknown host factors.

PATHOLOGY: The HPV-susceptible cell type has been identified as a cytokeratin 7–expressing stem cell located in the region of the cervical transformation zone between the columnar endocervix and squamous exocervix. ***It is the location of the transformation zone and its component cell types on the exposed portion of the cervix that determines the distribution of SIL, and hence cervical cancer.***

The normal process by which cervical squamous epithelium matures is disturbed across the full thickness of SIL, as evidenced by changes in cellularity, differentiation, polarity, nuclear features and mitotic activity. While the height to which the basaloid cells extend upward in the epithelium generally differs between LSIL and HSIL, this is an oversimplification. For example, the most dramatic changes in **LSIL (CIN-1)** occur not in the base, but rather in koilocytes of the superficial epithelium, which show ballooned cytoplasm and irregular large nuclei caused by episomal virus propagation within differentiated squamous cells that are absent in the base. Features in the basal region related to genomic integration of virus in propagating basal cells are prominent in **HSIL (CIN-2/-3)**. These include disorganization of basal cell alignment along the basement membrane and nuclear changes that persist as cells are pushed upward in the epithelium.



Desquamation of squamous cells and transmission of virus
HPV
Basal cells of squamous epithelium
Assembly of viral particles
Early (nonstructural) protein synthesis (any HPV type)
Late (capsid) protein synthesis
Episomal DNA replication
Productive DNA synthesis
Latent infection
Condyloma or low grade intraepithelial lesion
Integration into cellular genome (HPV 16, 18)
Inactivation of suppressor genes
Co-factors
High grade intraepithelial lesion
INVASIVE CARCINOMA

FIGURE 24-19. Role of human papillomavirus (HPV) in the pathogenesis of cervical neoplasia.

Abnormal mitotic figures, pathognomonic of chromosomal aneuploidy, may also be present in HSILs. Thus, grading of individual lesions as HSIL and LSIL requires consideration of all features described in Fig. 24-18. The differing histologic changes of LSIL and HSIL are shown in Fig. 24-20.

Since abnormal cells are present throughout the epithelium in women with SIL, they are shed into the Pap smear. Nuclear abnormalities and the degree of cytoplasmic differentiation in exfoliated abnormal cells are used to identify SIL and subclassify it as LSIL or HSIL. That this distinction can usually be made in shed cells indicates that morphologic differences between HSIL and LSIL are reflected in superficial as well as deep aspects of the epithelium. But while the Pap smear is an exquisitely sensitive screen for SIL lesions, it is only a screen. Definitive classification is best made in a histologic specimen where the full epithelium can be assessed.

Altered vasculature and epithelial changes in cervical SIL can be seen on colposcopic examination. Mosaicism (irregular surface resembling inlaid woodwork) (Fig. 24-21) and vascular punctation are two patterns most often seen in HSIL. The oncogenic process occurs more often on the anterior than the posterior cervical lip and often involves the endocervical glands.

CLINICAL FEATURES: The mean age at which women develop SIL has declined over the past few decades and is now 25–30 years. Seventy percent of cases of LSIL regress, 6% progress to HSIL and less than 1% become invasive cancer. Progression of HSIL to invasive squamous carcinoma occurs with greater frequency and over a shorter interval, but the exact figures vary with intervening management. ***Ten to 20% of cases of HSIL progress to invasive carcinoma if untreated.***

Biopsy is indicated when SIL is discovered on Pap smear. Targeted biopsies may be visually directed by colposcopy, or the entire transformation zone can be removed by a wire "loop" electrosurgical excision procedure (LEEP). LEEP may fulfill both diagnostic and therapeutic functions. Diagnostic endocervical curettage also helps determine the extent of endocervical involvement. Women with LSIL are often followed conservatively (i.e., repeated Pap smears plus close follow-up), although some gynecologists advocate local ablative treatment. High-grade lesions are treated by ablation methods determined by their anatomic distribution. LEEP may be sufficient, if margins are negative. Cervical conization (removal of a cone of tissue around the external os), cryosurgery and (rarely) hysterectomy may also be done. Follow-up smears and clinical examinations should continue for life, as vaginal or vulvar squamous cancer may develop later.

Superficially Invasive Squamous Cell Carcinoma Is the Earliest Stage of Invasive Cervical Cancer

In this setting, stromal invasion usually arises from overlying HSIL. About 7% of specimens removed for CIS show focal superficially invasive cancer. Superficially invasive disease is based on width and depth of invasion, defined by the International Federation of Gynecology and Obstetrics (FIGO) as follows (Table 24-2):

- Invasion less than 3 mm from the basement membrane point of origin
- Less than or equal to 7-mm maximum lateral extension

The earliest recognizable invasive changes are tiny irregular epithelial buds emanating from the base of HSILs (Fig. 24-22), previously called "microinvasive" (Fig. 24-23). These small (<1 mm) tongues of neoplastic epithelial cells do not affect the prognosis of HSILs; hence, both can be treated similarly with conservative surgery. The LAST consensus group further limits use of the term "superficially invasive squamous cell carcinoma" to tumors that are not grossly visible. Conization or simple hysterectomy generally cures superficially invasive squamous cell carcinomas.

If the maximum dimensions described above are exceeded, the lesion is no longer considered "superficially invasive," but rather "invasive" squamous cell carcinoma of the cervix (Fig. 24-22; see below). The FIGO clinical staging criteria (Table 24-2) are widely used to guide management of gynecologic malignancies.

Invasive Squamous Cell Carcinoma Remains Common Worldwide

EPIDEMIOLOGY: Squamous cell carcinoma is by far the most common type of cervical cancer. In the United States (Table 24-3), roughly 12,000 new

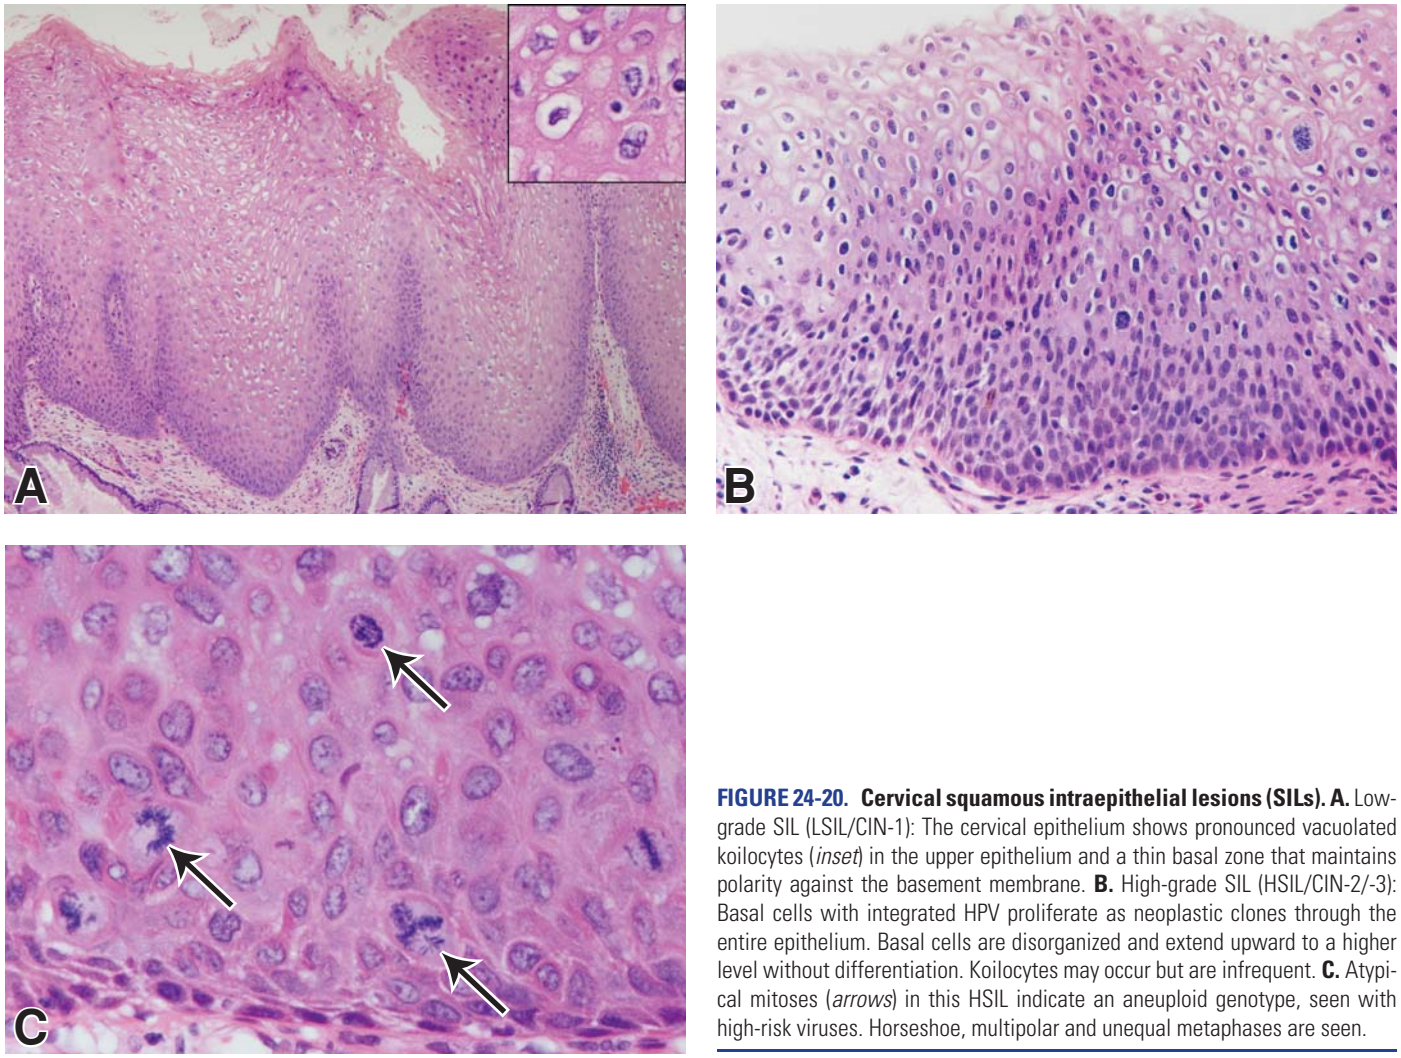


FIGURE 24-20. Cervical squamous intraepithelial lesions (SILs). A. Low-grade SIL (LSIL/CIN-1): The cervical epithelium shows pronounced vacuolated koilocytes (*inset*) in the upper epithelium and a thin basal zone that maintains polarity against the basement membrane. **B.** High-grade SIL (HSIL/CIN-2/-3): Basal cells with integrated HPV proliferate as neoplastic clones through the entire epithelium. Basal cells are disorganized and extend upward to a higher level without differentiation. Koilocytes may occur but are infrequent. **C.** Atypical mitoses (*arrows*) in this HSIL indicate an aneuploid genotype, seen with high-risk viruses. Horseshoe, multipolar and unequal metaphases are seen.

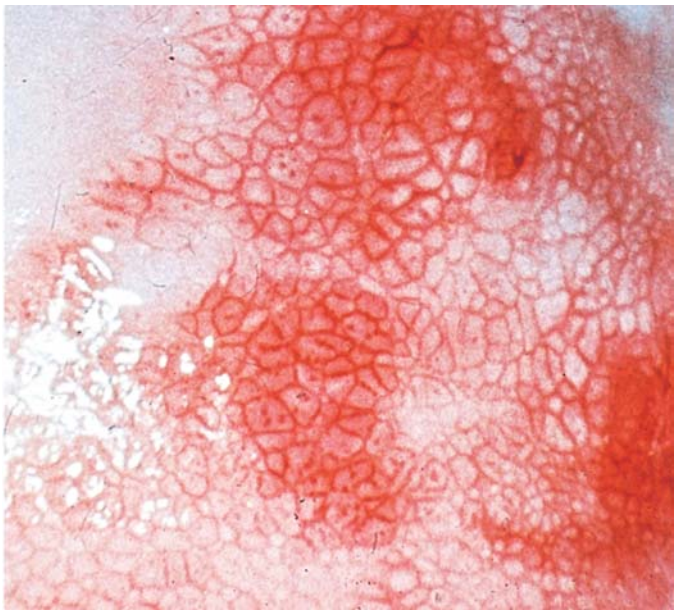

FIGURE 24-21. High-grade squamous intraepithelial lesion (HSIL) of the cervix. Examination with the colposcope discloses a mosaic pattern resembling inlaid woodwork.

cases occur annually, which is less than either endometrial or ovarian cancer. However, in underdeveloped areas, where cytologic screening is less available, cervical squamous cancer is still a major cause of cancer death. The HPV vaccine (often termed the **cervical cancer vaccine**) decreases individual risk of cervical cancer by 97%. Vaccinated women have reduced rates of both HPV-associated precancers and invasive cervical cancer.

PATHOLOGY: Early stages of cervical cancer are often poorly defined, granular, eroded lesions or nodular and exophytic masses (Fig. 24-24A). If the tumor resides mainly within the endocervical canal, it can be an endophytic mass that infiltrates stroma and causes diffuse enlargement and hardening of the cervix. Most tumors are nonkeratinizing, with solid nests of large malignant squamous cells and no more than individual cell keratinization. Most remaining cancers show nests of keratinized cells in concentric whorls, so-called keratin pearls (Fig. 24-24B). The least common, and most aggressive, tumor is small cell carcinoma. It consists of infiltrating masses of small, cohesive, nonkeratinized, malignant cells, and has the worst prognosis.

Cervical cancer spreads by direct extension or through lymphatic vessels (Fig. 24-25) and only rarely by the hematogenous route. Local extension into surrounding tissues

TABLE 24-2
FIGO (2009) STAGING OF TUMORS OF THE UTERINE CERVIX

Stage	Anatomic Distribution
Stage I	Carcinoma confined to the uterus
IA	Invasive carcinoma that can be diagnosed only by microscopy, with deepest invasion ≤5 mm and largest extension ≤7 mm
IA1	Measured stromal invasion of ≤3.0 mm in depth and extension of ≤7.0 mm
IA2	Measured stromal invasion of >3.0 mm and <5.0 mm with an extension of not more than 7.0 mm
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage IA
Stage II	Tumor invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
IIA	Without parametrial invasion
IIB	With obvious parametrial invasion
Stage III	Tumor extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Tumor extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney
Stage IV	Tumor has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum
IVA	Spread to adjacent organs
IVB	Spread to distant organs

FIGO = International Federation of Gynecology and Obstetrics.

TABLE 24-3
INCIDENCE OF GYNECOLOGIC CANCER IN THE UNITED STATES (2013, ESTIMATED)

	New Cases		Death	
	Cases	%[a]	Cases	%[a]
Endometrium	49,560	6	8190	3
Ovary	22,240	3	14,030	5
Cervix, invasive	12,340	2	4030	2
Vulva, invasive	4700	<1	990	<1
Vagina and other, invasive	2890	<1	840	<1

[a]% = percentage of all cases of cancer in females.
American Cancer Society Statistics.

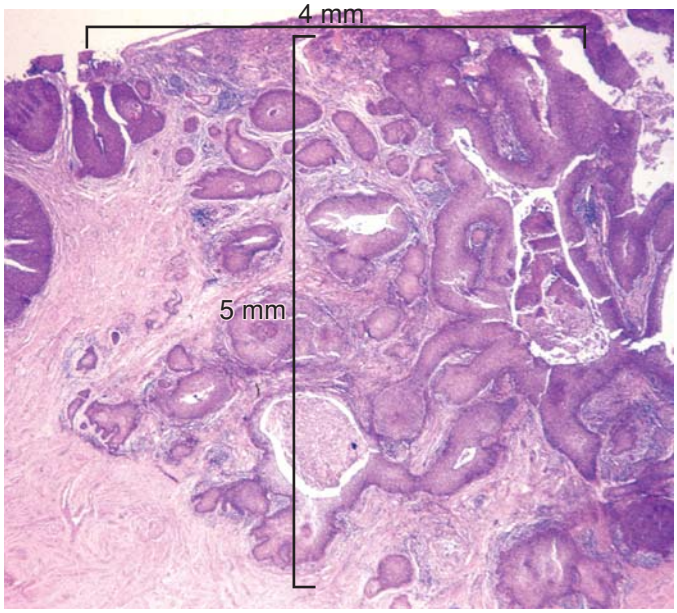

FIGURE 24-22. Invasive squamous cell carcinoma. The tumor invades 5 mm deep and 4 mm wide, exceeding the 3-mm depth limit placed on superficially invasive tumors.

(parametrium) (stage IIIB) may result in **ureteral compression** and cause clinical complications of hydroureter, hydronephrosis and renal failure, the most common cause of death (50% of patients). Bladder and rectal involvement (stage IVA) may lead to fistula formation. Lymphatic spread leads to metastases in paracervical, hypogastric and external iliac nodes. Overall, tumor growth and spread are relatively slow; the average age for patients with stage 0 tumor (HSIL) is 35–40 years; for stage IA, 43 years; and for stage IV, 57 years.

CLINICAL FEATURES: In early stages of cervical cancer, patients complain most often of vaginal bleeding after intercourse or douching. With more

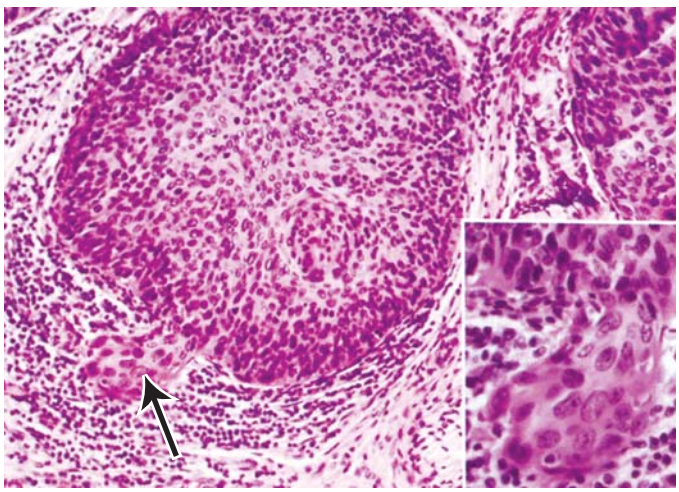

FIGURE 24-23. Early ("microinvasive") stromal invasion in a superficially invasive squamous cell carcinoma. Section of the cervix shows that high-grade squamous intraepithelial lesion (HSIL) in an endocervical gland has broken through the basement membrane (*arrow*) to invade the stroma. **Inset.** A higher-power view of the early invasive focus.

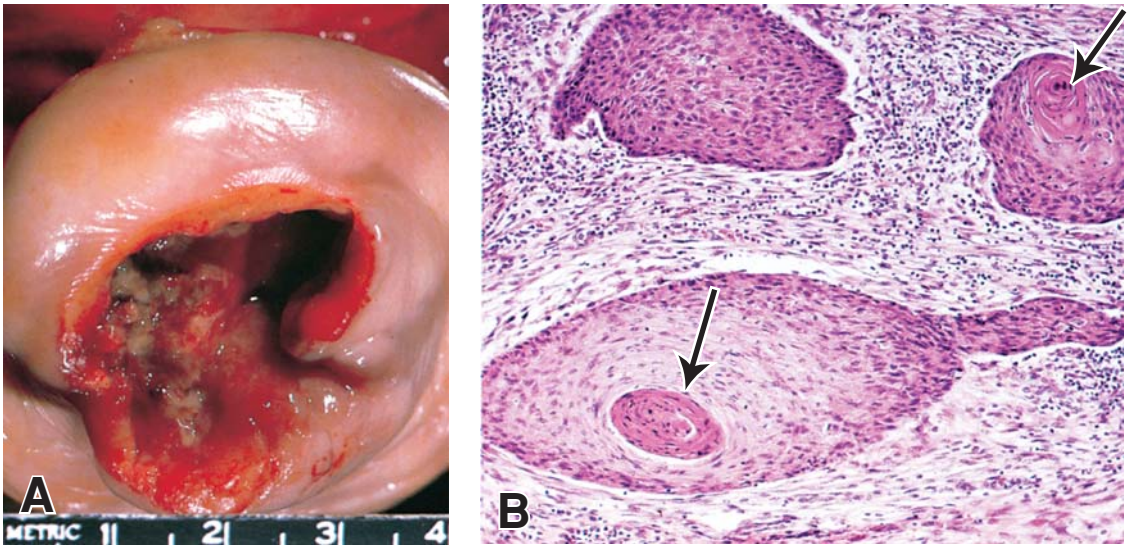

FIGURE 24-24. Squamous cell cancer. A. The cervix is distorted by the presence of an exophytic, ulcerated squamous cell carcinoma. **B.** The keratinizing pattern of the tumor is manifested as whorls of keratinized cells ("keratin pearls") (*arrows*).

advanced tumors, symptoms are referable to the route and degree of spread. The Pap smear remains the most reliable screening test for detecting cervical cancer.

The anatomic stage of cervical cancer is the best predictor of survival (Tables 24-2 and 24-3): 5-year survival is 90% in stage I; 75% in II; 35% in III; and 10% in VI, for an overall 5-year survival rate of 60%. About 15% of patients develop recurrences on the vaginal wall, bladder, pelvis or rectum within 2 years of therapy. Radical hysterectomy is favored for localized tumor, especially in younger women; radiation therapy or combinations of the two are used for more advanced tumors.

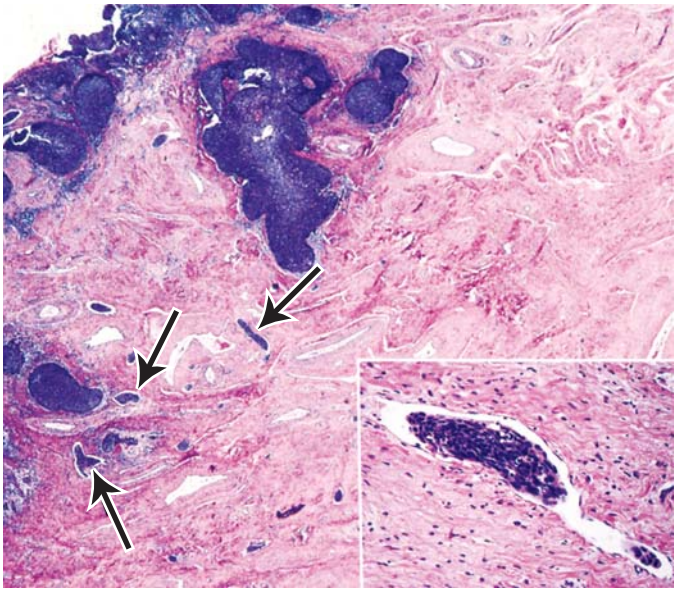

FIGURE 24-25. Squamous cell cancer of the cervix with lymphatic invasion. Low magnification shows a squamous cell carcinoma that has invaded the stroma and permeated the lymphatics (*arrows*). **Inset.** A high-power view of lymphatic invasion.

Endocervical Adenocarcinoma Accounts for 20% of Malignant Cervical Tumors

The incidence of cervical adenocarcinoma has increased recently, with a mean age of 56 years at presentation. Most tumors are of endocervical cell (mucinous) type, but the various subtypes have little bearing on overall survival. Adenocarcinoma shares epidemiologic factors with squamous carcinoma of the cervix and spreads similarly. They are often associated with adenocarcinoma in situ and contain HPV types 16 or 18.

PATHOLOGY:

ADENOCARCINOMA IN SITU: Also called **cervical glandular intraepithelial neoplasia,** this lesion generally arises at the squamocolumnar junction and extends into the endocervical canal. It displays tall columnar cells with eosinophilic or mucinous cytoplasm, sometimes resembling goblet cells. The pattern of spread and involvement of endocervical glands resemble those of cervical SIL. Adenocarcinoma in situ typically is intraepithelial, maintaining normal endocervical gland architecture. The cells show slight enlargement, atypical hyperchromatic nuclei, increased nuclear-to-cytoplasmic ratio and variable mitoses. Abrupt transitions help distinguish neoplastic from neighboring normal endocervical cells. Squamous HSIL occurs in 40% of cases of adenocarcinoma in situ.

INVASIVE ADENOCARCINOMA: This tumor typically presents as a fungating polypoid (Fig. 24-26A) or papillary mass. Exophytic tumors often have a papillary pattern (Fig. 24-26B), whereas endophytic ones display tubular or glandular patterns. Poorly differentiated tumors are predominantly composed of solid sheets of cells.

Adenocarcinoma of the endocervix spreads by local invasion and lymphatic metastases, but overall survival is somewhat worse than for squamous carcinoma. Treatment is similar to that for squamous carcinoma.

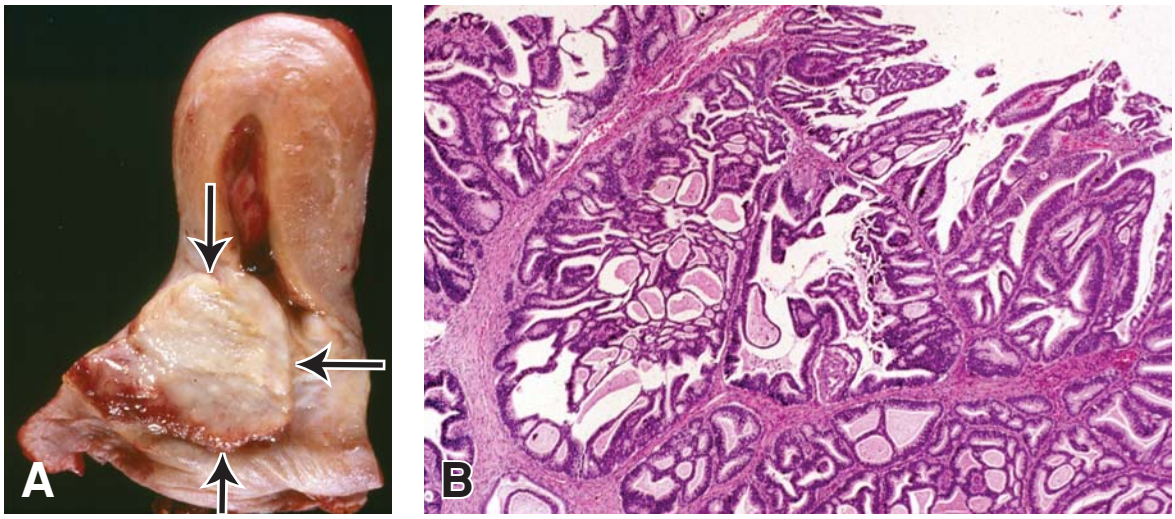

FIGURE 24-26. Endocervical adenocarcinoma. A. The endocervical tumor appears as a polypoid mass (*arrows*). **B.** Microscopic view of endocervical adenocarcinoma showing a papillary pattern of growth.

Uterus

ANATOMY

The uterine corpus (body) is smaller than the cervix at birth and during childhood but increases rapidly in size after puberty. The endometrium is composed of glands and stroma. It is thin at birth, when it consists of a continuous surface of cuboidal epithelium that dips to line a few sparse tubular glands. After puberty, it thickens. The superficial two thirds, the "zona functionalis," responds to hormones and is shed with each menstrual phase. The deepest third, the basal layer, is the germinative portion that regenerates a new functional zone with each cycle.

The endometrium is supplied by arcuate arteries that traverse the outer myometrium and give off two sets of vessels, one to the myometrium and the other, the radial arteries, to the endometrium. In turn, the radial arteries branch into two types of vessels. The basal arteries supply the basal endometrium and the spiral arteries nourish the superficial two thirds.

THE MENSTRUAL CYCLE

Normal endometrium undergoes sequential changes that support growth of implanted fertilized ova (zygotes) (Fig. 24-27). If conception does not occur, the endometrium is shed, and then regenerated to support a fertilized ovum in the next cycle.

MENSTRUAL PHASE: Without a blastocyst to secrete human chorionic gonadotropin (hCG), ovarian granulosa and thecal cells degenerate. Progesterone levels fall. The endometrium becomes desiccated, spiral arteries collapse and stroma disintegrates. Menses start at day 28, last 3–7 days and is composed of about 35 mL of blood. The denuded surface is regenerated by extension of the residual glandular epithelium.

PROLIFERATIVE PHASE: The endometrium is under estrogenic stimulation during days 3–15 of the menstrual cycle. Tubular to coiled glands in the functional zone are evenly distributed and supported by a cellular, monomorphic stroma (Fig. 24-27A). Glands are narrow early in the proliferative phase but coil and increase slightly in caliber over time. Columnar cells lining tubules increase from one layer in thickness to a mitotically active pseudostratified epithelium. The glands secrete a watery alkaline fluid that facilitates passage of sperm through the endometrium into the fallopian tubes. The stroma is also mitotically active. Spiral arteries are narrow and inconspicuous.

SECRETORY PHASE: Ovulation occurs about 14 days after the last menstrual period. The graafian follicle that discharged its ovum becomes a corpus luteum. Granulosa cells of the corpus luteum secrete progesterone, which transforms the endometrium from a proliferative to a secretory state.

- **Days 17–19 (postovulatory days 3–5):** Endometrial glands enlarge, dilate and become more coiled. The lining cells develop abundant and prominent, glycogen-rich, subnuclear vacuoles (day 17). Over the next several days, these cells produce copious secretions that support the zygote as it develops early chorionic villi capable of invading the endometrium.
- **Days 20–22 (postovulatory days 6–8):** The endometrium displays prominent stromal edema. Glands have homogenous cytoplasm with a few discrete vacuoles and are dilated and more tortuous.
- **Day 23 (postovulatory day 9):** Stromal cells surrounding spiral arterioles enlarge and exhibit large, round, vesicular nuclei and abundant eosinophilic cytoplasm ("vascular cuffing"). With time, these cells become more extensively distributed until they fill the functionalis. They are precursors of the decidual cells of pregnancy and are referred to as "predecidua."
- **Day 27 (postovulatory day 13):** The entire stroma is now predecidualized and ready for menstruation. Tubular glands continue to dilate and develop serrated (saw-toothed) borders.

ATROPHIC ENDOMETRIUM: After menopause, the number of glands and quantity of stroma diminish.

Day of Cycle		3—15	15–16	17	18	19–22	23	24–25	26–27	1—2
Post-ovulatory day			1–2	3	4	5–8	9	10–11	12–13	14+
Cycle phases		Proliferative	Interval	Early secretory		Mid-secretory			Late secretory	Menstrual
Key feature		Mitoses	Mitoses and subnuclear vacuoles	Maximum subnuclear vacuoles	Subnuclear vacuoles present	Stromal edema	Focal predecidua around spiral arteries	Patchy predecidua	Extensive predecidua	Stromal crumbling
Microscopic features of functional zone	Stroma	Loose stroma. Mitoses	Same as proliferative	Loose stroma. Scanty mitoses	Loose stroma	Stromal edema	Focal predecidua around spiral arteries. Edema prominent	Predecidua throughout stroma. Some edema	Extensive predecidua. Prominent granulated lymphocytes	Stromal crumbling. Hemorrhage
	Glands	Straight to tightly coiled tubules. Mitoses	Some subnuclear vacuoles, otherwise as proliferative	Extensive subnuclear vacuoles	Dilated glands. Some subnuclear vacuoles	Dilated glands with irregular outline. Luminal secretion		`Saw tooth' glands	Prominent 'saw tooth' glands	Disrupted glands. Secretory exhaustion. Regenerating epithelium
Appearances										

FIGURE 24-27. Main histologic features of the endometrial phases of the normal menstrual cycle. A. Proliferative phase. Straight tubular glands are embedded in a cellular monomorphic stroma. **B.** Secretory phase, day 24. Dilated tortuous glands with serrated borders are situated in a predecidual stroma. **C.** Menstrual endometrium. Fragmented glands, dissolution of the stroma and numerous neutrophils are evident.

Remaining glands have a thin epithelium and the stroma contains abundant collagen. Glands of the atrophic endometrium are often quite dilated, and this condition is called **senile cystic atrophy of the endometrium**.

ENDOMETRIUM OF PREGNANCY

The corpus luteum of pregnancy requires continuous stimulation by hCG secreted by placental trophoblast of the developing embryo. Trophoblast begins to develop at about day 23. Under hCG stimulation, the corpus luteum increases its progesterone output, stimulating secretion of fluid by endometrial glands. In the hypersecretory endometrium of pregnancy, highly dilated glands are lined by cells with abundant glycogen. These features can persist for up to 8 weeks after delivery.

The hypersecretory response may be exaggerated with intrauterine pregnancy, ectopic pregnancy or trophoblastic disease. Glandular cell nuclei may enlarge and appear bulbous and polyploid, owing to DNA replication without cell division. These nuclei protrude beyond the apparent cellular cytoplasmic limits into the gland lumen, an appearance referred to as the **Arias-Stella phenomenon** (Fig. 24-28). Enlarged nuclei are polyploid rather than aneuploid, a condition sometimes seen in adenocarcinoma.

CONGENITAL ANOMALIES OF THE UTERUS

Congenital anomalies of the uterus are rare.

- **Congenital absence of the uterus (agenesis)** reflects failure of müllerian ducts to develop. Since elongation of these ducts during embryonic life requires the wolffian

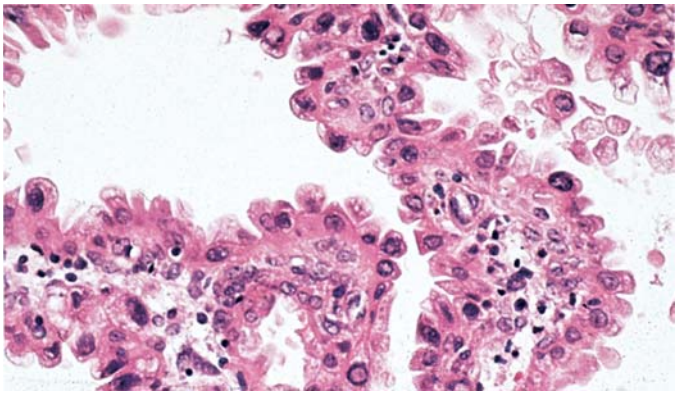

FIGURE 24-28. Arias-Stella reaction of pregnancy associated with human chorionic gonadotropin (hCG) stimulation. A section of endometrium shows enlarged, bulbous nuclei that protrude into the gland lumen.

ducts as guides, uterine agenesis is almost always accompanied by other urogenital tract anomalies and agenesis of the vagina and fallopian tubes.

- **Uterus didelphys** is a double uterus, due to failure of the two müllerian ducts to fuse in early embryonic life. A double vagina commonly accompanies this anomaly.
- **Uterus duplex bicornis** is a uterus with a common fused wall between two distinct endometrial cavities. The common wall between the apposed müllerian ducts fails to degenerate to form a single uterine cavity.
- **Uterus septus** is a single uterus with a partial septum, due to incomplete resorption of the wall of the fused müllerian ducts. These patients have increased risk for habitual abortion.
- **Bicornuate uterus** refers to a uterus with two cornua (horns) and a common cervix. Didelphic and bicornuate uterine fusion defects increase the risk of premature birth only slightly.

ENDOMETRITIS

In endometritis, or an inflamed endometrium, there is an abnormal inflammatory infiltrate in the endometrium. It must be distinguished from the normal presence of neutrophils during menstruation and mild lymphocytic infiltrates at other times. In most cases of endometritis, findings are nonspecific and rarely point to a specific cause.

ACUTE ENDOMETRITIS: This condition is defined as the abnormal presence of polymorphonuclear leukocytes in the endometrium. Most cases result from an ascending infection from the cervix (e.g., after the usually impervious cervical barrier is compromised by abortion, delivery or medical instrumentation). Curettage is diagnostic and often curative, because it removes necrotic tissue that has served as the nidus of the ongoing infection. Nowadays, the condition is of little significance, although it was quite dangerous before antibiotics.

CHRONIC ENDOMETRITIS: Although lymphocytes and lymphoid follicles occur occasionally in normal endometrium, plasma cells in the endometrium are diagnostic of chronic endometritis (Fig. 24-29). The disorder is associated with IUDs, PID and retained products of conception after an abortion or delivery. Without a culture, the pathologic findings alone do not distinguish between infective and noninfective causes. Patients usually complain of bleeding and/or pelvic pain. The condition is generally self-limited.

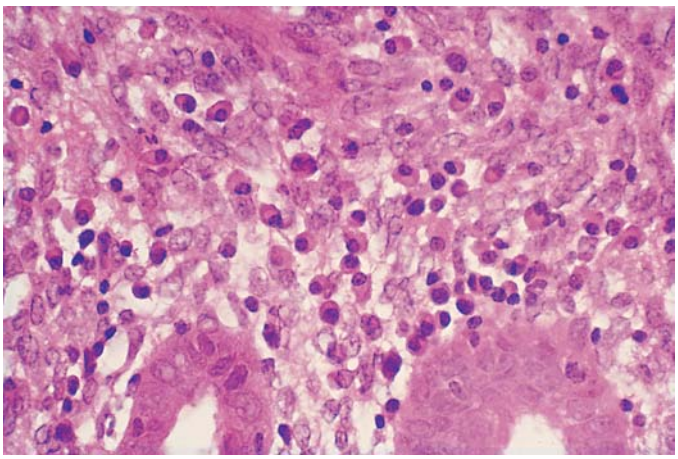

FIGURE 24-29. Chronic endometritis. The inflammatory infiltrate is composed largely of lymphocytes and plasma cells.

PYOMETRA: Defined as pus in the endometrial cavity, pyometra is associated with gross anatomic defects such as fistulous tracts between bowel and uterine cavity, bulky or perforating malignancies or cervical stenosis. Long-standing pyometra may rarely be associated with development of endometrial squamous cell cancer.

TRAUMATIC LESIONS

INTRAUTERINE DEVICE: IUDs predispose to (1) increased menstrual flow, (2) uterine perforation and (3) spontaneous abortion if conception occurs with the IUD in place. However, IUD use reduces endometrial cancer risk by half. Much of the adverse publicity about IUDs relates to early devices. Only 1% of women who desire contraception now use an IUD.

INTRAUTERINE ADHESIONS (ASHERMAN SYNDROME): Intrauterine fibrous adhesions sometimes develop after curettage, particularly for postpartum complications or therapeutic abortion. These bands traverse, but do not necessarily obliterate, the endometrial cavity. Additional complications include amenorrhea or, in the event of a subsequent pregnancy, increased abortion rates, preterm labor and placenta accreta.

ADENOMYOSIS

Adenomyosis is the presence of endometrial glands and stroma within the myometrium. Pain, dysmenorrhea or menorrhagia correlate with adenomyosis if the glands are 1 mm or more beneath the endometrial myometrial junction, with more severe symptoms as glands penetrate more deeply into the myometrium. Pain occurs as foci of adenomyosis enlarge when blood is entrapped during menses. One fifth of all uteri surgically removed show some adenomyosis.

PATHOLOGY: The uterus may be enlarged. The myometrium discloses small, soft, tan areas, some of which are cystic (Fig. 24-30). Microscopic examination shows glands lined by proliferative to inactive endometrium and surrounded by endometrial stroma with varying degrees of fibrosis. Secretory changes are rare, except during pregnancy or in patients treated with progestins. The adjacent myometrium is often hypertrophic and nodular. The uterus may also become enlarged from cyclic bleeding into these foci. Extension of hyperplastic or neoplastic endometrium from the endometrial functionalis into adenomyotic foci may occur.

CLINICAL FEATURES: Many patients with adenomyosis are asymptomatic, although pelvic pain, dysfunctional uterine bleeding, dysmenorrhea and dyspareunia are common. These symptoms appear in parous women of reproductive age and regress after menopause. The cause of adenomyosis remains unknown.

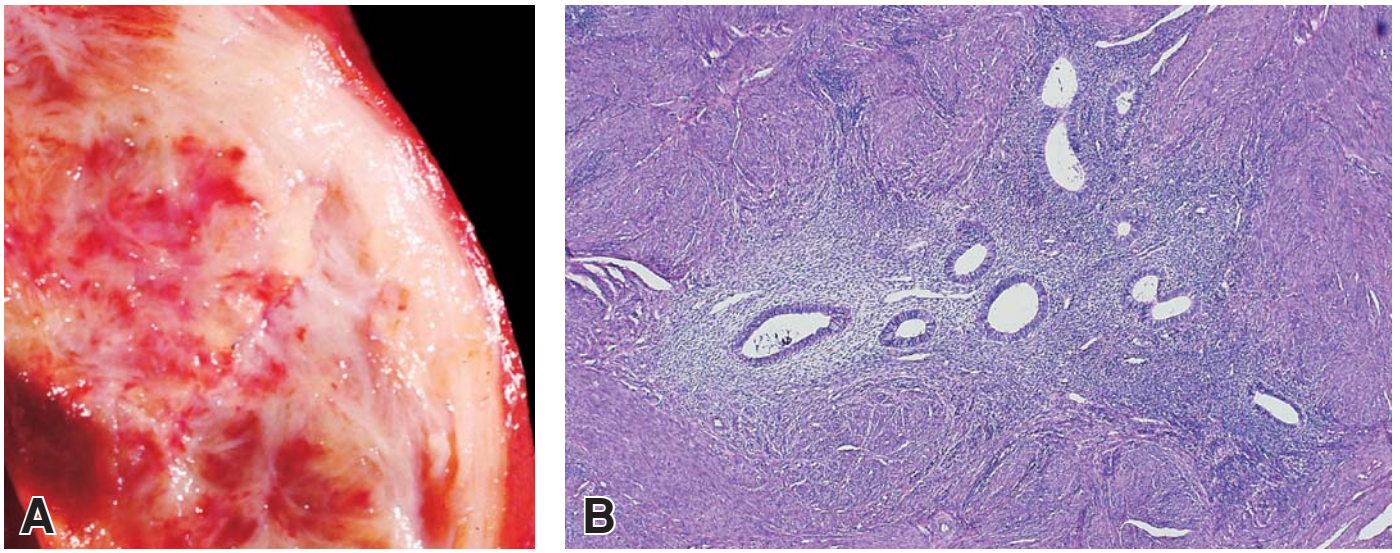

FIGURE 24-30. Adenomyosis. A. The cut surface of the uterus reveals small, red areas corresponding to endometrial glands in the myometrium. **B.** A microscopic view shows an endometrial gland and stroma in the myometrium.

HORMONAL EFFECTS

Contraceptive Steroids Prevent Pregnancy and Many Gynecologic Cancers

Oral contraceptive agents induce endometrial changes depending on the types, potencies and dosages of estrogens and progestins in individual formulations. Combined preparations generally contain potent progestins and weak estrogens. Pseudodecidual change thus appears early and overshadows the weak glandular growth. After several cycles, endometrial glands atrophy. Newer contraceptive combinations contain lower doses of hormones and elicit less change. Women who use contraceptives containing progestational agents have significantly lower rates of endometrial and ovarian cancer, reflecting the growth-inhibiting properties of progesterone and fewer ovulations (see below).

Dysfunctional Uterine Bleeding Occurs during or between Menstrual Periods

Dysfunctional bleeding is one of the most common gynecologic disorders of women of reproductive age but is still poorly understood. Its causes lie outside the uterus. Most cases are related to a disturbance of the hypothalamic–pituitary–ovarian axis (Table 24-4). Ovarian dysfunction also occurs, especially in the presence of anovulation.

Some causes of menstrual irregularity are intrinsic to the uterus and are not considered dysfunctional. These include (1) growths (e.g., carcinoma, endometrial intraepithelial neoplasia [EIN], submucosal leiomyomata and polyps), (2) inflammation (e.g., endometritis), (3) pregnancy (e.g., complications of intrauterine or ectopic pregnancy) and (4) the effects of IUDs (Table 24-4).

Anovulatory Bleeding Is the Most Common Form of Dysfunctional Bleeding

Anovulatory bleeding is a complex syndrome of many causes that manifests as the absence of ovulation during

TABLE 24-4
CAUSES OF ABNORMAL UTERINE BLEEDING (INCLUDING UTERINE AND EXTRAUTERINE CAUSES)

Newborn	Maternal Estrogen
Childhood	Iatrogenic (trauma, foreign body, infection of vagina) Vaginal neoplasms (sarcoma botryoides) Ovarian tumors (functional)
Adolescence	Hypothalamic immaturity Psychogenic and nutritional problems Inadequate luteal function
Reproductive age	Anovulatory Central: psychogenic, stress Systemic: nutritional and endocrine disease Gonadal: functional tumors End-organ: benign endometrial hyperplasia Pregnancy: ectopic, retained placenta, abortion, mole Ovulatory Organic: neoplasia, infections (PID), leiomyomas Polymenorrhea: short follicular or luteal phases Iatrogenic: anticoagulants, IUD
Menopause	Irregular shedding
Postmenopause	Carcinoma, EIN, benign hyperplasias, polyps, leiomyomata

EIN = endometrial intraepithelial neoplasia; IUD = intrauterine device; PID = pelvic inflammatory disease.

the reproductive years. It occurs most often at either end of reproductive life (i.e., menarche and menopause).

ETIOLOGIC FACTORS AND PATHOLOGY: In an anovulatory cycle, failure of ovulation leads to excessive and prolonged estrogen stimulation, without a postovulatory rise in progesterone. As a result, the endometrium remains in a proliferative state dominated by a disordered, cystic glandular appearance and excessive bulk. Lacking progesterone, the spiral arteries of the endometrium do not develop normally. "Breakthrough bleeding" can occur from damage to these fragile spiral arterioles. Thrombosis causes local tissue breakdown resembling that of menstrual endometrium, which the patient experiences as symptomatic bleeding out of synchrony with other areas of the endometrium. Elevated estrogen levels usually decline, either through delayed ovulation or involution of the stimulatory follicle. If the decline is rapid, the endometrium undergoes a heavy synchronized menstrual flow.

Luteal Phase Defect Is Caused by Inadequate Progesterone

Luteal phase defect results in an abnormally short cycle in which menses occur 6–9 days after the surge of luteinizing hormone (LH) associated with ovulation. It occurs when a corpus luteum develops improperly or regresses prematurely. Luteal phase defects are responsible for 3% of cases of infertility and must be considered in assessing infertility or in analysis of abnormal uterine bleeding. A biopsy showing an endometrium over 2 days out of synchrony with the chronologic day of the menstrual cycle confirms the diagnosis.

ENDOMETRIAL TUMORS

Endometrial Polyps Are Benign Stromal Neoplasms

Polyps occur mostly in the perimenopausal period and not before menarche. They are monoclonal outgrowths of endometrial stromal cells altered by chromosomal translocation, with secondary induction of polyclonal glandular elements. Stroma and glands of endometrial polyps respond poorly to hormonal stimulation and do not slough upon menstruation.

PATHOLOGY: Most endometrial polyps arise in the fundus (Fig. 24-31) but can be found anywhere within the endometrium. They vary from several millimeters to growths filling the entire endometrial cavity. Most are solitary, but 20% are multiple. Polyp cores are composed of (1) endometrial glands, often cystically dilated and hyperplastic; (2) fibrous endometrial stroma; and (3) thick-walled, coiled, dilated blood vessels, derived from a straight artery that normally would have supplied the basal zone of the endometrium. Cores are covered by endometrial epithelium, usually out of cycle from adjacent normal endometrium.

CLINICAL FEATURES: Endometrial polyps typically present with intermenstrual bleeding, owing to surface ulceration or hemorrhagic infarction. Since bleeding in an older woman may indicate endometrial cancer, this sign must be thoroughly evaluated. Endometrial polyps are not ordinarily precancerous, but up to 0.5% harbor adenocarcinoma.

Endometrial Hyperplasia Is Two Diseases, One of Which Is Neoplastic

The 2014 WHO classification of endometrial hyperplasias divides lesions into etiologic subgroups based on cancer risk and treatment options. **Nonatypical endometrial hyperplasia** is a functionally normal endometrium that responds to an abnormal hormonal state of excess estrogen; **endometrial intraepithelial neoplasia** (also called **atypical endometrial hyperplasia**) is composed of mutated precancerous cells that grow as a neoplastic clone.

- **Nonatypical hyperplasia:** Nonatypical endometrial hyperplasia is a spectrum of changes, dependant upon the duration and dose of estrogen exposure. Glands are irregularly distributed and punctuated by cysts, creating

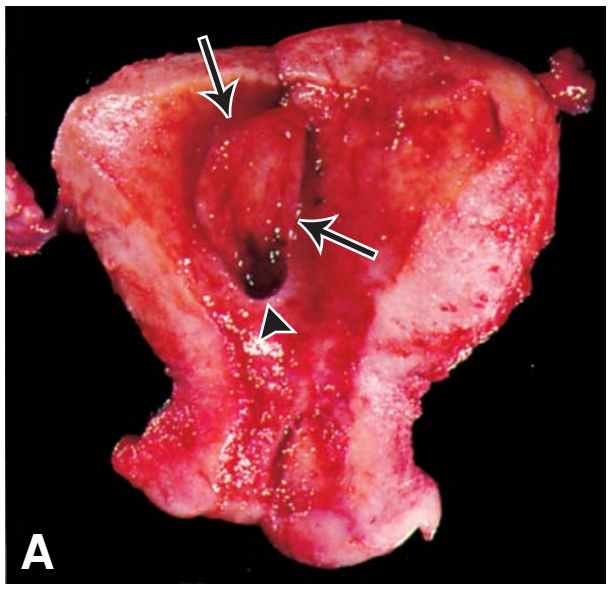

FIGURE 24-31. Endometrial polyp. **A.** A single polyp (*arrows*) extends into the endometrial cavity. The necrotic tip (*arrowhead*) is responsible for clinical bleeding. **B.** On microscopic section, a polyp exhibits slightly dilated endometrial glands embedded in a markedly fibrous stroma.

a variably increased ratio of glands to stroma. Cytologic change, when it occurs, is most often metaplastic and distributed in a scattered, nongeographic or random fashion. Adenocarcinoma develops in 1%–3%.

- **EIN (atypical hyperplasia):** Endometrial intraepithelial neoplasia, or atypical endometrial hyperplasia, is a clonal outgrowth of genetically altered endometrial glands with an increased risk of future endometrioid endometrial carcinoma through malignant transformation. EIN is composed of crowded aggregates of cytologically altered tubular or slightly branching glands. Within the geographic confines of the lesion, the area of glands exceeds that of stroma, with altered cytology compared to residual background normal glands, which may be adjacent to and/or admixed with the lesion. Thirty-seven percent of patients with EIN will develop adenocarcinoma, almost always of the endometrioid type.

Nonatypical Endometrial Hyperplasia Is Caused by Abnormal Estrogenic Stimulation

It is characterized by diffuse architectural and randomly distributed cytologic changes (Fig. 24-32). Estrogenic stimulation of the endometrium beyond the normal 2-week proliferative phase causes progressive changes associated with a 2–10-fold increased risk of endometrial cancer. Aside from women with coexisting EIN (see below), it is not possible to estimate cancer risk in these patients by a single histologic examination. Endometrial histopathology varies greatly as a function of the sequence and tempo of hormonal stimulation.

PATHOLOGY: Nonatypical endometrial hyperplasia affects the entire endometrium, in which remodeling of glands and stroma creates an irregular density of commingled cystic, slightly branching and tubular glands. The earliest changes are isolated cystic expansion of scattered proliferative glands without a substantial change in gland density, often designated **persistent proliferative** or **disordered proliferative** endometrium. Morphologic transition to **nonatypical endometrial hyperplasia** is gradual and arbitrarily defined but can be said to occur when gland density becomes irregular throughout, with some regions having more glands than stroma.

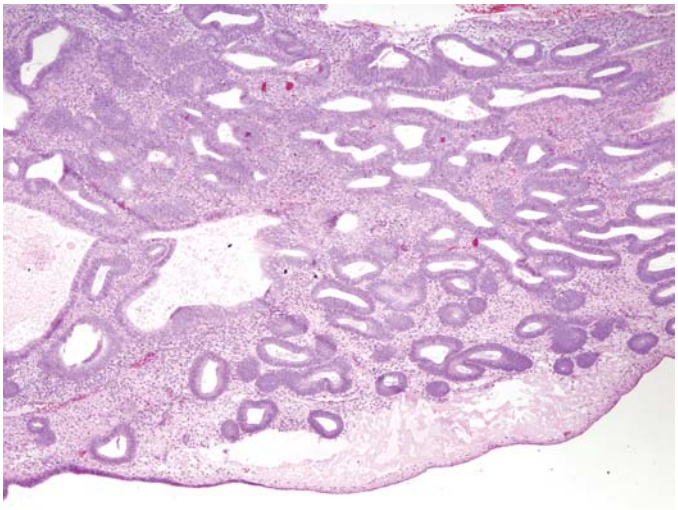

FIGURE 24-32. Nonatypical endometrial hyperplasia. Proliferative endometrial glands are irregularly distributed and randomly dilated. Gland density varies locally, but crowded and uncrowded areas have a consistent cytology throughout. This is a benign endometrium altered by unopposed estrogen.

As long as circulating estrogens persist, glands remain proliferative. Scattered glands may develop tubal differentiation with cilia formation. With increasing estrogen exposure, stromal breakdown and resultant gland collapse occur, often associated with fibrin vascular thrombi. Although prototypically an estrogenic lesion, architectural and metaplastic changes can persist after gradual weaning from a hyperestrogenic state. Sudden loss of estrogen leads to massive shedding with attendant heavy menses.

CLINICAL FEATURES: Nonatypical endometrial hyperplasia may result from anovulatory cycles, polycystic ovary syndrome, an estrogen-producing tumor, estrogen administration or obesity. In such cases, therapy for the primary cause may alleviate estrogenic stimulation. Large doses of progestins can produce temporary symptomatic relief or objective remission, depending on persistence of the underlying hormonal condition. Short-term risk of endometrial cancer is low, if extensive sampling of the endometrium shows no EIN. Long-term risks of refractory nonatypical endometrial hyperplasia are best assessed by repeat biopsy.

Endometrial Intraepithelial Neoplasia Is a Clonal Precancer

EIN is a monoclonal neoplastic growth of genetically altered cells with greatly increased risk of becoming endometrioid type of endometrial adenocarcinoma (Fig. 24-33). It shows a continuity of acquired genetic markers upon transformation into a malignant phase. EIN and nonatypical endometrial hyperplasia coexist in many patients but have different histologies. Systemic hormonal factors are relevant to both, as they can be positive or negative selection factors for mutated cells in an EIN lesion.

PATHOLOGY: EIN lesions begin at a single point and then expand centripetally as proliferating neoplastic glands that displace and separate normal glands. The densely crowded EIN glands differ cytologically from the background endometrium, have areas exceeding their stromal areas and measure more than 1 mm in dimension in a single fragment. A key diagnostic feature is the coordination of cytologic changes within the topographical region of crowded glands. Such changes are evident by comparison with flanking normal glands and usually include alterations in nuclear size, shape and texture and altered cytoplasmic differentiation. Eventually, EIN lesions overrun the entire endometrial compartment, but carcinoma can arise at any time. Malignant transformation is evident when glands develop solid, cribriform or maze-like patterns characteristic of adenocarcinoma.

CLINICAL FEATURES: Women newly diagnosed with EIN have a 37% chance of having endometrial cancer diagnosed within 1 year. In most cases, cancer is probably present at the time of the initial biopsy, lending credence to the clinical adage "not cancer but better out." After excluding women with concurrent cancer

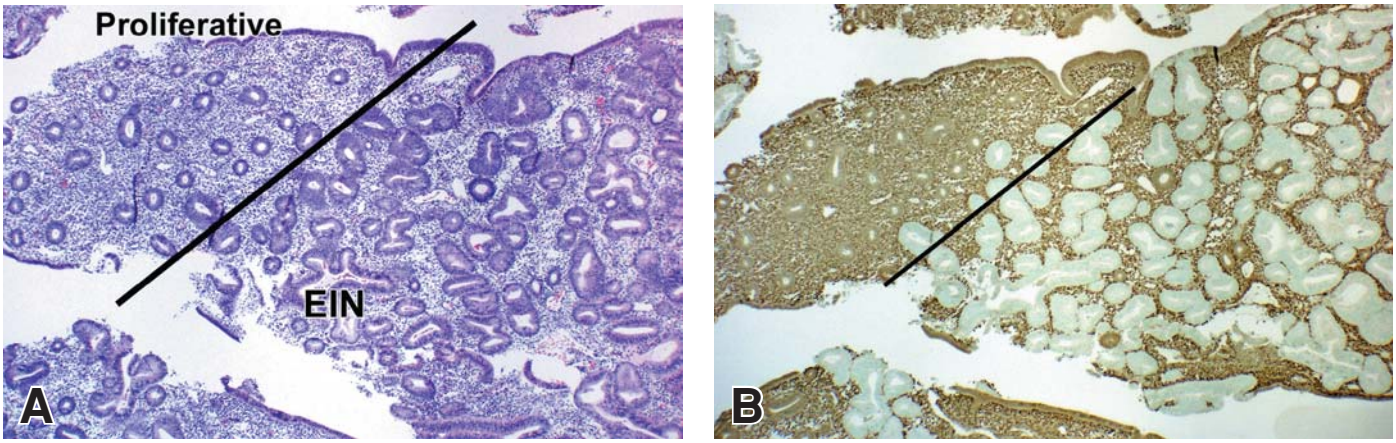

FIGURE 24-33. Endometrial intraepithelial neoplasia (EIN, atypical endometrial hyperplasia). A. Tight clusters of cytologically altered neoplastic endometrial glands with abundant cytoplasm and rounded nuclei (*right*) are offset from the background endometrium (*left*) in this geographic focus of EIN. Measurement across the perimeter of this aggregate of individual tubular glands exceeds 1 mm, and features of adenocarcinoma such as cribriform, maze-like, or solid architecture are lacking. **B.** Glands affected by EIN show loss of PTEN expression by immunohistochemistry (loss of brown staining).

and only looking at those with a cancer-free interval of 1 year, EIN-positive patients have a 45-fold increased risk of developing of endometrial cancer.

The goals of management are to rule out concurrent and prevent future cancer. Hysterectomy, usually the therapy of choice, meets both goals if a woman does not want more children. Those who want more children or are poor operative risks may be treated with progestins.

There Are two Main Types of Endometrial Adenocarcinoma

EPIDEMIOLOGY: Endometrial carcinoma is the 4th most frequent cancer in American women and the most common gynecologic cancer (Table 24-5). It caused 8200 deaths in the United States in 2013 (3% of all cancers in women). Incidence of this cancer was stable from 1950 to 1970, but by 1975 it had increased by 40%, possibly related to use of estrogens for easing symptoms of menopause. By 1985, rates had returned nearly to 1950 levels, a trend that correlated with use of lower doses of estrogen, incorporation of progestins (estrogen antagonists) into estrogen replacement regimens and increased surveillance of women treated with estrogens.

TABLE 24-5
CLINICOPATHOLOGIC FEATURES OF ENDOMETRIAL CARCINOMA

	Type I: Endometrioid Carcinoma	Type II: Serous Carcinoma
Age	Pre- and perimenopausal	Postmenopausal
Unopposed estrogen	Present	Absent
Hyperplasia precursor	Present	Absent
Grade	Low	High
Myometrial invasion	Superficial	Deep
Growth behavior	Stable	Progressive
Genetic alterations	Microsatellite instability, PTEN, PIK3CA, β-catenin	p53 mutations, loss of heterozygosity (LOH)

The incidence of endometrial cancer varies with age, from 12 cases per 100,000 women at age 40 to 7-fold higher in 60-year-olds. Three quarters of women with endometrial cancer are postmenopausal. The median age at diagnosis is 63.

Endometrial carcinoma is broadly grouped into two histologic types (Fig. 24-34 and Table 24-5). Type I tumors (about 80%), endometrioid carcinomas, often arise from EIN precursors and are associated with estrogenic stimulation. They occur mainly in pre- or perimenopausal women and are associated with obesity, hyperlipidemia, anovulation, infertility and late menopause. Most endometrioid carcinomas are confined to the uterus and follow a favorable course. In contrast, type II tumors (about 10%) are nonendometrioid, largely papillary serous carcinomas, arising occasionally in endometrial polyps. A preinvasive form of disease, serous endometrial intraepithelial carcinoma (serous EIC, not to be confused with EIN) can metastasize to the peritoneum by exfoliation and surface spread. Although serous EIC can exhibit malignant behavior, it is not generally considered a precancerous lesion. Type II tumors are not associated with estrogen stimulation or hyperplasia, readily invade myometrium and vascular spaces and are highly lethal. The molecular alterations of endometrioid (type I) carcinomas are different from those of the nonendometrioid (type II) carcinomas.

These tumors overlap in clinical, pathologic, immunohistochemical and molecular characteristics. Some nonendometrioid (type II) carcinomas may arise from preexisting endometrioid carcinomas and share pathologic and molecular features of both types I and II endometrial carcinomas. The type II tumor category consists primarily of serous carcinomas but also includes rarer clear cell carcinoma and carcinosarcoma histotypes that have distinct molecular and clinical features.

Endometrial cancer occurs in association with a higher incidence of both breast and ovarian cancer in closely related women, suggesting a genetic predisposition. It is also the

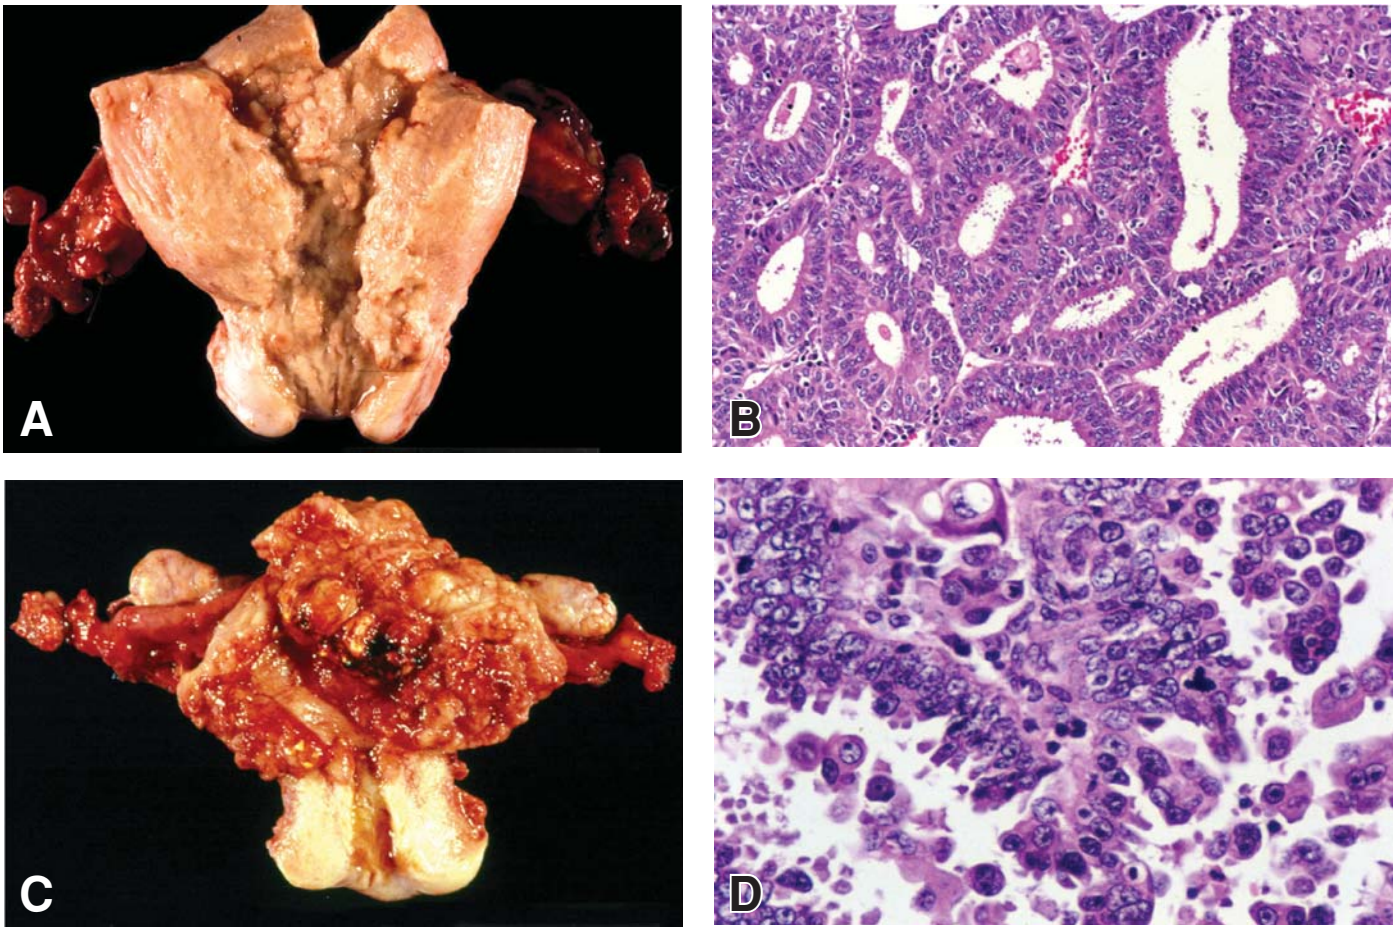

FIGURE 24-34. Adenocarcinoma of the endometrium. A, B. Endometrioid carcinoma. Polypoid tumor with only superficial myometrial invasion. Well-differentiated (grade 1) adenocarcinoma. The neoplastic glands resemble normal endometrial glands. **C, D. Nonendometrioid carcinoma.** Large hemorrhagic and necrotic tumor with deep myometrial invasion. Serous carcinoma (severe cytologic atypia) exhibiting stratification of anaplastic tumor cells and abnormal mitoses.

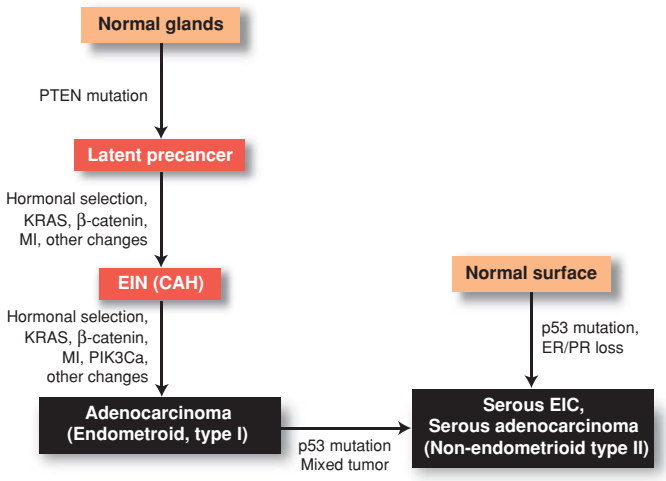
most common extracolonic cancer in women with hereditary nonpolyposis colon cancer syndrome, a defect in DNA mismatch repair (see Chapter 19) that is also associated with breast and ovarian cancers.

MOLECULAR PATHOGENESIS: A dualistic model of endometrial carcinogenesis has been proposed in which normal endometrial cells transform into endometrioid carcinoma by accumulating mutations in oncogenes and tumor suppressor genes. The most commonly affected genes and mechanisms of genetic damage differ between endometrioid (type I) and nonendometrioid (type II) cancers.

Genetic alterations accumulate in the type I carcinoma pathway, during the transition from normal to EIN to endometrioid carcinoma (Fig. 24-35). These may occur over a period of years and involve a combination of small-scale deletions, point mutations and epigenetic modifications of cells that maintain normal or near-normal karyotypes. *PTEN* is the most often inactivated tumor suppressor gene in endometrial tumorigenesis (2/3 of cases), resulting from deletion, mutation and/or promoter hypermethylation (Figs. 24-33 and 24-35). *PIK3CA* is the most commonly activated oncogene (by mutation, in up to 39% of cases) in endometrial carcinoma. *PTEN* inactivation frees the PI3K-Akt pathway, evading apoptosis and resulting in tumor growth advantage; *PIK3CA* mutations are rarely seen in such cases. Other frequently mutated genes include *KRAS* (10%–30%) and β-catenin (*CTNNB1*) with nuclear protein accumulation (25%–38%). *TP53* mutations are rare (5%–10%). In a quarter of sporadic tumors, a specific type of genetic damage,



Normal glands
PTEN mutation
Latent precancer

Normal surface
p53 mutation, ER/PR loss
Serous EIC, Serous adenocarcinoma (Non-endometrioid type II)

FIGURE 24-35. From endometrial hyperplasia to endometrioid carcinoma: molecular and genetic events. MI, microsatellite instability.

microsatellite instability (MSI), results from promoter hypermethylation of *MLH1* and leads to microsatellite instability and accelerated mutation in several critical target genes involved in apoptosis, cell proliferation and differentiation. The wide range of resultant mutations, in both microsatellite-stable and -unstable endometrioid tumors, creates genetically heterogeneous tumors.

Over 90% of type II nonendometrioid carcinomas have p53 mutations, and 80% lose estrogen and progesterone receptors. Mechanisms of DNA damage are different from endometrioid tumors. MSI is rare (<5%), and gross structural and numerical chromosomes abnormalities are more common. Nonendometrioid carcinomas may also develop from endometrioid tumors via p53 mutations and other means.

PATHOLOGY: Endometrial cancer grows in diffuse or exophytic patterns (Fig. 24-34). Regardless of its site of origin, the tumor often tends to involve multiple areas. Large tumors are usually hemorrhagic and necrotic.

ENDOMETRIOID ADENOCARCINOMA OF THE ENDOMETRIUM: This type of endometrial cancer, composed entirely of glandular cells, is the most common histologic variant (80%–85%). The FIGO system divides this tumor into three grades depending on the ratio of glandular to solid elements, the latter signifying poorer differentiation (Fig. 24-36).

- **Grade 1:** Well differentiated; almost only neoplastic glands, with minimal (<5%) solid areas
- **Grade 2:** Moderately differentiated; 5%–50% of malignant epithelium forms glands
- **Grade 3:** Poorly differentiated; large (>50%) areas of solid tumor

Nuclei of endometrial adenocarcinoma range from bland to markedly pleomorphic, usually with prominent nucleoli. Mitoses are abundant and may be abnormal in less differentiated tumors. Tumor cells that grow in solid sheets are generally poorly differentiated. The FIGO system also defines stages of endometrial cancer (Table 24-6).

ENDOMETRIOID ADENOCARCINOMA, WITH SQUAMOUS DIFFERENTIATION: One third of endometrial carcinomas contain squamous cells as well as glands. If the squamous element shows only minimal atypia, the tumor is a **well-differentiated adenocarcinoma with squamous differentiation** (previously, **adenoacanthoma**) (Fig. 24-37). If the squamous element appears malignant, the tumor is **poorly differentiated adenocarcinoma with squamous differentiation** (also known as **adenosquamous carcinoma**). These variants represent 22% and 7% of all endometrial cancers, respectively.

ENDOMETRIOID ADENOCARCINOMA, SECRETORY TYPE: This variant usually occurs in premenopausal women. It is an extremely well-differentiated but otherwise typical endometrial adenocarcinoma. Large subnuclear vacuoles of glycogen occur in some cases owing to progesterone stimulation. Secretory carcinoma, perhaps because it is very well differentiated, has the most favorable prognosis.

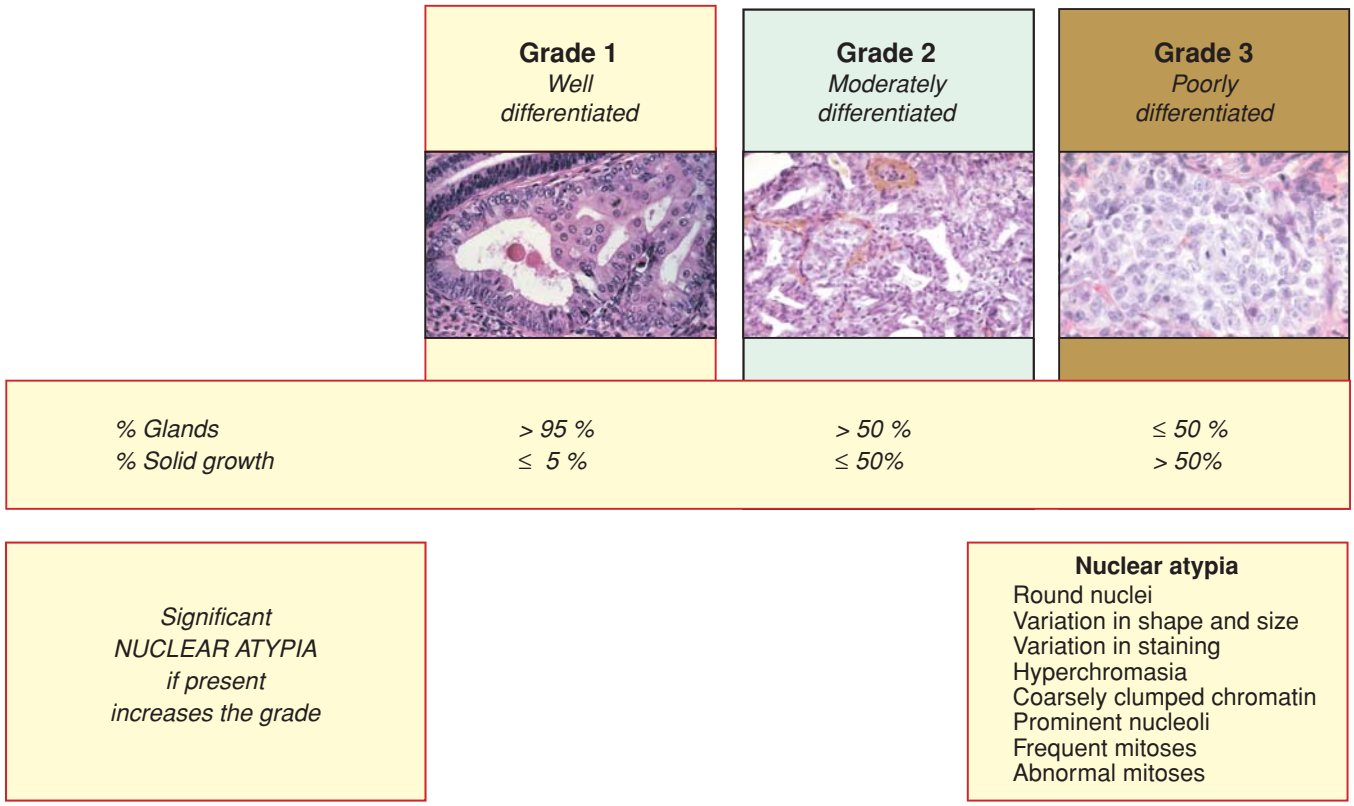

FIGURE 24-36. Grading of endometrial adenocarcinoma. The grade depends primarily on the architectural pattern, but significant nuclear atypia changes a grade 1 tumor to grade 2, and a grade 2 tumor to grade 3. Nuclear atypia is characterized by round nuclei; variation in shape, size and staining; hyperchromasia; coarsely clumped chromating; prominent nucleoli; and frequent and abnormal mitoses. Significant nuclear atypia if present increases the tumor grade.

TABLE 24-6
FIGO (2009) STAGING OF CANCER OF THE ENDOMETRIUM

Stage	Anatomic Distribution
Stage I	Tumor confined to the corpus uteri
IA	No myometrial invasion or invasion <50% of myometrium thickness
IB	Tumor invades ≥50% of myometrium thickness
Stage II	Tumor invades cervical stroma but does not extend beyond the uterus
Stage III	Local and/or regional spread of the tumor
IIIA	Tumor invades the serosa of the corpus uteri and/or adnexa
IIIB	Vaginal and/or parametrial involvement
IIIC	Metastases to pelvic and/or para-aortic lymph nodes
Stage IV	Tumor invades bladder and/or bowel mucosa, and/or distant metastases
IVA	Tumor invasion of bladder and/or bowel mucosa
IVB	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

FIGO = International Federation of Gynecology and Obstetrics.

OTHER TYPES (NONENDOMETRIOID) OF ENDOMETRIAL CARCINOMA: Nonendometrioid types of endometrial carcinoma are less common and are not associated with estrogen exposure. They are aggressive as a group, and histologic grading is not clinically useful or separately diagnosed, as all cases are considered high grade.

- **Serous adenocarcinoma** histologically resembles, and behaves like, serous adenocarcinoma of the ovary (Fig. 24-34D). It often shows transtubal spread to peritoneal surfaces. An in situ form is termed "serous endometrial intraepithelial carcinoma" (serous EIC), not to be confused with EIN, described earlier.
- **Clear cell adenocarcinoma** is a tumor of older women. It contains large cells with abundant cytoplasmic glycogen ("clear cells") or cells with bulbous nuclei that line glandular lumens ("hobnail cells") (Fig. 24-38A). Serous and clear cell carcinomas have poor prognoses.
- **Carcinosarcoma (malignant mixed mesodermal tumor):** In this highly malignant tumor (Fig. 24-38B), pleomorphic **epithelial** cells comingle with areas showing **mesenchymal** differentiation (Fig. 24-38C). These mixed neoplasms are derived from a common clone believed to be of epithelial origin. Prognosis is determined by the presence of a mesenchymal component admixed with the malignant epithelial component, rather than the specific type of mesenchymal histology displayed. Overall 5-year survival is 25%.

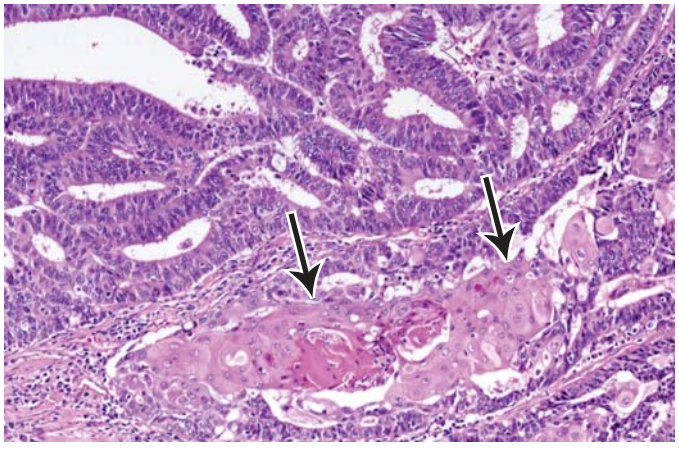

FIGURE 24-37. Squamous differentiation in endometrioid adenocarcinoma of the endometrium. The well-differentiated squamous cells (*arrows*) show minimal atypia. The pattern has been called adenoacanthoma when the squamous cells form squamous morules and nest among glands.

Most endometrial carcinomas arise in the uterine corpus, but a small proportion originate in the lower uterine segment (isthmus). These tumors often occur in women under the age of 50 and are often high grade and deeply invasive.

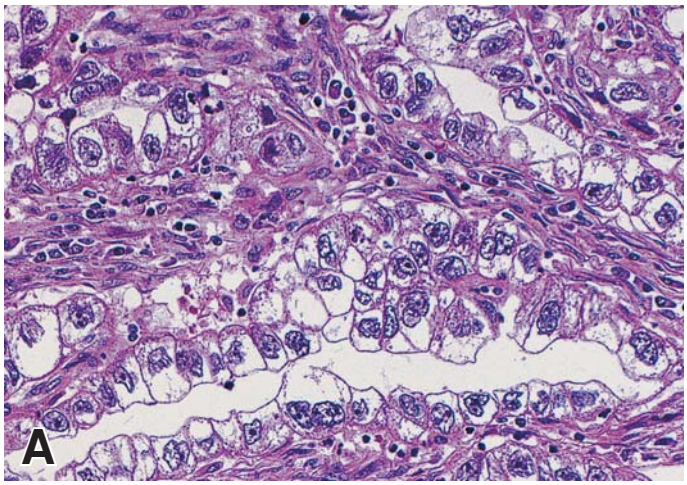
CLINICAL FEATURES: Endometrial cancers usually occur in peri- or postmenopausal women. The chief complaint is commonly abnormal uterine bleeding, especially in the early stages of tumor growth confined to the endometrium. Unfortunately, cervicovaginal cytologic screening does not efficiently detect early endometrial cancer. Fractional curettage is needed to assess spread to the cervix, whereas peritoneal washing detects tubal reflux and abdominal contamination. Transvaginal ultrasound is valuable diagnostically in postmenopausal patients in whom an endometrium greater than 5 mm thick is considered highly suspicious. Unlike cervical cancer, endometrial cancer may bypass pelvic lymph nodes and spread directly to para-aortic nodes. Patients with advanced cancers may also have pulmonary metastases (40% of cases with metastases).

Women with well-differentiated cancers confined to the endometrium are usually treated by simple hysterectomy. Postoperative radiation is considered if the tumor is poorly differentiated or nonendometrioid in type, the myometrium is deeply invaded, the cervix is involved or lymph nodes contain metastases.

Survival in endometrial carcinoma depends on stage and histotype. For endometrioid tumors, additional prognostic factors include histologic grade and age. High tumor levels of estrogen and progesterone receptors and low mitotic rates correlate with a better prognosis. Actuarial survival for all patients with endometrial cancer following treatment is 80% after 2 years, decreasing to 65% after 10 years. Tumors that have penetrated the myometrium or invaded lymphatics are more likely to have spread beyond the uterus. Endometrial cancers involving the cervix have a poorer prognosis. Spread outside the uterus carries the worst outlook (Table 24-7).

Fewer than 2% of Uterine Cancers Are Endometrial Stromal Tumors

Some endometrial stromal tumors are pure sarcomas; in others, sarcomatous (stromal) and epithelial elements are intermingled. The nomenclature of these tumor types, the



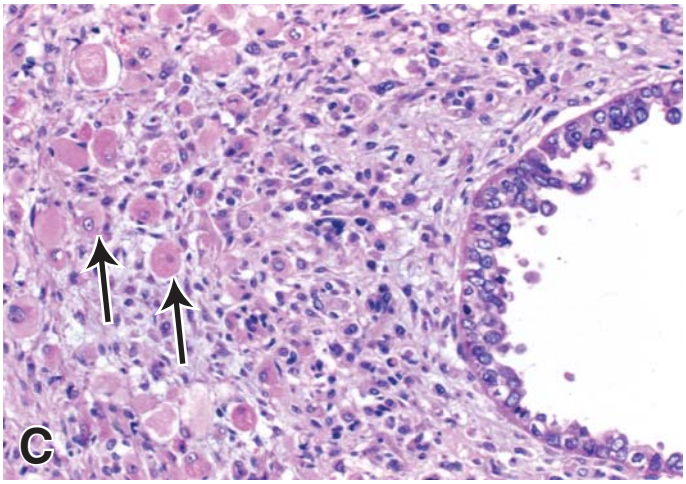


FIGURE 24-38. Nonendometrioid types of endometrial adenocarcinoma. A. Clear cell endometrial adenocarcinoma. The clear appearance of the cytoplasm is due to the dissolution of glycogen when the specimen was processed for microscopic examination. Hobnail cells with bulbous nuclei line glandular lumina. **B.** Carcinosarcoma (malignant mixed müllerian tumor). Solid, partially cystic and necrotic mass that expands the uterine cavity. **C.** Rhabdomyoblasts (heterologous elements, *arrows*) appear as pleomorphic, rounded cells with ample eosinophilic cytoplasm adjacent to malignant epithelium.

spectrum of their histologic components and the correlation of each tumor type with its potential for malignant behavior are presented in Table 24-8.

Endometrial Stromal Sarcoma

Pure stromal tumors are divided into two major categories, based on whether the tumor margin is expansile or infiltrating. Expansile lesions that do not invade are **benign stromal nodules,** which have little clinical significance. Tumors with infiltrating margins are termed **stromal sarcomas** and are classified into low-grade (most common) and high-grade categories.

TABLE 24-7
STAGE, GRADE AND SURVIVAL FOR ENDOMETRIAL CANCER

	5-Year Survival (%)		
Stage	**G-1[a]**	**G-2**	**G-3**

II	80	42	12
III, IV	25	33	17

[a]G = FIGO (International Federation of Gynecology and Obstetrics) grade.

PATHOLOGY: Low-grade endometrial stromal sarcomas may be polypoid and fill the endometrial cavity, or they may diffusely invade the myometrium. Large masses of spindle cells with scant cytoplasm dissect the myometrium and invade vascular channels (Fig. 24-39). Tumor cells resemble endometrial stromal cells in the proliferative phase and show little or no cytologic atypia and low mitotic activity. Expression of CD-10 and estrogen

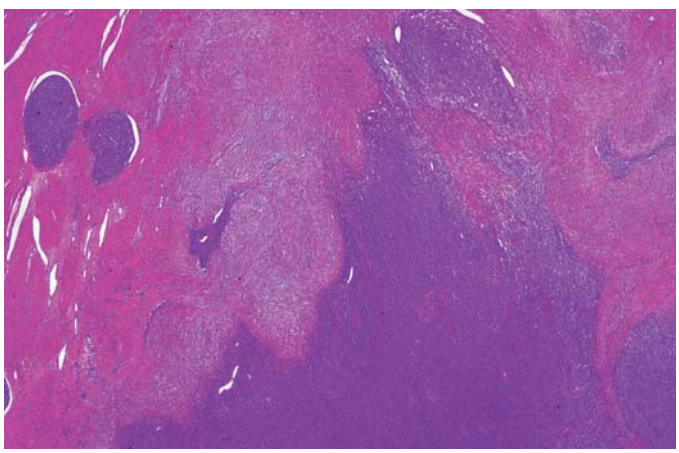

FIGURE 24-39. Endometrial stromal sarcoma, low grade. The myometrium is irregularly invaded by the tumor, which invades vascular spaces.

TABLE 24-8
NOMENCLATURE OF UTERINE TUMORS

Tumor	Epithelium	Stroma	Clinical Behavior
Epithelium and Stroma			
Endometrial polyp	Polyclonal benign	Neoplastic	Benign
Nonatypical endometrial hyperplasia	Polyclonal benign	Polyclonal benign	Benign
Endometrial intraepithelial neoplasia	Neoplastic	—	Premalignant
Endometrial adenocarcinoma	Neoplastic	—	Malignant
Endometrial stromal nodule	—	Neoplastic	Benign
Endometrial stromal sarcoma	—	Neoplastic	Low-grade malignant
Undifferentiated sarcoma	—	Neoplastic	Malignant
Adenosarcoma	Unknown	Neoplastic	Low-grade malignant
Carcinosarcoma	Neoplastic	Neoplastic, transformed epithelial cells	Malignant
Smooth Muscle			
Leiomyoma	—	Neoplastic	Benign
Cellular leiomyoma	—	Neoplastic	Benign
Intravenous leiomyomatosis	—	Neoplastic	Locally aggressive
Leiomyosarcoma	—	Neoplastic	Malignant

and progesterone receptors (ER and PR) helps confirm the diagnosis. Most low-grade endometrial stromal sarcomas harbor t(7;17)(p21;q15), which results in a fusion between JAZF1 and SUZ12. By contrast, the high-grade endometrial stromal sarcomas, characterized by the recurrent aberration t(10;17)(q22;p13), exhibit an atypical round cell (predominant) and a low-grade spindle cell component. CD10, ER and PR are negative, but cyclin D1 is strongly positive. Higher-grade sarcomas originating in the endometrium lose all antigenic and morphologic resemblance to endometrial stroma and are thus designated as **undifferentiated uterine sarcoma**.

CLINICAL FEATURES: Many years may elapse before low-grade endometrial stromal sarcomas recur clinically, and metastases may occur even if the original tumor was confined to the uterus at initial surgery. Recurrences usually involve the pelvis first, followed by lung metastases. Prolonged survival and even cure are feasible, despite metastases. By contrast, high-grade endometrial stromal and undifferentiated uterine sarcomas recur early, generally with widespread metastases, even if there had been little myometrial invasion. Low-grade endometrial stromal sarcomas can be successfully treated with surgery and progestin therapy, with an expectation of 90% survival 10 years after diagnosis.

Uterine Adenosarcoma

Uterine (müllerian) adenosarcoma is a distinctive low-grade tumor with benign glandular epithelium and malignant stroma (Fig. 24-40). It differs from carcinosarcoma, in which both epithelial and stromal elements are malignant (see above).

Adenosarcoma typically presents as a polypoid mass within the endometrial cavity. The glandular epithelium resembles proliferative phase endometrial glands, but occasionally squamous epithelium and mucinous-type epithelium are seen. The stroma is cellular, may exhibit mitotic activity, is often densest about the glandular epithelium (periglandular cuffing) and resembles endometrial stromal

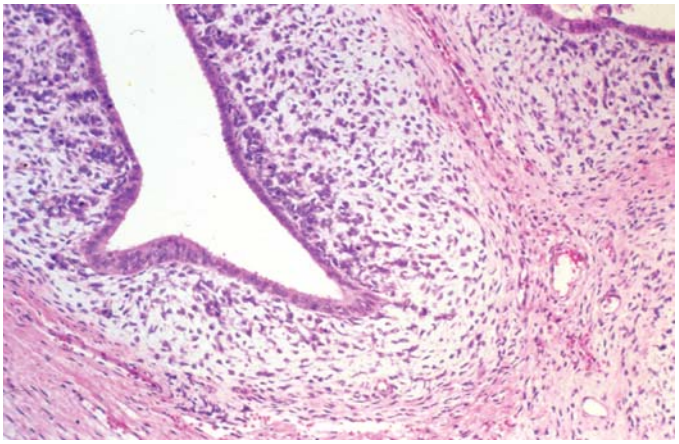

FIGURE 24-40. Adenosarcoma. There is periglandular cuffing by atypical stromal cells with mitotic activity.

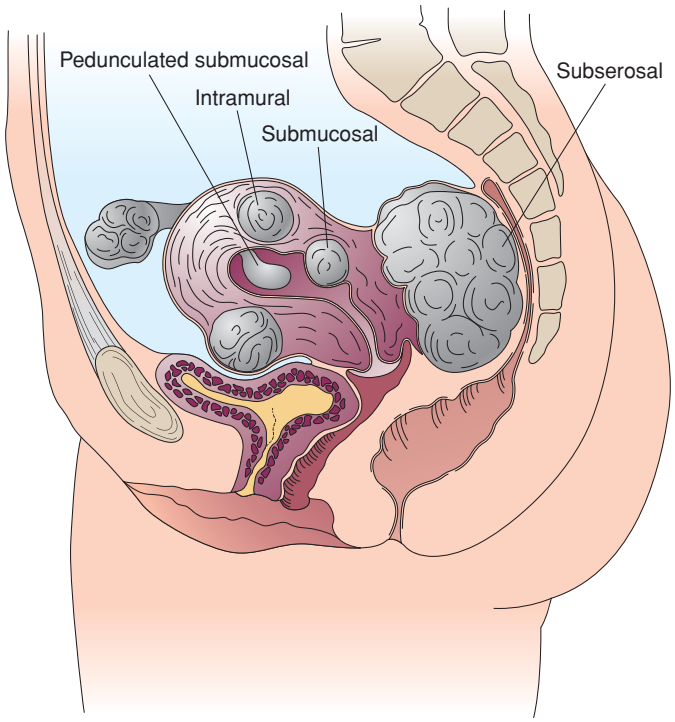

FIGURE 24-41. Leiomyomas of the uterus. The leiomyomas are intramural, submucosal (a pedunculated one appearing in the form of an endometrial polyp) and subserosal (one compressing the bladder and the other the rectum).

cells in the proliferative phase of the cycle. One fourth of patients with adenosarcoma eventually succumb to local recurrence or metastatic spread. In these patients, myometrial invasion and/or high-grade sarcomatous overgrowth usually occur.

Leiomyomas Are the Most Common Female Genital Tract Tumors

Leiomyomas, benign tumors of smooth muscle origin, are colloquially known as "myomas" or "fibroids." Including minute tumors, leiomyomas occur in 75% of women over age 30. They are rare before age 20, and most regress after menopause. Although often multiple, each tumor is monoclonal (see Chapter 5). Estrogen promotes their growth but does not initiate them.

PATHOLOGY: Grossly, leiomyomas are firm, pale gray, whorled and without encapsulation (Figs. 24-41 and 24-42). They vary from 1 mm to over 30 cm in diameter. Their cut surface bulges, and borders are smooth and distinct from neighboring myometrium. Most leiomyomas are intramural, but some are submucosal, subserosal or pedunculated. Many, especially larger ones, show areas of degenerative hyalinization that are sharply demarcated from adjacent normal myometrium. Leiomyomas show little mitotic activity (<4 mitoses per 10 high-power fields [HPFs]), lack nuclear atypia and geographical necrosis and have little or no malignant potential. A **"mitotically active leiomyoma"** is one that shows brisk mitotic activity but is relatively small, is sharply demarcated from adjacent normal myometrium and lacks both geographical necrosis and significant cellular atypia. It is usually benign.

Microscopically, leiomyomas exhibit interlacing fascicles of uniform spindle cells containing elongated nuclei with blunt ends (Fig. 24-42B). Cytoplasm is abundant, eosinophilic and fibrillar. The cells of leiomyomas and adjacent normal myometrium are cytologically identical, but leiomyomas are easily distinguished by their circumscription, nodularity and denser cellularity.

CLINICAL FEATURES: Submucosal leiomyomas may cause bleeding owing to ulceration of thinned, overlying endometrium, or become pedunculated and protrude through the cervical os, eliciting cramping pains. Many intramural leiomyomas are symptomatic because of their sheer bulk, and large ones may interfere with bowel or bladder function or cause dystocia in labor. Pedunculated leiomyomas on the uterine serosa may interfere with the function of neighboring viscera. Leiomyomas may also infarct and become painful if they undergo torsion.

Leiomyomas usually grow slowly but occasionally enlarge rapidly during pregnancy. Large symptomatic leiomyomas are removed by myomectomy or hysterectomy. Ablation by arterial thrombosis has also been used recently.

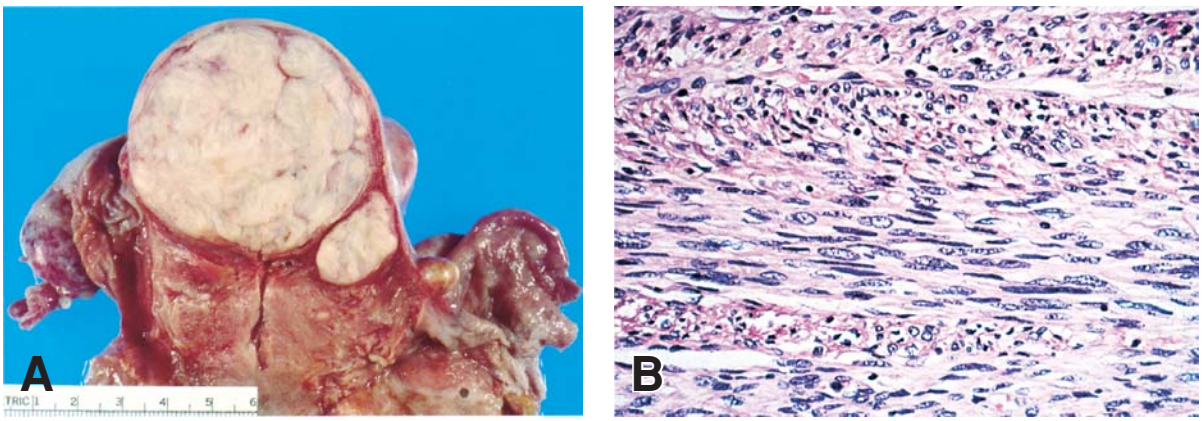

FIGURE 24-42. Leiomyoma of the uterus. A. A bisected uterus displays a prominent, sharply circumscribed, fleshy tumor. **B.** Microscopically, smooth muscle cells intertwine in bundles, some of which are cut longitudinally (elongated nuclei) and others transversely.

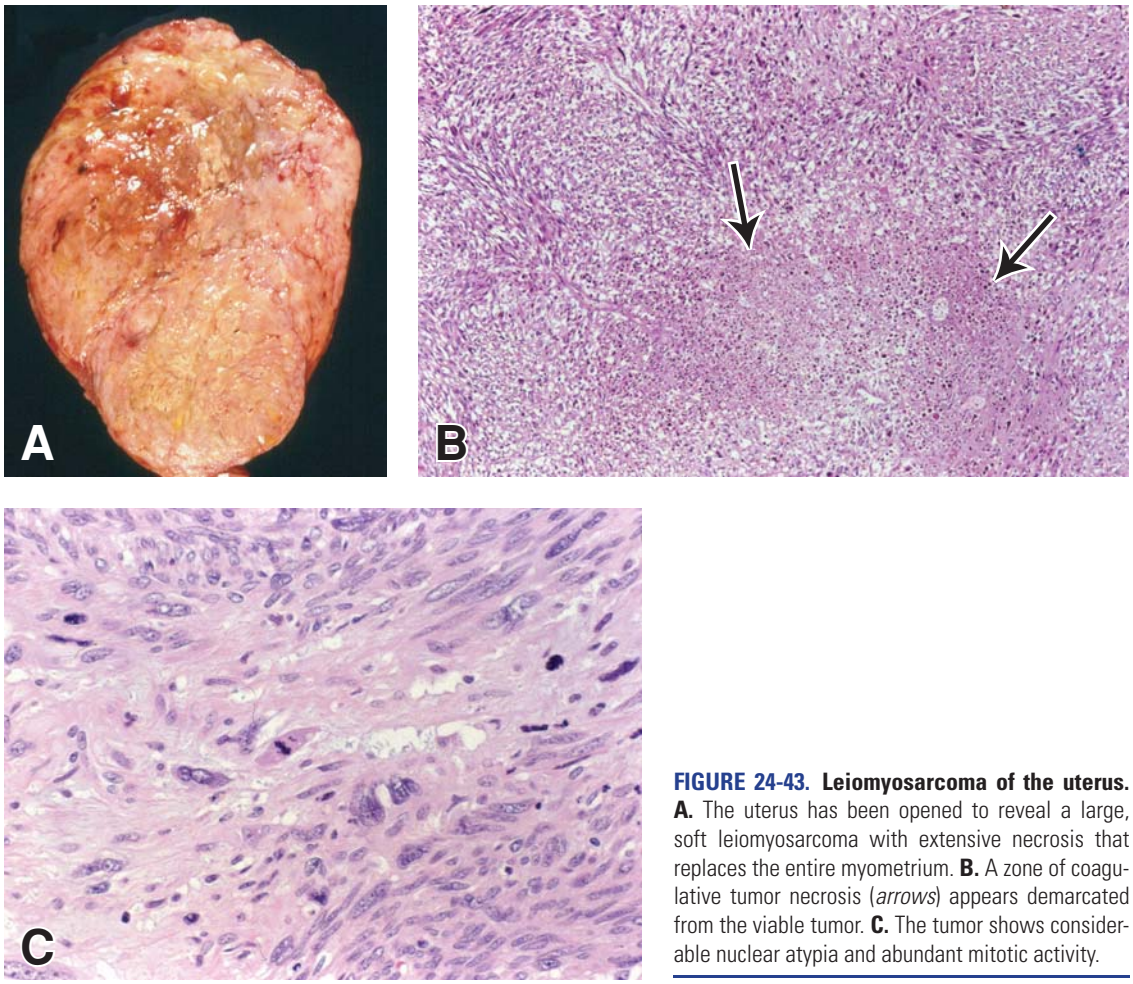

FIGURE 24-43. Leiomyosarcoma of the uterus. **A.** The uterus has been opened to reveal a large, soft leiomyosarcoma with extensive necrosis that replaces the entire myometrium. **B.** A zone of coagulative tumor necrosis (*arrows*) appears demarcated from the viable tumor. **C.** The tumor shows considerable nuclear atypia and abundant mitotic activity.

Intravenous Leiomyomatosis Does Not Metastasize

Intravenous leiomyomatosis is a rare condition in which benign smooth muscle grows within uterine and pelvic veins. It may develop after vascular invasion by a uterine leiomyoma or from growth of venous smooth muscle. At surgery, it appears as worm-like extensions near the external uterine surface or as projections into uterine veins in the broad ligament. Although they may grow extensively inside blood vessels, these neoplasms do not metastasize. Rare fatalities have resulted from direct extension of leiomyomas from pelvic veins into the inferior vena cava and right atrium. Treatment consists of total abdominal hysterectomy.

Leiomyosarcomas Are Very Rare Compared to Leiomyomas

Leiomyosarcoma is a smooth muscle malignancy whose incidence is 1/1000th of its benign counterpart. It accounts for 2% of uterine cancers. Its pathogenesis is uncertain, but at least some appear to arise within leiomyomas. Women with leiomyosarcomas are on average more than a decade older (age above 50) than those with leiomyomas, and the malignant tumors are larger (10–15 cm vs. 3–5 cm) (Fig. 24-43A).

PATHOLOGY: Leiomyosarcoma should be suspected when an apparent leiomyoma is soft, shows areas of necrosis on gross examination, has irregular borders (invasion of adjacent myometrium) or fails to protrude above the surface when cut. Evidence that a uterine smooth muscle tumor is a leiomyosarcoma includes (1) presence of geographical necrosis with a sharp transition from viable tumor (Fig. 24-43B); (2) 10 or more mitoses per 10 HPFs (Fig. 24-43C), if the tumor is more than 5 cm in diameter; (3) 5 or more mitoses per 10 HPFs, with geographical necrosis and diffuse cytoplasmic/nuclear atypia; and (4) myxoid and epithelioid smooth muscle tumors with 5 or more mitoses per 10 HPFs.

Size is important: tumors under 5 cm in diameter almost never recur. However, most leiomyosarcomas are large and advanced when detected and are usually fatal despite surgery, radiation therapy and/or chemotherapy. Nearly half of recurrences first present in the lung, and 5-year survival is about 20%.

Fallopian Tube

ANATOMY

The fallopian tubes extend from the uterine fundus to the ovaries. An interstitial portion, the **isthmus,** lies within the cornua of the uterus and connects the uterine cavity with the straight portion of the tube. As the tube extends to the

ovary, it increases in diameter to form the **ampulla,** which merges with the **infundibulum**. The fimbriated end opens like the bell of a trumpet and has finger-like extensions that envelop the ovary. The lining cells are ciliated and are important in transport of ova.

SALPINGITIS

Salpingitis is inflammation of the fallopian tubes, typically due to infections ascending from the lower genital tract. The most common causative organisms are *N. gonorrhoeae, Escherichia coli, Chlamydia* and *Mycoplasma,* and most infections are polymicrobial. Acute episodes of salpingitis (particularly if due to chlamydia) may be asymptomatic. A fallopian tube damaged by prior infection is very susceptible to reinfection. In most cases, chronic salpingitis develops only after repeated episodes of acute salpingitis.

PATHOLOGY AND CLINICAL FEATURES: In acute salpingitis, there is marked neutrophil infiltration, edema and congestion of mucosal folds (plicae). In chronic salpingitis, the inflammatory infiltrate is mainly lymphocytes and plasma cells; edema and congestion are usually minimal. In late stages, the fallopian tube may seal and become distended with pus **(pyosalpinx)** or a transudate **(hydrosalpinx)**.

The fallopian tube allows infections from the lower genital tract to ascend to the peritoneal cavity, leading to peritonitis and PID. Fibrinous adhesions between the fallopian tube serosa and surrounding peritoneal surfaces organize into thin fibrous bands ("violin string" adhesions). The adjacent ovary may also be involved, sometimes as a **tuboovarian abscess**. Destruction of the fallopian tube epithelium or deposition of fibrin on its surface leads to fibrin bridges connecting the plicae to one another. In severe chronic salpingitis, dense adhesions cause the end of the tube to become blunted and clubbed. A blocked lumen may lead to hydrosalpinx or pyosalpinx. The damage wrought by chronic salpingitis may also impair tubal motility and passage of sperm, resulting in **infertility**. Chronic salpingitis is a common cause of **ectopic pregnancy,** since adherent mucosal plicae create pockets in which ova are entrapped.

ECTOPIC PREGNANCY

Ectopic pregnancy is implantation of a fertilized ovum outside the endometrium. The frequency of ectopic pregnancy in the United States has increased 3-fold, to 1.5% of live births, during the past two decades, although mortality has sharply declined. **Over 95% of such pregnancies are in the fallopian tube, mostly in the distal and middle thirds.**

PATHOLOGY: Ectopic pregnancy results when passage of a conceptus along a fallopian tube is impeded, for example, by mucosal adhesions or abnormal tubal motility due to inflammatory disease or endometriosis. The trophoblast readily penetrates the tubal mucosa and musculature. Blood from the tubal implantation site enters the peritoneum, causing abdominal pain. Ectopic pregnancy is also associated with anomalous uterine bleeding after a period of amenorrhea and Arias-Stella cells in the endometrium. The thin tubal wall usually ruptures by the 12th week of gestation. ***Tubal rupture is life-threatening as it can lead to rapid exsanguination.***

Rupture of the tube's interstitial portion produces greater intra-abdominal hemorrhage than rupture in other locations because vasculature there is richer and rupture occurs later in gestation. In the isthmus, the tube ruptures early (within the first 6 weeks), because its thick muscular wall does not allow much distention. Tubal pregnancies in the ampulla tend to be of longer duration, since the distensible tubal wall can accommodate a growing pregnancy for a longer time.

Ectopic pregnancy must be treated promptly with surgery or chemotherapy. Administration of methotrexate terminates ectopic pregnancy and is used when the conceptus is smaller than 4 cm.

FALLOPIAN TUBE TUMORS

Benign tumors arising within the fallopian tube are rare. The most common is the small, circumscribed **adenomatoid tumor,** which is of mesothelial origin. It arises in the mesosalpinx and shows benign mesothelial cells that line slit-like spaces.

Thorough evaluation of the fallopian tube in women at heightened hereditary risk for "ovarian" cancer (*BRCA* mutation) has shown that many resultant cancers arise in the tubal fimbria as s**erous tubal intraepithelial carcinoma** (STIC). The tubal fimbria have also been shown to be an early site of involvement of some sporadic (nonhereditary) serous adenocarcinomas. STIC lesions are physically small, often grossly inapparent and composed of mitotically active regions of atypical epithelium expressing mutant *TP53.* An unknown proportion of **high-grade pelvic serous adenocarcinomas** previously classified as ovarian or peritoneal primary tumors may in fact be tubal carcinomas metastatic to those sites. This revised biological model of pelvic serous carcinogenesis has identified new targets for prevention (the fallopian tube). Clinical tumor staging at these sites has been revised to consider ovarian and tubal carcinomas in an integrated fashion (Table 24-9).

Fallopian tube involvement by metastases or implants from adjacent ovarian and uterine neoplasms also occurs. Most primary malignancies are adenocarcinomas, with peak incidence among 50- to 60-year-olds.

Ovary

ANATOMY AND EMBRYOLOGY

The ovaries are paired organs that flank the uterus. They are attached to the posterior surface of the broad ligament in a shallow peritoneal fossa between the external iliac vessels and the ureter. Each ovary has an epithelial surface, a mesenchymal stroma containing steroid-producing cells and germ cells, an outer cortex and an inner medulla.

Ovaries appear early in fetal life as swellings of the genital ridges. At the 19th gestational day, germ cells migrate from the primitive yolk sac to the gonads and multiply by mitotic division. By the 40th day, ovaries and testes are

TABLE 24-9
FIGO (2012) STAGING OF CANCER OF THE OVARY, FALLOPIAN TUBE AND PERITONEUM

Stage	Anatomic Distribution
Stage I	Tumor confined to ovaries or fallopian tube(s)
IA	Tumor limited to one ovary (capsule intact) or fallopian tube Surface free of tumor and washings negative
IB	Tumor limited to both ovaries (capsules intact) or fallopian tubes Surface free of tumor and washings negative
IC	Tumor limited to one or both ovaries or fallopian tubes, with any of the following:
IC1	Surgical spill intraoperatively
IC2	Capsule ruptured before surgery or tumor on ovarian or fallopian tube surface
IC3	Malignant cells in the ascites or peritoneal washings
Stage II	Tumor involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim) or primary peritoneal cancer
IIA	Extension and/or implants on the uterus and/or fallopian tubes and/or ovaries
IIB	Extension to other pelvic intraperitoneal tissues
Stage III	Cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes
IIIA	Metastasis to the retroperitoneal lymph nodes with or without microscopic peritoneal involvement beyond the pelvis
IIIA1	Positive retroperitoneal lymph nodes only (cytologically or histologically proven)
IIIA1 (i)	Nodal metastasis ≤10 mm in greatest dimension
IIIA1 (ii)	Nodal metastasis >10 mm in greatest dimension
IIIA2	Microscopic extrapelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes
IIIB	Macroscopic peritoneal metastases beyond the pelvic brim ≤2 cm in greatest dimension with or without positive retroperitoneal nodes
IIIC	Macroscopic peritoneal metastases beyond the pelvic brim >2 cm in greatest dimension with or without positive retroperitoneal nodes
Stage IV	Distant metastasis excluding peritoneal metastases
IVA	Pleural effusion with positive cytology
IVB	Metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of abdominal cavity)

FIGO = International Federation of Gynecology and Obstetrics.

histologically distinct. Toward the third trimester of fetal life, germ cells stop multiplying and instead continue to develop by meiosis. Of 1 million primordial follicles present at birth, only 70% remain by puberty and fewer than 15% persist to age 25 years. Only some 450 ova are actually shed during a woman's average 35-year reproductive lifetime.

The ovarian cortex mesenchyme consists of spindle-shaped, fibroblast-like cells. These give rise to granulosa and theca cells, which form a functional unit about each ovum (theca interna and theca externa). The complex of a germ cell and supporting granulosa cells is known first as a **primordial follicle**. During the reproductive period, a dominant follicle develops every month into a **graafian follicle,** which then ruptures during ovulation. Ovulation itself is often associated with mild cramping pain, which, if severe, is called **mittelschmerz** (i.e., midcycle pain). It is frequently confused with appendicitis. After ovulation, the follicle granulosa cells luteinize, with hypertrophy and lipid accumulation. They then secrete progesterone in addition to estrogens. The collapsed follicle turns bright yellow and becomes the **corpus luteum** (yellow body).

Cells of ovarian stromal origin include hilus cells and those resembling luteinized cells of the theca interna, both of which respond to pituitary hormones. These specialized cells make and secrete both androgens and estrogens, which stimulate proliferation in end-organs (e.g., uterus). They inhibit hypothalamic function by negative feedback loops.

CYSTIC LESIONS OF THE OVARIES

Cysts usually arise from invaginated surface epithelium (serous cysts) and are the most common cause of enlarged ovaries. Almost all of the rest derive from ovarian follicles.

Follicle Cysts Tend to Be Asymptomatic

Follicle cysts are thin-walled, fluid-filled structures lined internally by granulosa cells and externally by theca interna cells. They occur at any age up to menopause, are uniocular and may be single or multiple, unilateral or bilateral. They arise from ovarian follicles and are probably related to abnormalities in pituitary gonadotropin release.

PATHOLOGY: Follicle cysts rarely exceed 5 cm. In an unstimulated state, the granulosa cells of the cyst have uniform, round nuclei and little cytoplasm. Thecal cells are small and spindle shaped. Occasionally, the layers may be luteinized, and the lumen wall contains fluid high in estrogen or progesterone. If the cyst persists, hormonal output can cause precocious puberty in a child and menstrual irregularities in an adult. The only significant complication is mild intraperitoneal bleeding (Fig. 24-44).

Corpus Luteum Cysts Can Bleed

A corpus luteum cyst results from delayed resolution of a corpus luteum's central cavity. Continued progesterone synthesis by the luteal cyst leads to menstrual irregularities. Rupture of a cyst can cause mild hemorrhage into the abdominal cavity. A corpus luteum cyst is typically unilocular, 3–5 cm in size with a yellow wall. Cyst contents vary

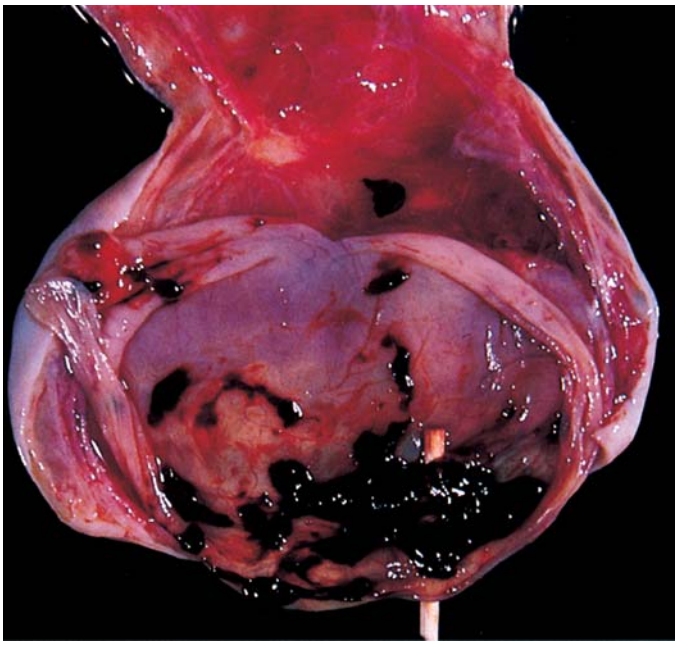

FIGURE 24-44. Follicle cyst of the ovary. The rupture of this thin-walled follicular cyst (dowel stick) led to intra-abdominal hemorrhage.

from serosanguineous fluid to clotted blood. Microscopic examination shows numerous large, luteinized granulosa cells. The condition is self-limited.

Theca Lutein Cysts Relate to High Gonadotropin Levels

Theca lutein cysts, also called *hyperreactio luteinalis*, are often multiple and bilateral. They are associated with high levels of circulating gonadotropin (as in pregnancy, hydatidiform mole, choriocarcinoma or exogenous gonadotropin therapy) or physical impediments (dense adhesions, cortical fibrosis) to ovulation. Excessive gonadotropin levels lead to exaggerated stimulation of the theca interna and extensive cyst formation.

PATHOLOGY: Multiple thin-walled cysts filled with clear fluid and a markedly luteinized layer of theca interna replace both ovaries. Ovarian parenchyma shows edema and foci of luteinized stromal cells. Intra-abdominal hemorrhage due to torsion or rupture of the cyst may require surgical intervention.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome, or **Stein-Leventhal syndrome,** reflects (1) excess secretion of androgenic hormones, (2) persistent anovulation and (3) many small subcapsular ovarian cysts. It was first described as a syndrome of **secondary amenorrhea, hirsutism and obesity,** but clinical presentations are now known to be far more variable and include amenorrheic women who appear otherwise normal and, even rarely, have ovaries lacking polycystic features. ***This condition is a common cause of infertility: up to 7% of women experience polycystic ovary syndrome.***

PATHOPHYSIOLOGY: Polycystic ovary syndrome is a state of functional ovarian hyperandrogenism with elevated levels of LH, although increased LH is probably a result, rather than a cause, of ovarian dysfunction (Fig. 24-45).

1. The central abnormality is thought to be increased ovarian production of androgens, although adrenal hypersecretion of androgens may also occur. The rate-limiting enzyme in androgen biosynthesis, cytochrome $P450_{c17\alpha}$ (17α-hydroxylase), expressed in both the ovary and the adrenal gland, is abnormally regulated.
2. Excess ovarian androgens act locally to cause (1) premature follicular atresia, (2) multiple follicular cysts and (3) a persistent anovulatory state. Impaired follicular maturation results in decreased secretion of progesterone. Peripherally, hyperandrogenism leads to hirsutism, acne and male-pattern (androgen-dependent) alopecia. Affected patients may have high serum levels of androgens, such as testosterone, androstenedione and dehydroepiandrosterone sulfate. But there are individual variations and some patients have normal androgen levels.
3. Excess androgens are converted to estrogens in peripheral adipose tissue, an effect that is exaggerated by obesity. Acyclic estrogen production and progesterone deficiency increase pituitary secretion of LH.
4. Women with polycystic ovary syndrome exhibit marked peripheral insulin resistance, out of proportion to the degree of obesity. The mechanism appears to involve a post–insulin-receptor defect, possibly related to decreased expression of a glucose transporter. In any event, the resulting hyperinsulinemia seems to contribute to increased ovarian hypersecretion of androgens and direct stimulation of pituitary LH production.

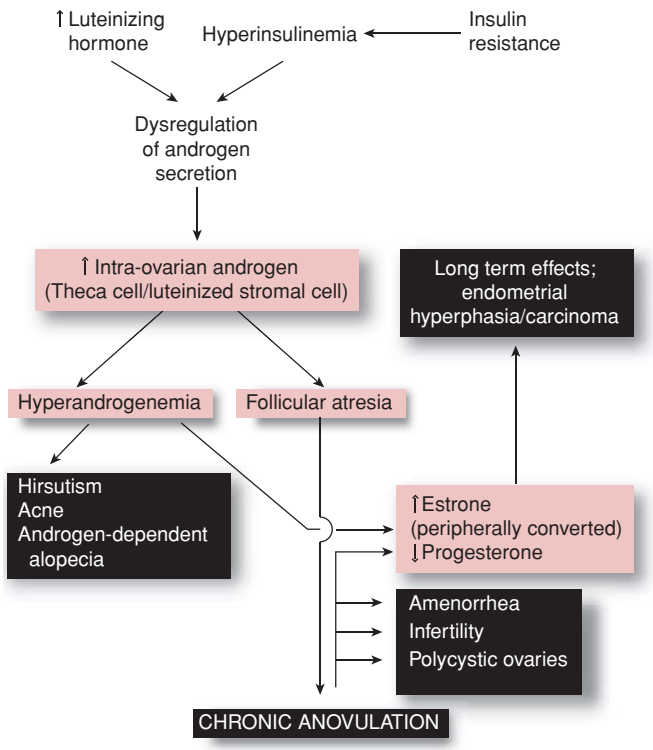

FIGURE 24-45. Pathogenesis of polycystic ovary syndrome.

FIGURE 24-46. Polycystic disease of the ovary. Cut sections of an ovary show numerous cysts embedded in a sclerotic stroma.

PATHOLOGY: Both ovaries are enlarged. The surface is smooth, owing to lack of ovulation. On cut section, the cortex is thickened and contains numerous theca lutein–type cysts, typically 2–8 mm in diameter, arranged peripherally around a dense core of stroma or scattered throughout an expanded stroma (Fig. 24-46). Microscopic features include (1) numerous follicles in early developmental stages; (2) follicular atresia; (3) increased stroma, occasionally with luteinized cells (hyperthecosis); and (4) features of anovulation (thick, smooth capsule and absence of corpora lutea and corpora albicantia). Many subcapsular cysts show thick zones of theca interna, in which some cells may be luteinized.

CLINICAL FEATURES: ***Nearly three quarters of women with anovulatory infertility have polycystic ovary syndrome.*** Patients are typically in their 20s and tell of early obesity, menstrual problems and hirsutism. Half of women with polycystic ovary syndrome are amenorrheic and most others have irregular menses. Only 75% are actually infertile, indicating that some do occasionally ovulate. Unopposed acyclic estrogen activity increases incidence of endometrial hyperplasia and adenocarcinoma.

Treatment of polycystic ovary syndrome targets two common problems in reproductive endocrinology—hirsutism and anovulation. Therapy is mostly hormonal and seeks to interrupt the constant excess of androgens. Wedge resection of the ovary provides temporary remission of the syndrome but is rarely used today.

STROMAL HYPERTHECOSIS

Stromal hyperthecosis is focal luteinization of ovarian stromal cells. These stromal cells are often functional and cause **virilization**. The condition is most common in postmenopausal women and, in a microscopic form, is found in one third of postmenopausal ovaries.

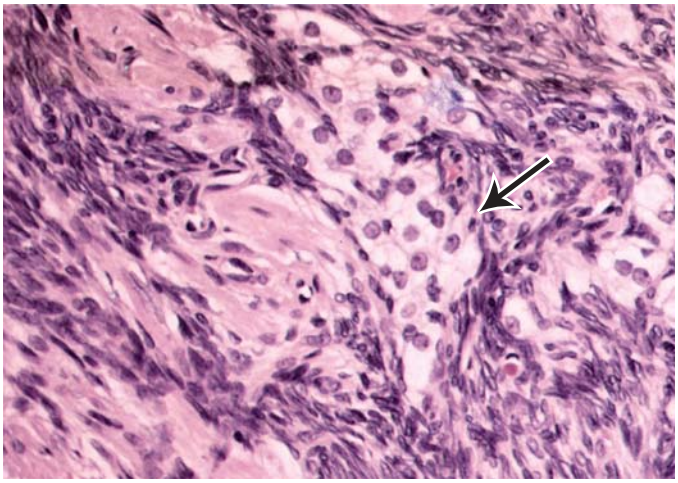

FIGURE 24-47. Hyperthecosis of the ovary. Nests of luteinized (lipid-rich) stromal cells are present (*arrow*).

PATHOLOGY: If stromal hyperthecosis is detected clinically, usually owing to masculinizing signs, both ovaries may be enlarged, sometimes up to 8 cm in greatest dimension. The serosa is smooth, and the cut surface is homogeneous, firm and brown to yellow. Single nests or nodules of luteinized stromal cells with deeply eosinophilic, often vacuolated cytoplasm are seen in the cortex or medulla (Fig. 24-47). Luteinized cells have a large central nucleus and a prominent nucleolus, features shared with all hormonally active stromal cells in the ovary.

OVARIAN TUMORS

There are many types of ovarian tumors including benign, borderline and malignant ones. About two thirds occur in women of reproductive age; less than 5% develop in children. Approximately 80% are benign. Almost 90% of malignant and borderline tumors are diagnosed after the age of 40 years.

Ovarian tumors are classified by the ovarian cell type of origin (Fig. 24-48). Most are **common epithelial tumors** (approximately 60%) that arise directly or indirectly from müllerian epithelium. Other important groups are germ cell tumors (30%), sex cord/stromal tumors (8%) and tumors metastatic to the ovary. In the Western world, common epithelial tumors account for about 90% of ovarian malignancies, serous adenocarcinoma being the most common among these.

Ovarian cancer is the second most frequent gynecologic malignancy after endometrial cancer and carries a higher mortality rate than all other female genital cancers combined (Table 24-3). As it is difficult to detect at a curable stage, over three fourths of patients have tumor spread to the pelvis or abdomen at the time of diagnosis. Approximately 22,000 new cases of ovarian cancer are diagnosed each year in the United States, and more than 14,000 women die from the disease (Table 24-3). Lifetime risk of developing ovarian cancer is 2%. These tumors predominate in women older than 60 years but may occur in younger women with a family history of the disease.

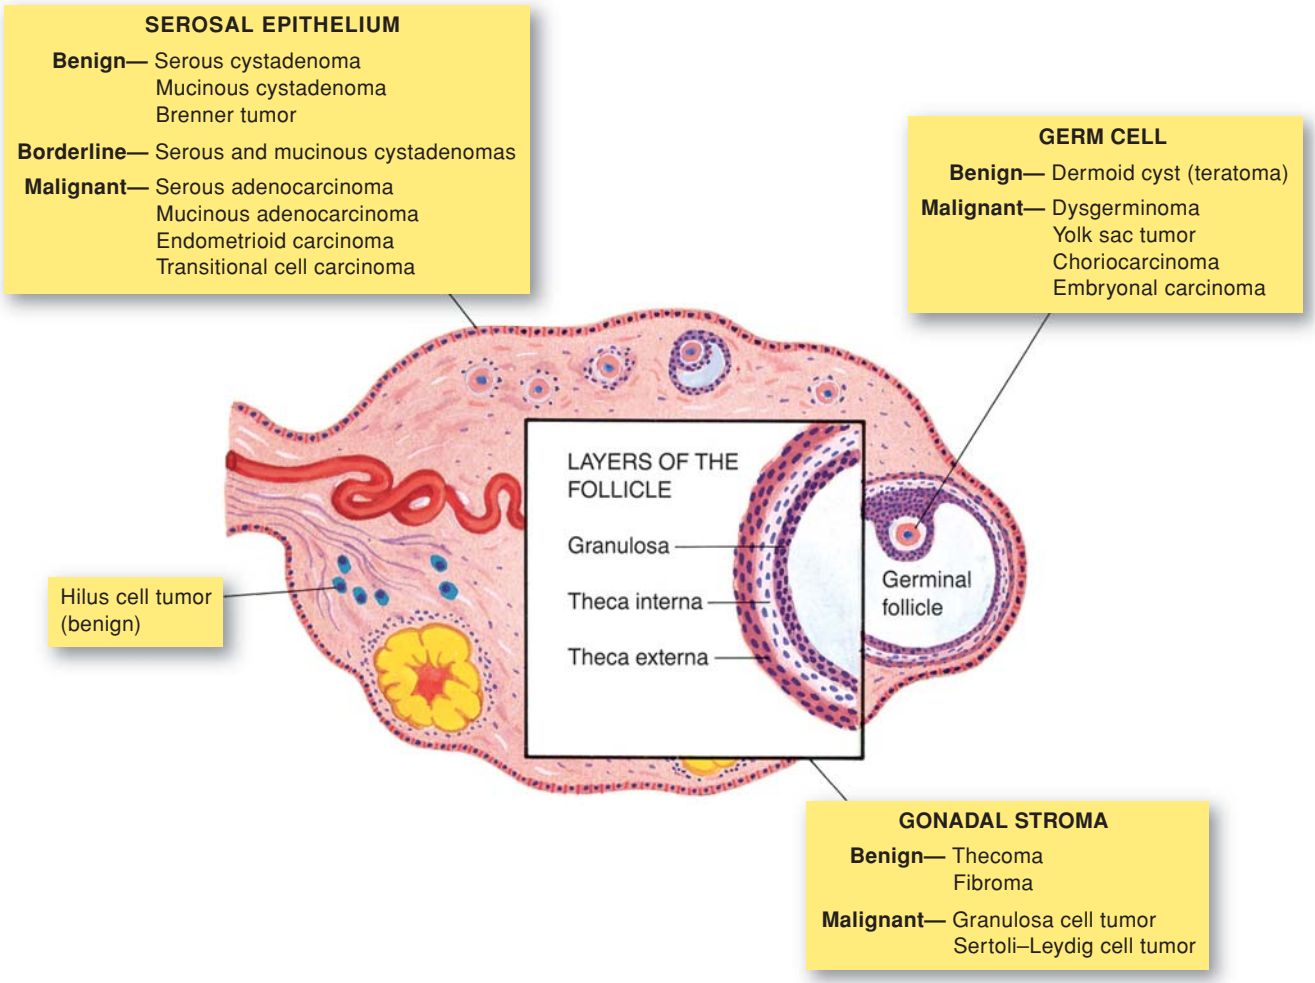

FIGURE 24-48. Classification of ovarian neoplasms based on cell of origin.

Epithelial Tumors Account for Over 90% of Ovarian Cancers

Tumors of common epithelial origin are broadly classified, according to cell proliferation, degree of nuclear atypia and presence or absence of stromal invasion: (1) **benign,** (2) of **borderline malignancy** (also called **low malignant potential**) and (3) **malignant** (Fig. 24-49).

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: Common epithelial neoplasms are apparently related to repeated disruption and repair of the epithelial surface resulting from cyclic or "incessant" ovulation. Thus, tumors occur most commonly in nulliparous women and least often in women in whom ovulation has been suppressed (e.g., by pregnancy or oral contraceptives). Persistent, high concentrations of pituitary gonadotropins after menopause may stimulate surface epithelial cells, promoting accumulation of genetic changes and carcinogenesis. Irritants, such as talc or asbestos, transported up the reproductive tract to the ovaries have also been implicated.

Common epithelial tumors, particularly serous carcinomas, are thought to arise from ovarian surface epithelium (mesothelium) or serosa. During embryonic life, the celomic cavity is lined by mesothelium, parts of which specialize to form the serosal epithelium covering the gonadal ridge. The same mesothelial lining gives rise to müllerian ducts, from which the fallopian tubes, uterus and vagina arise (Fig. 24-50). Thus, as the ovary develops, the surface epithelium may extend into the ovarian stroma to form glands and cysts, and in some cases, these inclusion cysts become neoplastic and show a variety of müllerian-type differentiations (Fig. 24-49).

Approximately 10% of patients with high-grade serous carcinoma (HGSC) have a family history of ovarian cancer. If a first-degree relative had ovarian cancer, a woman's risk of developing ovarian cancer is increased 3.5-fold. Women with a history of ovarian carcinoma are also at greater risk for breast cancer and vice versa. Defects in repair genes implicated in hereditary breast cancers, *BRCA1* and *BRCA2*, are incriminated in familial ovarian cancers as well. Ovarian carcinomas arising in patients with germline *BRCA1* or *BRCA2* mutations are almost invariably of high-grade serous type. Women with *BRCA1* mutations tend to develop ovarian cancers at younger ages than those who develop sporadic ovarian tumors, but *BRCA1*–related tumors have better prognoses. The traditional view that HGSCs arise exclusively from ovarian surface epithelium or epithelial inclusion cysts has been challenged recently by the identification,

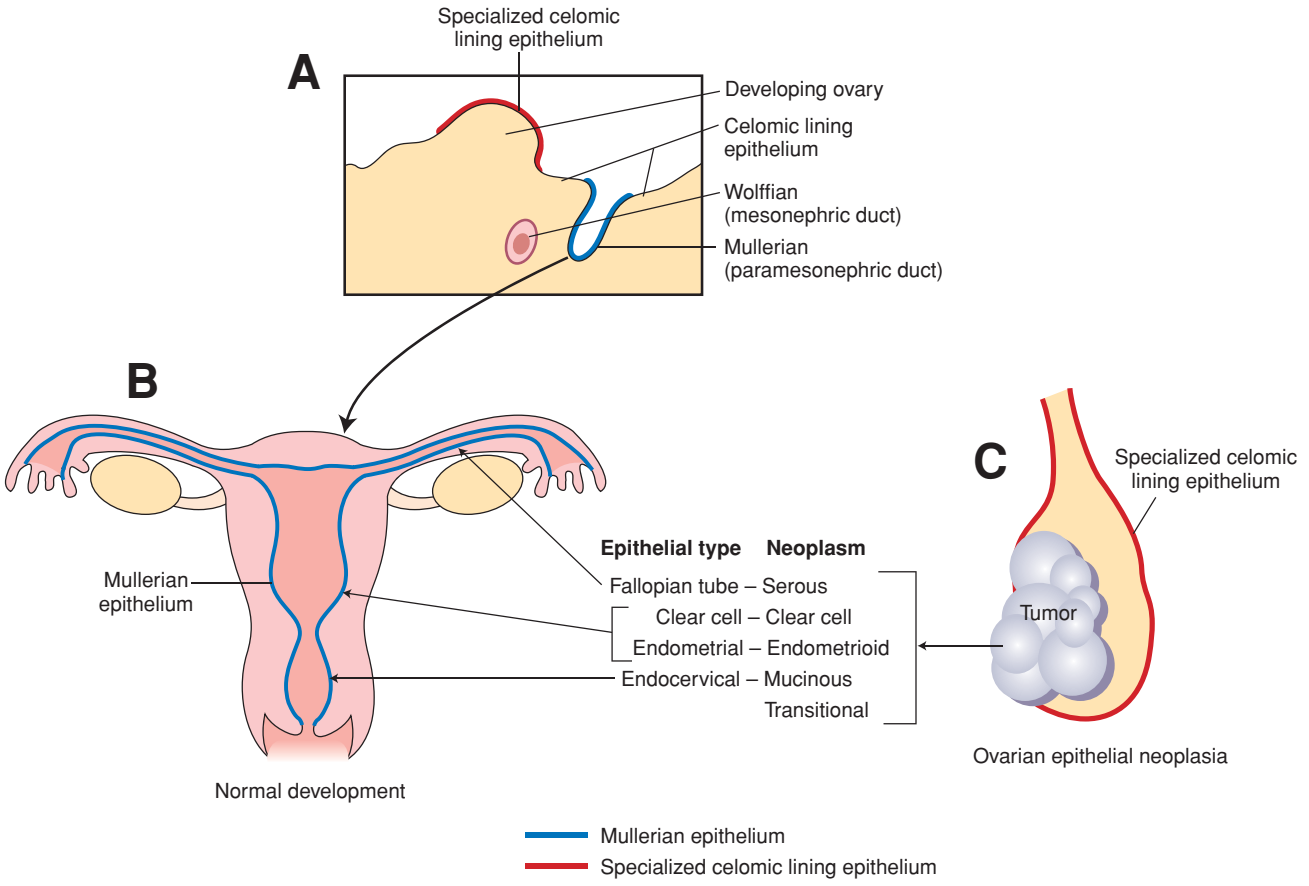

FIGURE 24-49. Histogenesis of ovarian epithelial/stromal tumors.

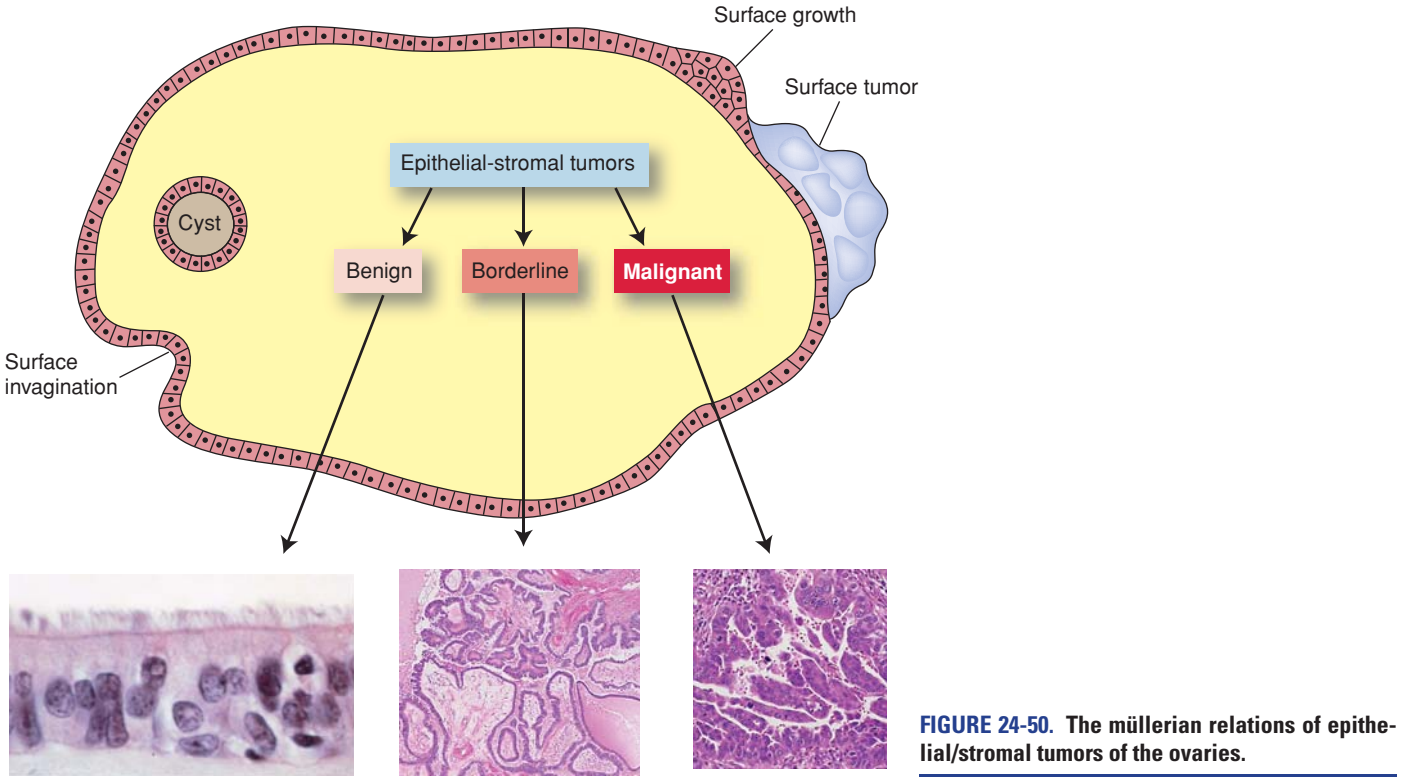

FIGURE 24-50. The müllerian relations of epithelial/stromal tumors of the ovaries.

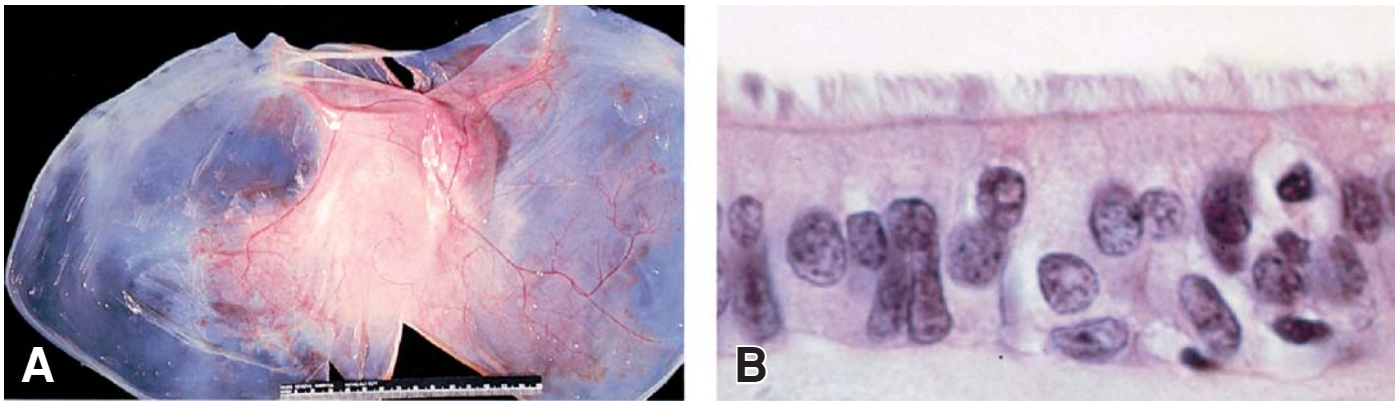

FIGURE 24-51. Serous cystadenoma of the ovary. A. Gross appearance of serous cystadenoma of the ovary. The fluid has been removed from this huge unilocular serous cystadenoma. The wall is thin and translucent. **B.** On microscopic examination, the cyst is lined by a single layer of ciliated tubal-type epithelium.

in women with *BRCA1* or *BRCA2* germline mutations, of serous tubal intraepithelial carcinoma (STIC) in the distal fimbriated end of the fallopian tube as a malignant lesion related to advanced HGSC. Currently, the relative proportion of HGSC of ovarian and tubal derivation is unknown mainly because the primary site is obscured in advanced stage cancers. As for endometrial carcinoma, women with hereditary nonpolyposis colon cancer (HNPCC) are also at greater risk for ovarian cancer. Most endometrioid and clear cell carcinomas of the ovary are thought to originate from ovarian endometriosis.

PATHOLOGY: In order of decreasing frequency, the **common epithelial tumors** are:

- **Serous tumors** that resemble fallopian tube epithelium
- **Mucinous tumors** that mimic the mucosa of the endocervix
- **Endometrioid tumors** that are similar to the glands of the endometrium
- **Clear cell tumors** with glycogen-rich cells like endometrial glands in pregnancy
- **Transitional cell tumors** that resemble the mucosa of the bladder
- **Mixed tumors**

Cystadenomas

Common benign epithelial tumors are almost always serous or mucinous adenomas and generally arise in women 20–60 years old. These tumors are frequently large, often 15–30 cm in diameter. Some, particularly mucinous ones, reach massive proportions, exceeding 50 cm in diameter, and may mimic the appearance of a term pregnancy. Benign epithelial tumors are typically cystic, hence the term **cystadenoma**. Serous cystadenomas are more often bilateral (15%) than mucinous cystadenomas and tend to be unilocular (Fig. 24-51). By contrast, **mucinous tumors** usually show hundreds of small cysts (locules) (Fig. 24-52). Unlike their malignant counterparts, benign ovarian epithelial tumors tend to have thin walls and lack solid areas. A single layer of tall columnar epithelium lines the cysts. Papillae, if present, have a fibrovascular core covered by a layer of tall columnar epithelium identical to the cyst lining.

Transitional Cell Tumor (Brenner Tumor)

The typical Brenner tumor is benign and occurs at all ages. Half of cases present in women over the age of 50. Size varies from microscopic foci to masses 8 cm or more in diameter.

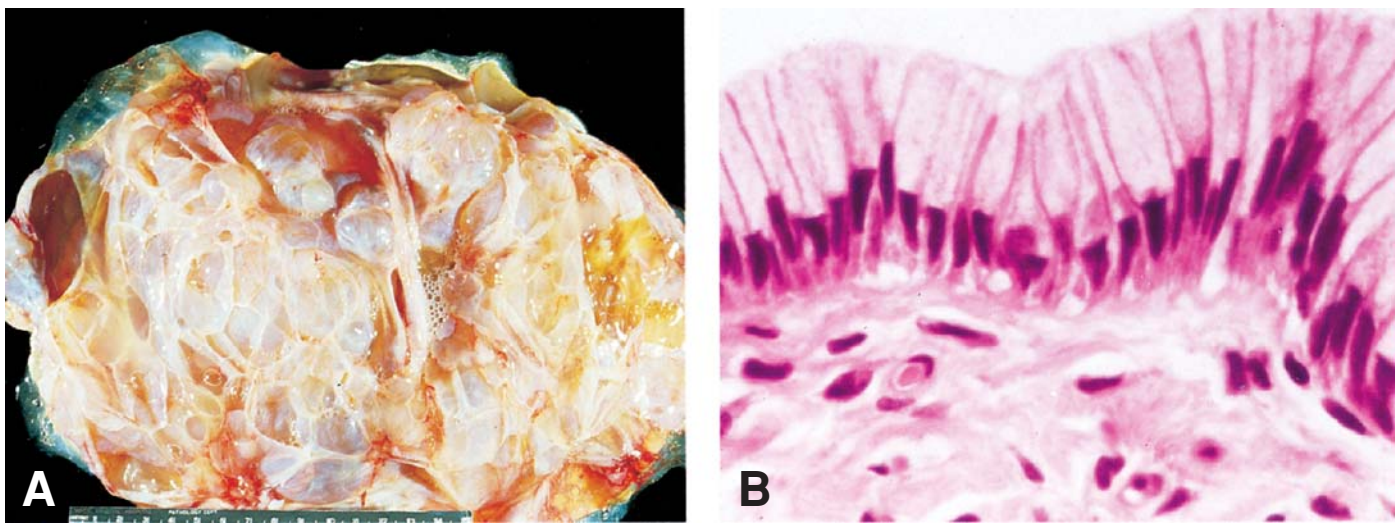

FIGURE 24-52. Mucinous cystadenoma of the ovary. A. The tumor is characterized by numerous cysts filled with thick, viscous fluid. **B.** A single layer of mucinous epithelial cells lines the cyst.

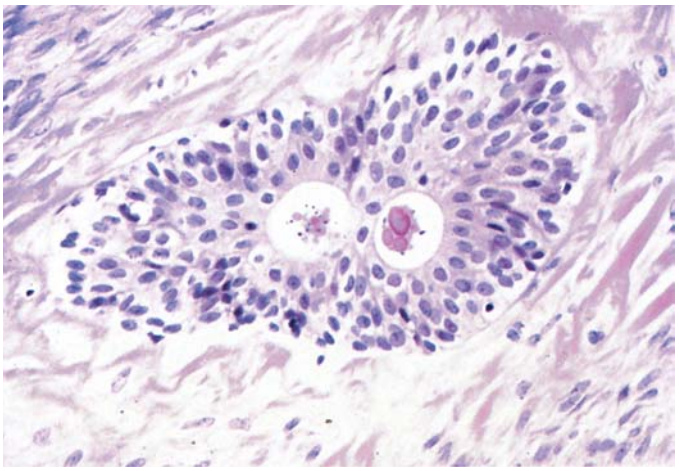

FIGURE 24-53. Brenner tumor. A nest of transitional-like cells is embedded in a dense, fibrous stroma.

Brenner tumors are adenofibromas, typically showing solid nests of transitional-like (urothelium-like) cells encased in a dense, fibrous stroma (Fig. 24-53). Epithelial nests are often cavitated and the most superficial epithelial cells may exhibit mucinous differentiation.

Borderline Tumors (Tumors of Low Malignant Potential)

"Borderline tumors" are a well-defined group of ovarian tumors characterized by epithelial cell proliferation and nuclear atypia but not destructive stromal invasion. Despite histologic features suggesting aggressiveness, they share an excellent prognosis. Serous borderline tumors generally occur in women 20–50 years old (average, 46 years) but are also seen in older women. Surgical cure is almost always possible if the tumor is confined to the ovaries. Even if it has spread to the pelvis or abdomen, 80% of patients are alive after 5 years. Although there is a significant rate of late recurrence, tumors rarely recur beyond 10 years. Late progression to low-grade serous carcinoma occurs in approximately 7% of cases.

Serous tumors of borderline malignancy are more commonly bilateral (34%) than mucinous ones (6%) or other types. The tumors vary in size, although mucinous ones may be gigantic. In serous tumors of borderline malignancy, papillary projections, ranging from fine and exuberant to grape-like clusters arising from the cyst wall, are common (Fig. 24-54). These structures resemble papillary fronds in benign cystadenomas, but they show (1) epithelial stratification, (2) moderate nuclear atypia and (3) mitotic activity. The same criteria apply to borderline mucinous tumors, although papillary projections are less conspicuous. ***By definition, the presence of more than focal microinvasion (i.e., discrete nests of epithelial cells <3 mm into the ovarian stroma) identifies a tumor as low-grade invasive serous carcinoma, rather than a borderline tumor.*** However, borderline tumors with lymph node metastases or peritoneal implants (Fig. 24-55), whether noninvasive or invasive, are still "borderline," reflecting the fact that this well-defined category carries a far better prognosis than usual adenocarcinomas. The presence of ovarian surface excrescences does not seem to predict progression of disease.

Malignant Epithelial Tumors

Carcinomas of the ovary are most common in women 40–60 years old and are rare under the age of 35. Based on light microscopy and molecular genetics, ovarian carcinomas are classified into five main subtypes (Table 24-10), which, in descending order of frequency, are high-grade serous carcinomas (>70%), endometrioid carcinomas (10%), clear cell carcinomas (10%), mucinous carcinomas (3%–4%) and low-grade serous carcinomas (<5%). These subtypes, which account for 98% of ovarian carcinomas, can be reproducibly diagnosed and identified as diseases based on differences in epidemiologic and genetic risk factors, precursor lesions, patterns of spread, molecular events during oncogenesis, responses to chemotherapy and outcomes. Advances in subtype-specific management of ovarian cancer make accurate subtype assignment increasingly important.

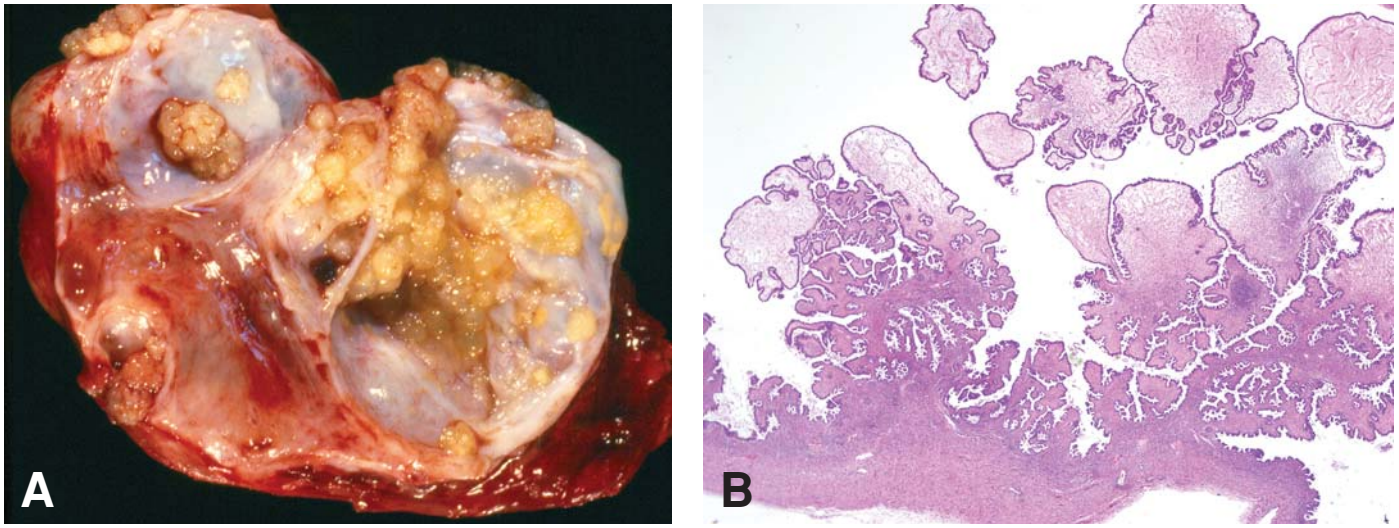

FIGURE 24-54. Serous cystic borderline tumor. A. The inner surface of the cysts is partly covered by closely packed papillae (endophytic growth). **B.** Microscopic view of the papillary tumor. The papillae show hierarchical and complex branching without stromal invasion. Some papillae have fibroedematous stalks.

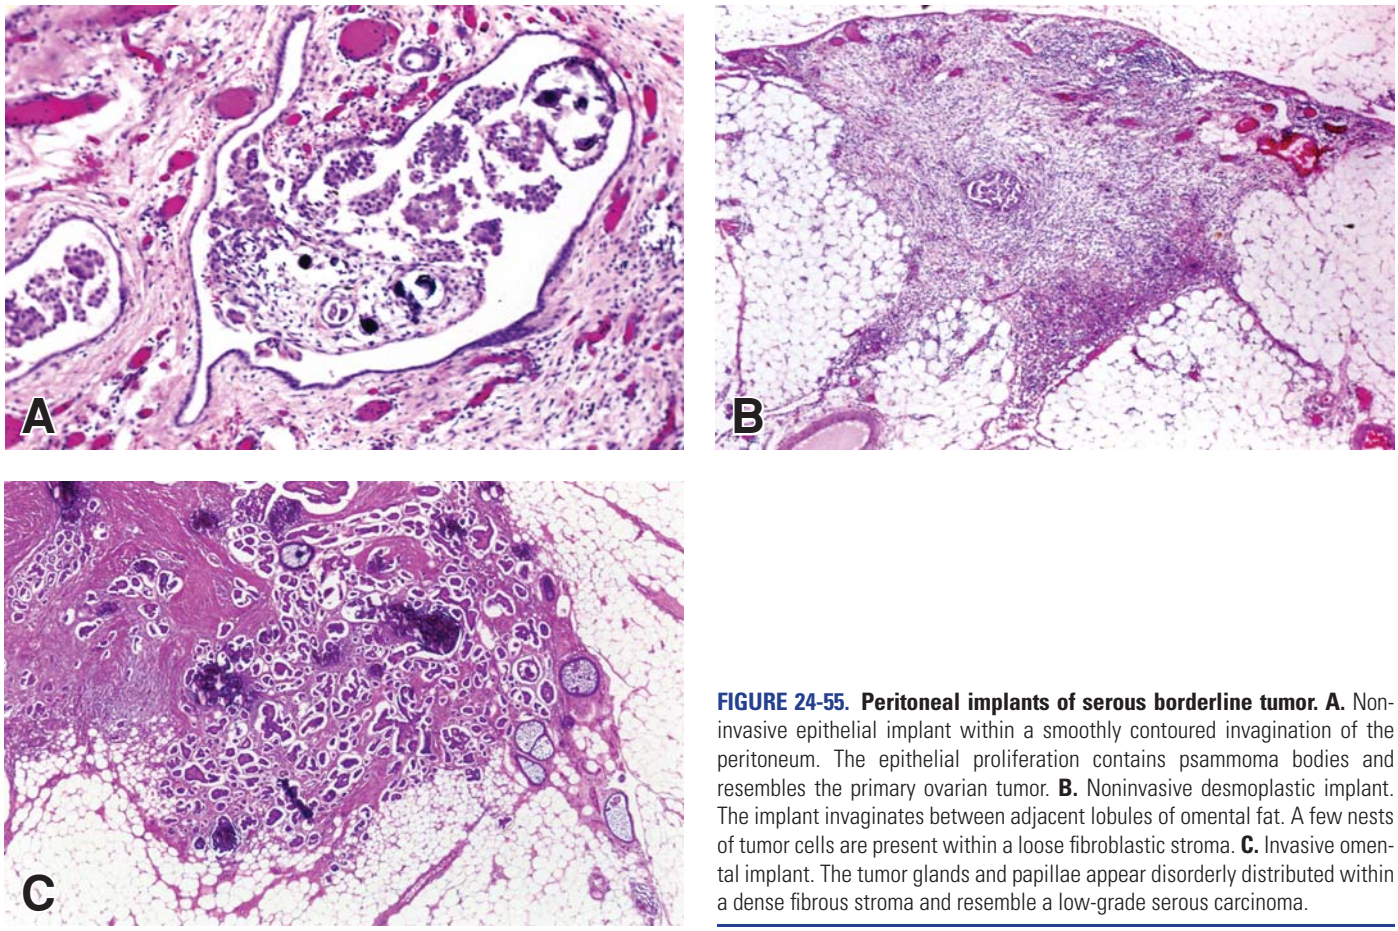

FIGURE 24-55. Peritoneal implants of serous borderline tumor. A. Noninvasive epithelial implant within a smoothly contoured invagination of the peritoneum. The epithelial proliferation contains psammoma bodies and resembles the primary ovarian tumor. **B.** Noninvasive desmoplastic implant. The implant invaginates between adjacent lobules of omental fat. A few nests of tumor cells are present within a loose fibroblastic stroma. **C.** Invasive omental implant. The tumor glands and papillae appear disorderly distributed within a dense fibrous stroma and resemble a low-grade serous carcinoma.

SEROUS ADENOCARCINOMAS:

MOLECULAR PATHOGENESIS: Low-grade and high-grade serous carcinomas are fundamentally different tumors. Whereas low-grade tumors are frequently associated with serous borderline tumors and have mutations of *KRAS* or *BRAF* oncogenes, high-grade serous carcinomas appear to arise de novo without identifiable precursor lesions and have a high frequency of mutations in *p53,* but not in *KRAS* or *BRAF.* Interestingly,

TABLE 24-10
MAIN SUBTYPES OF OVARIAN CARCINOMA

	Low-Grade Serous	High-Grade Serous	Clear Cell	Endometrioid	Mucinous
Usual stage at diagnosis	Early or advanced	Advanced	Early	Early	Early
Presumed tissue of origin/precursor lesion	Serous borderline tumor	Fallopian tube or tubal metaplasia in inclusions of ovarian surface epithelium	Endometriosis, adenofibroma	Endometriosis, adenofibroma	Adenoma–borderline–carcinoma sequence; teratoma
Genetic risk	?	BRCA1/2	?	HNPCC	?
Significant molecular abnormalities	BRAF or K-ras	p53 and pRb pathways	HNF-1β	PTEN, β-catenin, K-ras MI	K-ras
Proliferation	Low	High	Low	Low	Intermediate
Response to primary chemotherapy	26%–28%	80%	15%	?	15%
Prognosis	Favorable	Poor	Intermediate	Favorable	Favorable

HNF-1β = hepatocyte nuclear factor-1β; HNPCC = hereditary nonpolyposis colon cancer.

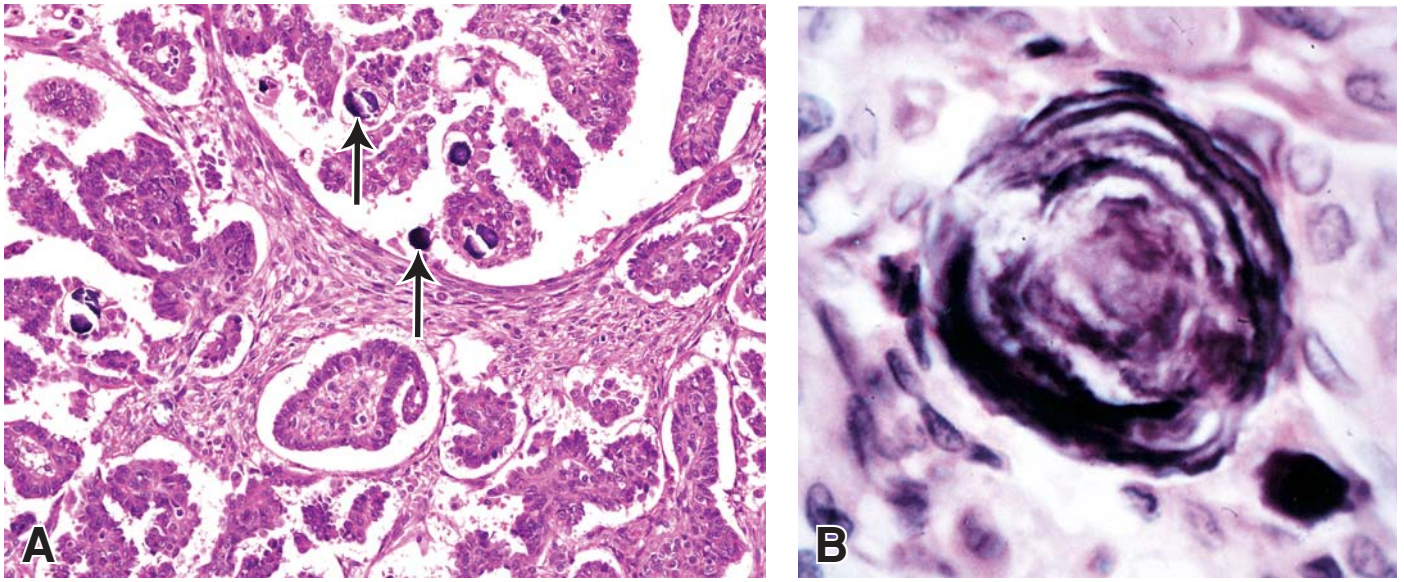

FIGURE 24-56. Low-grade serous carcinoma. A. The nests of tumor cells are disorderly distributed and appear surrounded by clefts. In contrast to high-grade serous carcinoma, the nuclei are low grade. Psammoma bodies (*arrows*) are seen. **B.** A higher-power view shows the laminated structure of a psammoma body.

carcinomas arising in patients with germline *BRCA1* or *BRCA2* mutations (hereditary ovarian cancers) are almost invariably the high-grade serous type and commonly have *p53* mutations. A significant number of *BRCA1*- or *BRCA2*-related tumors arise from epithelium of the fimbriated end of the fallopian tube, suggesting that at least some sporadic high-grade ovarian and "primary" peritoneal serous carcinomas may actually develop from the distal fallopian tube and "spill over" onto adjacent tissues.

PATHOLOGY: Low-grade serous carcinomas are characterized by irregular invasion of the ovary by small, tight nests of tumor cells with variable desmoplasia (Fig. 24-56). Nuclear uniformity is the principal criterion for distinguishing low- and high-grade serous carcinomas. Low-grade serous carcinomas rarely progress to high-grade tumors.

High-grade serous carcinomas (often called "cystadenocarcinoma") are mainly solid, multinodular masses, usually with necrosis and hemorrhage (Fig. 24-57A). Once a tumor has reached 10–15 cm, it has often spread beyond the ovary and seeded the peritoneum. Two thirds of serous cancers with extraovarian spread are bilateral. High-grade serous cancers typically show obvious stromal invasion. Most tumors have a high nuclear grade with irregularly branching, highly cellular papillae with little or no stromal support and slit-like glandular lumens within more solid areas (Fig. 24-57B). The mitotic rate is very high. Psammoma bodies are often present.

MUCINOUS ADENOCARCINOMA:

MOLECULAR PATHOGENESIS: Mucinous ovarian tumors are often heterogeneous. Benign, borderline, noninvasive and invasive carcinoma components may coexist within the same tumor. Such a morphologic continuum suggests progression from cystadenoma

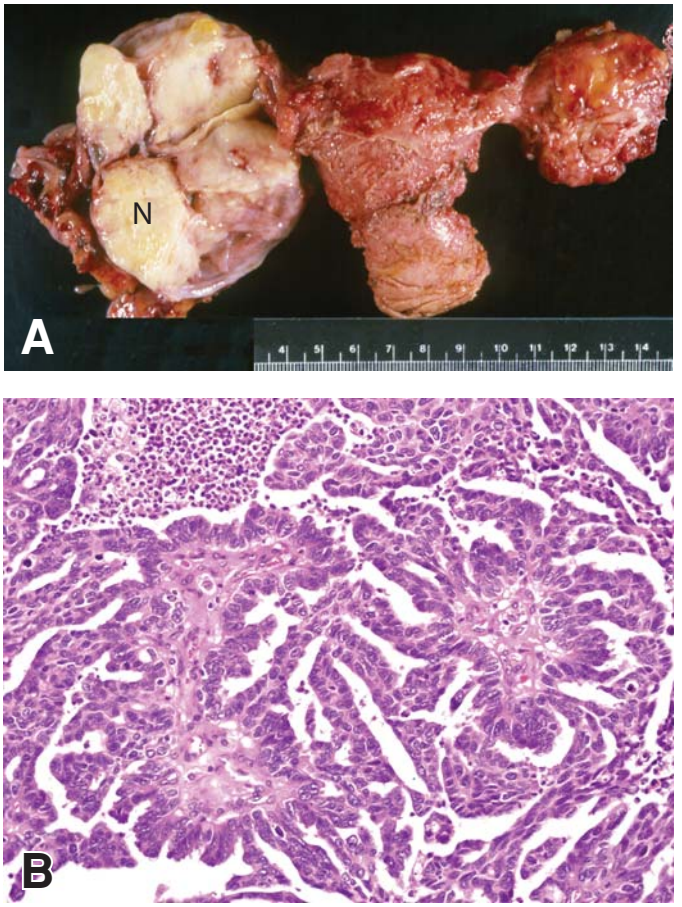

FIGURE 24-57. High-grade serous cystadenocarcinoma. A. In addition to cysts (*left*), the ovary is enlarged by a solid tumor that exhibits extensive necrosis (N). **B.** Microscopic examination shows complex papillae, lined by atypical nuclei, forming glomeruloid structures.

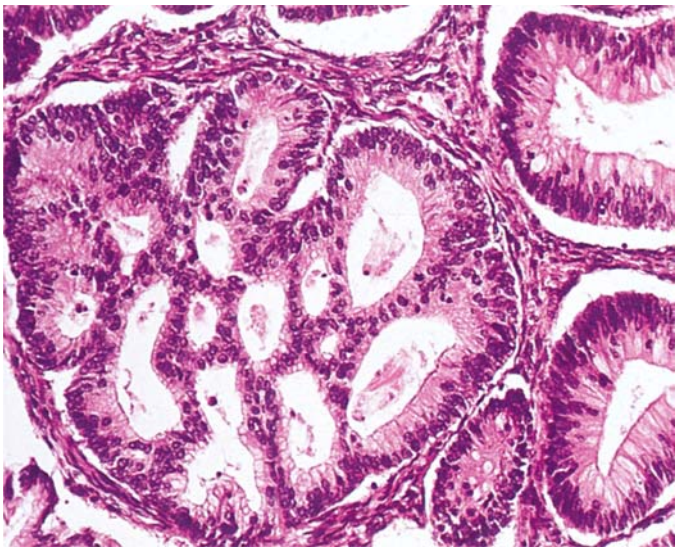

FIGURE 24-58. Mucinous cystadenocarcinoma. The malignant glands are arranged in a cribriform pattern and are composed of mucin-producing columnar cells.

and borderline tumor to noninvasive, microinvasive and invasive carcinomas. This hypothesis is supported by a similar progression in the incidence of *KRAS* mutations in mucinous tumors: 56% of cystadenomas and 85% of carcinomas express mutated *KRAS,* with borderline tumors being intermediate.

PATHOLOGY: Mucinous carcinomas are usually large, unilateral, multilocular or unilocular cystic masses containing mucinous fluid. They often include papillary and solid areas that may be soft and mucoid or firm, hemorrhagic and necrotic. Since these tumors are bilateral in only 5% of cases, finding bilateral or unilateral mucinous tumors smaller than 10 cm raises suspicion of metastatic mucinous carcinoma from the gastrointestinal tract or elsewhere.

The category of mucinous borderline tumor with intraepithelial carcinoma is reserved for tumors that lack architectural features of invasive carcinoma but focally show unequivocal malignant cells lining glandular spaces. Mucinous borderline tumors with intraepithelial carcinoma have a very low likelihood of recurrence.

Mucinous adenocarcinomas may be further subdivided into (1) **expansile** or **confluent glandular pattern,** lacking destructive stromal invasion (Fig. 24-58) but there are back-to-back or complex malignant glands have minimal or no intervening stroma, and (2) **infiltrative,** with obvious glandular stromal invasion. The expansile pattern appears to have a more favorable prognosis than the infiltrative type. The combination of extensive, infiltrative stromal invasion; high nuclear grade; and tumor rupture should be considered a strong predictor of recurrence for stage I mucinous adenocarcinomas.

Pseudomyxoma peritonei is a clinical condition of abundant gelatinous or mucinous ascites in the peritoneum, fibrous adhesions and frequently mucinous tumors involving the ovaries. The appendix is involved by a similar mucinous tumor in 60% of the cases and appears normal in the remaining 40%. In most cases, the ovarian tumors are metastases from the appendiceal lesions. Concordant *KRAS* mutations have been found in both the appendiceal and ovarian tumors of individual patients.

ENDOMETRIOID ADENOCARCINOMA: Endometrioid adenocarcinoma histologically resembles its endometrial counterpart (Fig. 24-59A), may have areas of squamous differentiation and is second only to serous adenocarcinoma in frequency. It accounts for 10% of all ovarian cancers. These tumors occur most commonly after menopause. Unlike serous and mucinous neoplasms, most endometrioid tumors are malignant. Up to one half of these cancers are bilateral and, at diagnosis, most tumors are confined either to the ovary or within the pelvis.

MOLECULAR PATHOGENESIS: Endometrioid carcinomas are thought to arise by malignant transformation of endometriosis, and not ovarian surface epithelium (Fig. 24-59B). AT-rich interactive domain 1A gene (*ARID1A*) mutations have been implicated not only in endometrioid and clear cell carcinomas but also in adjacent endometriosis. *ARID1A* behaves as a tumor suppressor. Lack

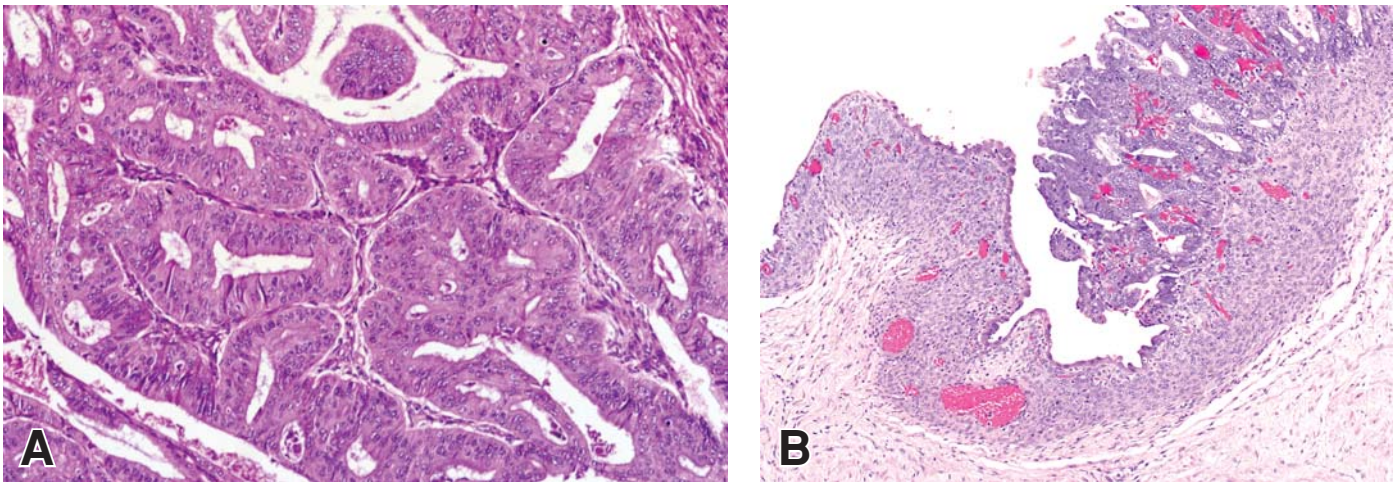

FIGURE 24-59. Endometrioid adenocarcinoma. A. The crowded neoplastic glands are lined by stratified non–mucin-containing epithelium. Nuclear atypia is moderate to severe. **B.** Endometrioid adenocarcinoma (*right*) arising in endometriosis. Note the stromal cells of endometriosis.

of expression of the BAF250 protein, encoded by *ARID1A*, may increase risk of developing clear cell or endometrioid ovarian cancer. Other common genetic abnormalities in sporadic endometrioid carcinoma of the ovary are somatic mutations of β-catenin (*CTNNB1*) and *PTEN* genes and microsatellite instability. Endometrioid borderline tumors also have β-catenin mutations.

PATHOLOGY: Endometrioid carcinomas vary from 2 cm to more than 30 cm. Most are largely solid with areas of necrosis, although they may be cystic. Endometrioid tumors are graded like their endometrial counterparts. Between 15% and 20% of patients with endometrioid carcinoma of the ovary also harbor an endometrial cancer. If ovarian and endometrial cancers coexist, they generally arise independently, although one may be metastatic from the other. This distinction has important prognostic implications. Various molecular methods including loss of heterozygosity (LOH), gene mutation and clonal X-inactivation analysis can be helpful. The 5-year survival exceeds 85% in synchronous tumors. As with all malignant epithelial tumors of the ovary, prognosis depends on the stage at which it presents.

CLEAR CELL ADENOCARCINOMA: This enigmatic ovarian cancer is closely related to endometrioid adenocarcinoma and often occurs in association with endometriosis (Fig. 24-60A). It constitutes 5%–10% of all ovarian cancers usually occurring after menopause.

Roughly half of clear cell carcinomas (46%–57%) carry *ARID1A* mutations and lack BAF250 protein. Other common genetic abnormalities are inactivating *PTEN* mutations and activating *PIK3CA* mutations. Hepatocyte nuclear factor-1β (HNF-1β) regulates several specific genes in clear cell carcinoma, including dipeptidyl peptidase IV (glycogen synthesis), osteopontin (progesterone-regulated endometrial secretory protein), angiotensin-converting enzyme 2 (ferritin induction, iron deposition, antiapoptosis), annexin 4 (paclitaxel resistance) and UGT1A1 (detoxification).

Although patients typically present with stage I or II disease, clear cell carcinomas have a poor prognosis compared with other low-stage ovarian carcinomas. Tumors range in size from 2 to 30 cm, and 40% are bilateral. Most are partially cystic and show necrosis and hemorrhage in the solid areas.

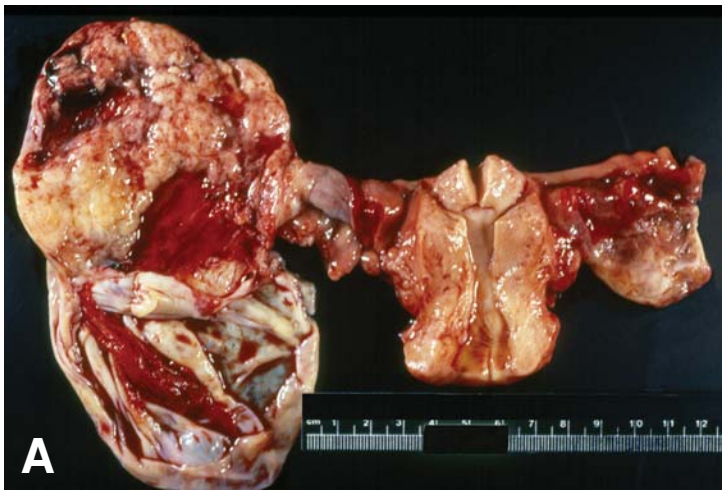
Clear cell ovarian adenocarcinomas resemble their counterparts in the vagina and have sheets or tubules of malignant cells with clear cytoplasm (Fig. 24-60B). In the tubular form, malignant cells often display bulbous nuclei that protrude into the lumen of the tubule ("hobnail cell"), resembling an Arias-Stella reaction in gestational endometrium (Fig. 24-28). The clinical course parallels that of endometrioid carcinoma.

CLINICAL FEATURES: Most ovarian tumors do not secrete hormones. However, the cancer antigen, CA-125, is detectable in the serum in about half of epithelial tumors confined to the ovary and about 90% that have spread. The specificity of this test is highest when combined with transvaginal ultrasonography.

Ovarian masses rarely produce symptoms until they become large and distend the abdomen to cause pain, pelvic pressure or compression of regional organs. By the time ovarian cancers are diagnosed, many have metastasized to (i.e., implanted on) the surfaces of the pelvis, abdominal organs or bladder. Evaluation of a patient with an epithelial ovarian cancer requires knowledge of staging, grading and routes of tumor spread. For example, ovarian tumors have a tendency to implant in the peritoneal cavity on the diaphragm, paracolic gutters and omentum. Lymphatic spread preferentially involves para-aortic lymph nodes near the origin of the renal arteries and to a lesser extent to external iliac (pelvic) or inguinal lymph nodes. In addition to local symptoms, metastatic cancers may cause ascites, weakness, weight loss and cachexia.

Survival in patients with malignant ovarian tumors is generally poor. The most important prognostic index is the surgical stage of the tumor at the time of detection (Table 24-9). Overall, 5-year survival is only 35%, because more than half of tumors have spread to the abdominal cavity (stage III) or elsewhere by the time they are discovered. Prognostic indices for epithelial tumors also include grade, histologic type and the size of the residual neoplasm.

Surgery, which removes the primary tumor, establishes the diagnosis and determines the extent of spread, is the mainstay of therapy. The peritoneal surfaces, omentum, liver, subdiaphragmatic recesses and all abdominal regions



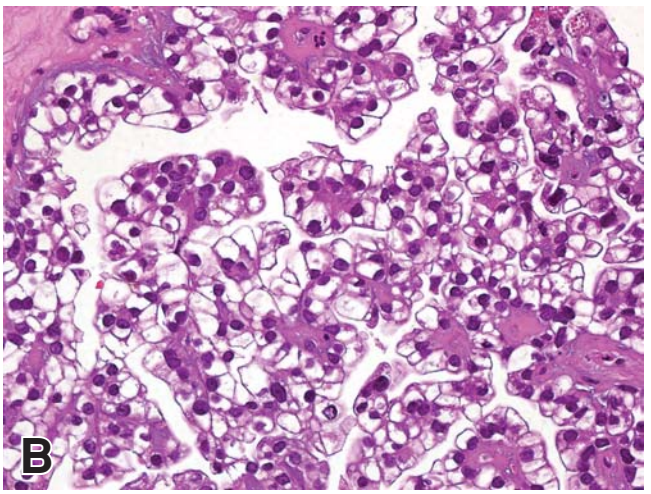


FIGURE 24-60. Clear cell adenocarcinoma. A. Clear cell adenocarcinoma arising as an ovarian mass in a large, hemorrhagic endometriotic cyst. **B.** The clear cells are polyhedral and have eccentric, hyperchromatic nuclei without prominent nucleoli.

must be visualized, and as much metastatic tumor removed as possible. Adjuvant chemotherapy is used to treat distant occult sites of tumor spread.

At some time after the initial operation, another exploratory (second-look) laparotomy may be used to assess effectiveness of therapy. Even if no residual disease is apparent, one third of older patients still develop recurrences. Risk factors for recurrence are (1) high stage, (2) high grade and (3) more than 2 cm of residual disease remaining after the primary operation.

Germ Cell Tumors Tend to Be Benign in Adults and Malignant in Children

Tumors derived from germ cells make up 1/4 of ovarian tumors. In adult women, ovarian germ cell tumors are virtually all benign (mature cystic teratoma, dermoid cyst), but in children and young adults, they are largely cancerous. ***In children, germ cell tumors are the most common ovarian cancer (60%); they are rare after menopause.***

Neoplastic germ cells may differentiate along several lines (Fig. 24-61):

- **Dysgerminomas** are composed of neoplastic germ cells, similar to oogonia of fetal ovaries.
- **Teratomas** differentiate toward somatic (embryonic or adult) tissues.
- **Yolk sac tumors** form extraembryonic endodermal and mesenchymal tissue.
- **Choriocarcinomas** feature cells similar to those covering the placental villi.

Germ cell tumors in infants tend to be solid and immature (e.g., yolk sac tumor and immature teratoma). Tumors in young adults show greater differentiation, as in mature cystic teratoma. Malignant germ cell tumors in women older than 40 years usually result from transformation of a component of a benign cystic teratoma.

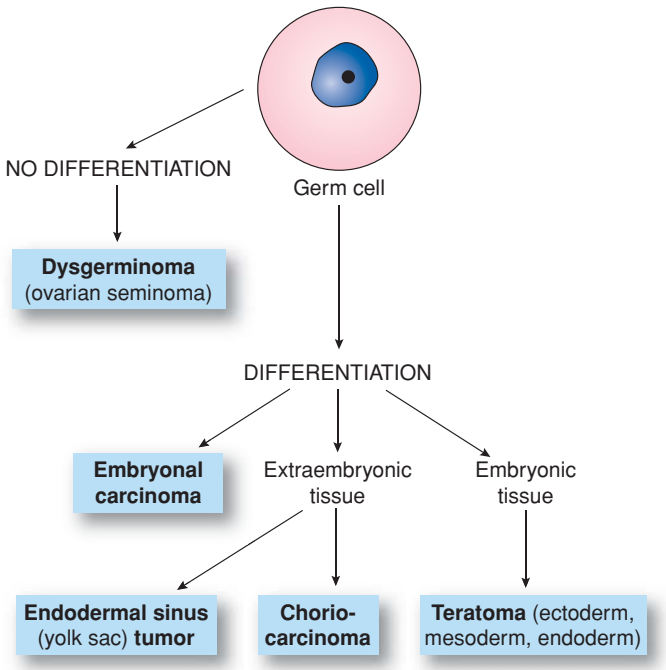

FIGURE 24-61. Classification of germ cell tumors of the ovary.

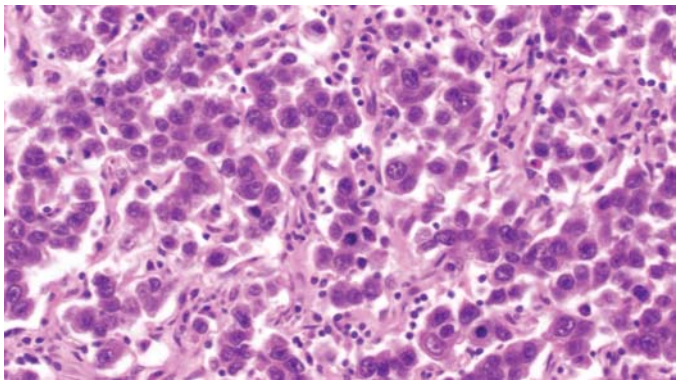

FIGURE 24-62. Dysgerminoma. The neoplastic germ cells are distributed in nests separated by delicate fibrous septa. The stroma contains lymphocytes.

Malignant germ cell tumors are very aggressive. Solid ovarian germ cell tumors were once always fatal, but now over 80% of patients survive with chemotherapy.

Dysgerminoma

Dysgerminoma, the ovarian counterpart of testicular seminoma, is composed of primordial germ cells. It accounts for less than 2% of ovarian cancers in all women, but constitutes 10% in women younger than 20 years. Most patients are between 10 and 30. The tumors are bilateral in about 15% of cases.

PATHOLOGY: Dysgerminomas are often large and firm and have a bosselated external surface. The cut surface is soft and fleshy. They contain large nests of monotonously uniform tumor cells that have clear glycogen-filled cytoplasm and irregularly flattened central nuclei (Fig. 24-62). Fibrous septa containing lymphocytes traverse the tumor.

Dysgerminomas are treated surgically; 5-year survival for patients with stage I tumor approaches 100%. Because the tumor is highly radiosensitive and also responsive to chemotherapy, even higher-stage tumors have 5-year survival rates exceeding 80%.

Teratoma

Teratoma is a tumor of germ cell origin that differentiates toward somatic structures. Most contain tissues from at least two, and usually all three, embryonic layers.

MATURE TERATOMA (MATURE CYSTIC TERATOMA, DERMOID CYST): This benign neoplasm accounts for 1/4 of all ovarian tumors, with peak incidence in the third decade. Mature teratomas develop by **parthenogenesis**. Haploid (postmeiotic) germ cells endoreduplicate to give rise to diploid genetically female tumor cells (46,XX).

PATHOLOGY: Mature teratomas are cystic and almost all contain skin, sebaceous glands and hair follicles (Fig. 24-63). Half have smooth muscle, sweat glands, cartilage, bone, teeth and respiratory epithelium. Other tissues, like gut, thyroid and brain, are seen less often. If present, nodular foci in the cyst wall ("mammary tubercles" or "Rokitansky nodules") contain tissue elements of all three germ cell layers: (1) ectoderm (e.g., skin, glia), (2) mesoderm (e.g., smooth muscle, cartilage) and (3) endoderm (e.g., respiratory epithelium).

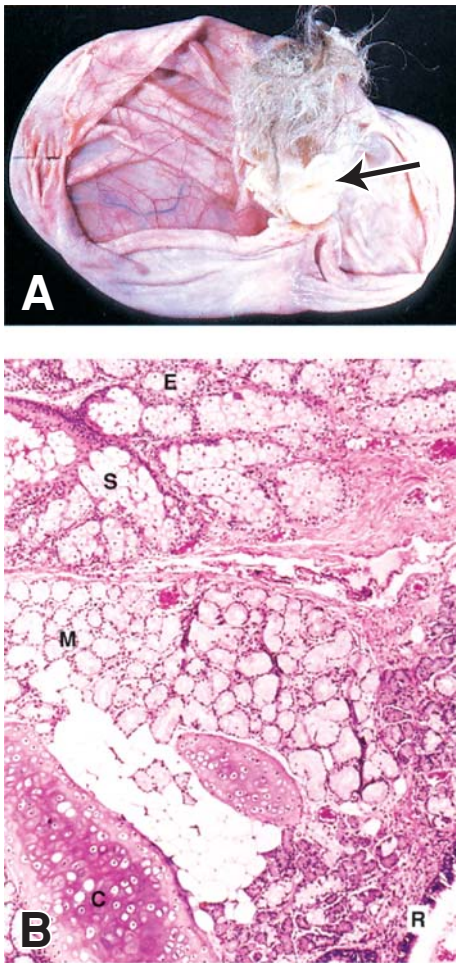

FIGURE 24-63. Mature cystic teratoma of the ovary. A. A mature cystic teratoma has been opened to reveal a solid knob (*arrow*) from which hair projects. **B.** A photomicrograph of the solid knob shows epidermal and respiratory components. Tissue resembling the skin exhibits an epidermis (E) with underlying sebaceous glands (S). The respiratory tissue consists of mucous glands (M), cartilage (C) and respiratory epithelium (R).

Struma ovarii is a cystic lesion with mainly thyroid tissue (5%–20% of mature cystic teratomas). Rarely hyperthyroidism has occurred with struma ovarii.

Very few (1%) dermoid cysts become malignant. These cancers usually occur in older women and correspond to the tumors that arise in other differentiated tissues of the body. Three fourths of cancers that arise in dermoid cysts are squamous cell carcinomas. The remainder are carcinoid tumors, basal cell carcinomas, thyroid cancers and others. Rarely, functional gut derivatives may cause carcinoid syndrome. The prognosis of patients with malignancies in mature cystic teratoma is related largely to the stage of the cancer.

IMMATURE TERATOMA: Immature teratomas of the ovary contain elements derived from the three germ layers. However, unlike mature cystic teratomas, immature teratomas contain embryonal tissues. These tumors account for 20% of malignant tumors at all sites in women under the age of 20 but become progressively less common in older women.

PATHOLOGY: Immature teratomas are predominantly solid and lobulated, with numerous small cysts. Solid areas may contain grossly recognizable immature bone and cartilage. Multiple tumor components are usually seen, including those differentiating toward nerve (neuroepithelial rosettes and immature glia) (Fig. 24-64), glands and other structures found in mature cystic teratomas. Grading is based on the amount of immature tissue present. Metastases of immature teratomas are composed of embryonal, usually stromal, tissues. By contrast, rare metastases of mature cystic teratomas resemble epithelial adult-type malignancies.

Survival reflects tumor grade. Well-differentiated immature teratomas have a good prognosis, but high-grade tumors (mainly embryonal tissue) are often lethal.

FIGURE 24-64. Immature teratoma of the ovary. Immature neural tissue exhibits rosettes (R) with multilayered nuclei. Embryonal glia (G) display densely packed, atypical nuclei.

Yolk Sac Tumor (Primitive Endodermal Tumor)

Yolk sac tumors are highly malignant tumors of women under the age of 30 that histologically resemble mesenchyme of the primitive yolk sac. They are the second most common malignant germ cell tumors and are almost always unilateral.

PATHOLOGY: Yolk sac tumors are large, with extensive necrosis and hemorrhage. Several patterns are seen. The most common is a reticular, honeycombed structure of communicating spaces lined by primitive epithelial cells with glycogen-rich, clear cytoplasm and large hyperchromatic nuclei (primitive endoderm). Glomerular or **Schiller-Duval bodies** (Fig. 24-65A) are found sparingly in a few tumors but are characteristic. They consist of papillae that protrude into a space lined by tumor cells, resembling the glomerular Bowman space. The papillae are covered by a mantle of embryonal cells and contain a fibrovascular core and a central blood vessel.

Yolk sac tumor should not be confused with embryonal cell carcinoma, which is common in the testis. The former secretes α-fetoprotein, which can be demonstrated histochemically (Fig. 24-65B). Detection of α-fetoprotein in the blood is useful for diagnosis and for monitoring the effectiveness of therapy. Although once uniformly fatal, 5-year survival with chemotherapy for stage I yolk sac tumors now exceeds 80%.

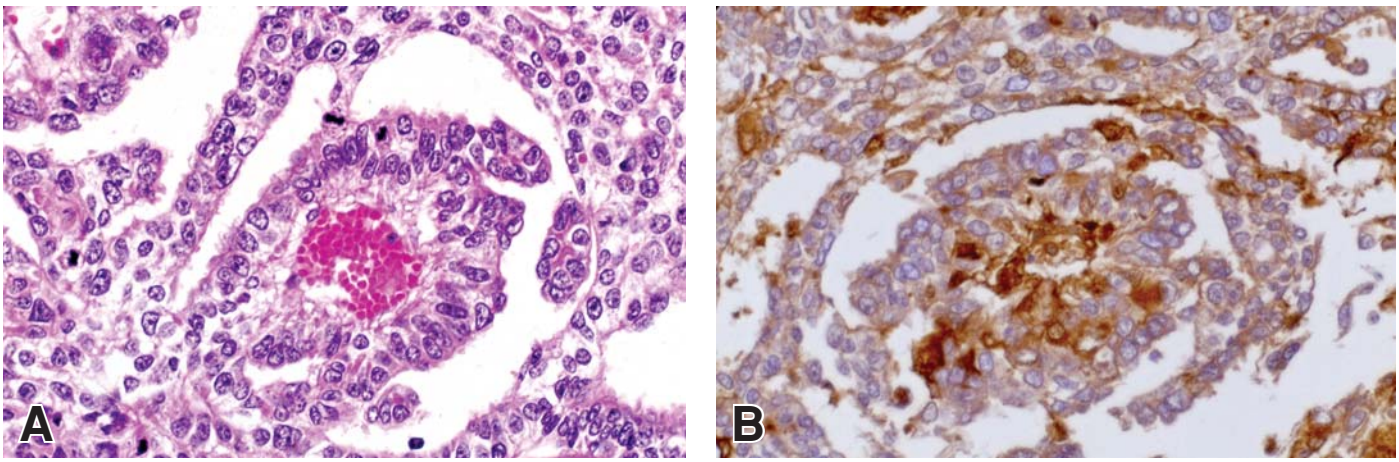

FIGURE 24-65. Yolk sac tumor of the ovary. A. Glomeruloid Schiller-Duval body that resembles the endodermal sinuses of the rodent placenta and consists of a papilla protruding into a space lined by tumor cells. **B.** Strong immunoreaction for α-fetoprotein.

Choriocarcinoma

Choriocarcinoma of the ovary is a rare tumor that mimics the epithelial covering of placental villi, namely, cytotrophoblast and syncytiotrophoblast. If it arises before puberty or together with another germ cell tumor, it most likely is of germ cell origin. Young girls may show precocious sexual development, menstrual irregularities or rapid breast enlargement. In women of reproductive age, however, it may also be a metastasis from an intrauterine gestational tumor.

PATHOLOGY: Choriocarcinoma is unilateral, solid and widely hemorrhagic. Microscopically, it shows a mixture of malignant cytotrophoblast and syncytiotrophoblast (see placenta, choriocarcinoma, below). The syncytial cells secrete hCG, which accounts for the frequent finding of a positive pregnancy test result. Bilateral theca lutein cysts, a result of hCG stimulation, may also be found. Serial serum hCG determinations are useful both for diagnosis and follow-up. The tumor is highly aggressive but responds to chemotherapy.

Gonadoblastoma

Gonadoblastoma is a rare ovarian tumor that is distinctively associated with gonadal dysgenesis, especially in women who bear a Y chromosome. It occurs in phenotypic women under 30 years of age, although 20% are found in phenotypic men with cryptorchidism, hypospadias and female internal sex organs. Most affected women are virilized and suffer from primary amenorrhea and developmental abnormalities of the genitalia. Cellular nests show a mixture of germ cells and sex cord derivatives that resemble immature Sertoli and granulosa cells, suggesting that the tumor is an in situ form of germinoma. In half of cases, it is overgrown by dysgerminoma. Gonadoblastomas do not metastasize, but their overgrowths do.

Sex Cord/Stromal Tumors Are Clinically Functional

Tumors of sex cord and stroma originate from either primitive sex cords or from mesenchymal stroma of developing gonads. They represent 10% of ovarian tumors, vary from benign to low-grade malignant and may differentiate toward female (granulosa and theca cells) or male (Sertoli and Leydig cells) structures.

Fibroma

Fibromas account for 75% of all stromal tumors and 7% of all ovarian tumors. They occur at all ages, peaking in the perimenopausal period, and are almost always benign.

PATHOLOGY: Tumors are solid, firm and white (Fig. 24-66). The cells resemble the stroma of the normal ovarian cortex, being well-differentiated spindle cells, with variable amounts of collagen. Half of the larger tumors are associated with ascites and, rarely, with ascites and pleural effusions **(Meigs syndrome)**.

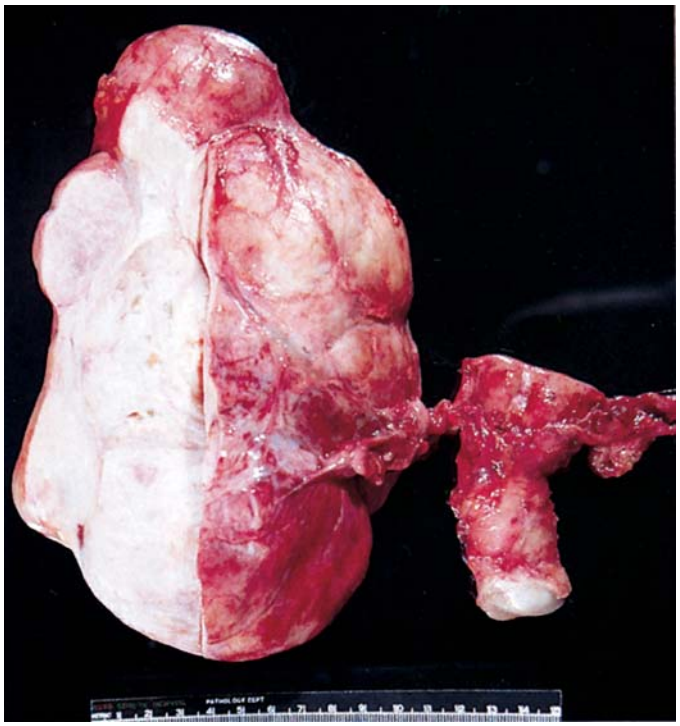

FIGURE 24-66. Fibroma of the ovary. The ovary is conspicuously enlarged by a firm, white, bosselated tumor.

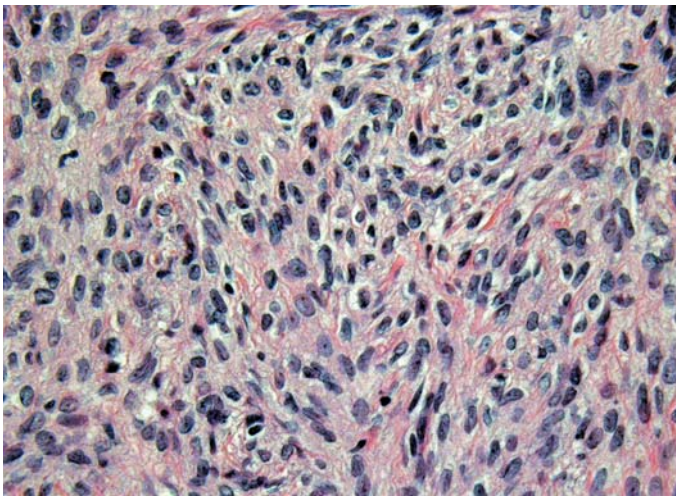

FIGURE 24-67. Thecoma of the ovary. Oblong cells are invested by collagen. The cytoplasm contains lipid.

Thecoma

Thecomas are functional ovarian tumors of postmenopausal women and are almost always benign. They are closely related to fibromas, but additionally contain varying amounts of steroidogenic cells that in many cases produce estrogens or androgen.

PATHOLOGY: Thecomas are solid, mostly 5–10 cm in diameter. Cut section is yellow, owing to the many lipid-laden theca cells, which are large and oblong to round, with lipid-rich vacuolated cytoplasm (Fig. 24-67). Bands of hyalinized collagen separate nests of theca cells.

Because they produce estrogen, thecomas in premenopausal women may cause irregular menstrual cycles and breast enlargement. Endometrial hyperplasia and cancer are well-recognized complications.

Granulosa Cell Tumor

Granulosa cell tumors are the prototypical functional neoplasms of the ovary associated with estrogen secretion. They should be considered malignant because of their potential for local spread and the rare occurrence of distant metastases.

ETIOLOGIC FACTORS: Most granulosa cell tumors occur after menopause (adult form) and are unusual before puberty. A juvenile form in children and young women has distinct clinical and pathologic features (hyperestrinism and precocious puberty). Development of granulosa cell tumors is linked to loss of oocytes. Oocytes appear to regulate granulosa cells, and tumorigenesis occurs when follicles are disorganized or atretic.

PATHOLOGY: Adult-type granulosa cell tumors, like most ovarian tumors, are large and focally cystic to solid. The cut surface shows yellow areas, owing to lipid-rich luteinized granulosa cells, white zones of stroma and focal hemorrhages (Fig. 24-68). Granulosa cell tumors show diverse growth patterns: (1) diffuse (sarcomatoid), (2) insular (islands of cells) or (3) trabecular (anastomotic bands of granulosa cells). Random nuclear arrangement about a central degenerative space **(Call-Exner bodies)** gives a characteristic follicular pattern (Fig. 24-68B). Tumor cells are typically spindle shaped and have a cleaved, elongated nucleus (coffee bean appearance). They secrete **inhibin,** a protein that suppresses pituitary release of follicle-stimulating hormone (FSH). These tumors can also express **calretinin,** a primarily neuronal protein, which suggests possible neural differentiation or derivation for these neoplasms.

CLINICAL FEATURES: ***Three fourths of granulosa cell tumors secrete estrogens.*** Thus, endometrial hyperplasia is a common presenting sign. EIN or endometrial adenocarcinoma may develop if a functioning granulosa cell tumor remains undetected. At diagnosis,

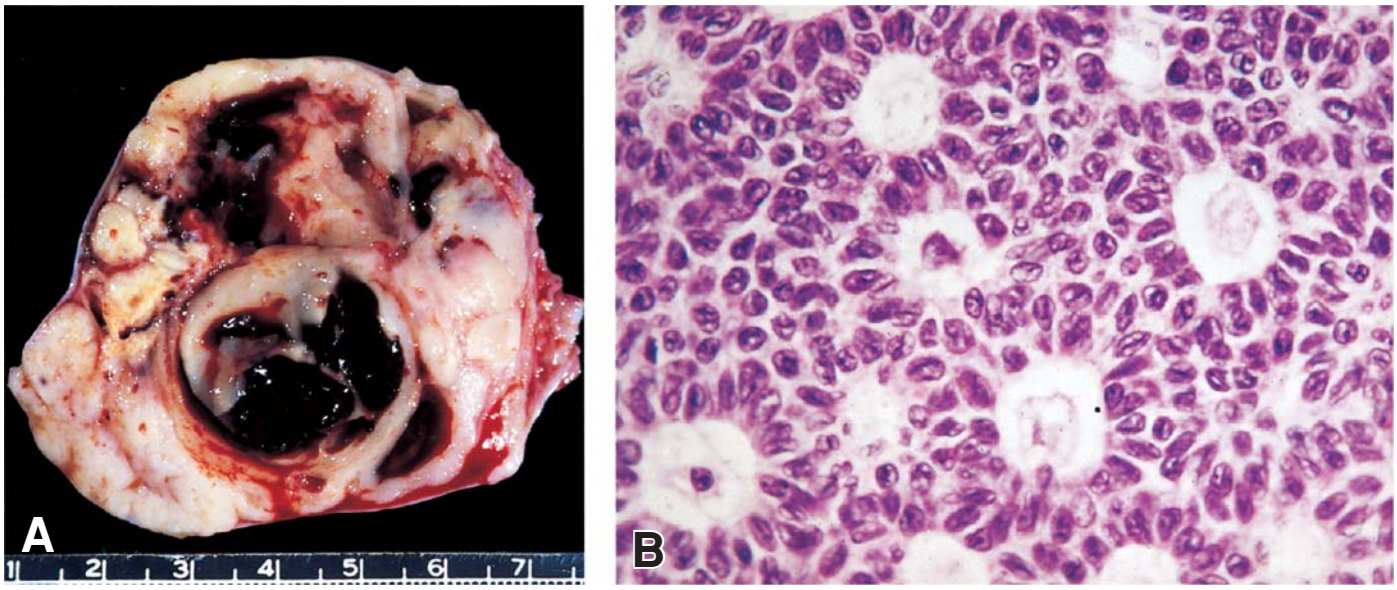

FIGURE 24-68. Granulosa cell tumor of the ovary. A. Cross-section of the enlarged ovary shows a variegated solid tumor with focal hemorrhages. The yellow areas represent collections of lipid-laden luteinized granulosa cells. **B.** The orientation of tumor cells about central spaces results in the characteristic follicular pattern (Call-Exner bodies).

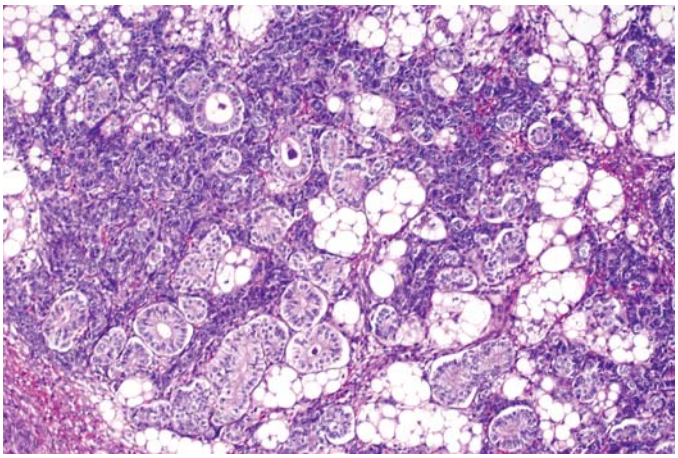

FIGURE 24-69. Sertoli-Leydig cell tumor, well differentiated. The hollow tubules are lined by mature Sertoli cells. The intervening stroma contains numerous Leydig cells with vacuolated cytoplasm.

90% of granulosa cell tumors are within the ovary (stage I). Over 90% of these patients survive 10 years. Tumors that have extended into the pelvis and lower abdomen have a poorer prognosis. Late recurrence 5–10 years after surgical removal is not uncommon and is usually fatal.

Sertoli-Leydig Cell Tumors

Ovarian Sertoli-Leydig cell tumors (**arrhenoblastoma** or **androblastoma**) are rare androgen-secreting mesenchymal neoplasms of low malignant potential that resemble embryonic testis. Tumor cells typically secrete weak androgens (dehydroepiandrosterone), so tumors are usually quite large before patients complain of masculinization. Sertoli-Leydig cell tumors occur at all ages but are most common in young women of childbearing age.

PATHOLOGY: Sertoli-Leydig cell tumors are unilateral, usually 5–15 cm, and tend to be lobulated, solid and brown to yellow. They vary from well to poorly differentiated and some contain heterologous elements (e.g., mucinous glands and, rarely, even cartilage). Large Leydig cells have abundant eosinophilic cytoplasm and a central round to oval nucleus with a prominent nucleolus. Tumor cells are embedded in a sarcomatoid stroma (Fig. 24-69). The stroma in some areas often differentiates into immature solid tubules of embryonic Sertoli cells.

CLINICAL FEATURES: Nearly half of all patients with Sertoli-Leydig cell tumors exhibit signs of virilization: hirsutism, male escutcheon, enlarged clitoris and deepened voice. Initial signs are often defeminization, manifested as breast atrophy, amenorrhea and loss of hip fat. Once the tumor is removed, these signs disappear or lessen. Well-differentiated tumors are virtually always cured by surgical resection, but poorly differentiated ones may metastasize.

Steroid Cell Tumor

Steroid cell tumors of the ovary, also called **lipid cell** or **lipoid cell tumors,** are composed of cells that resemble lutein cells, Leydig cells and adrenal cortical cells. Most steroid cell tumors are hormonally active, usually with androgenic manifestations. Some secrete testosterone; others synthesize weaker androgens. **Hilus cell tumor** is a specialized form of steroid cell tumor that is typically a benign neoplasm of Leydig cells. It arises in the hilus of the ovary, usually after menopause. Because it secretes testosterone, the most potent of the common androgens, masculinizing signs are frequent (75%), even with small tumors. Most hilus cell tumors contain "crystalloids of Reinke" (rod-like cytoplasmic structures).

Tumors Metastatic to the Ovary May Mimic a Primary Tumor

About 3% of cancers found in the ovaries arise elsewhere, mostly in the breast, large intestine, endometrium and stomach, in descending order. These tumors vary from microscopic lesions to large masses. Those from the breast are usually tiny and are seen in 10% of ovaries removed prophylactically in cases of advanced breast cancer. Metastatic tumors large enough to cause symptoms originate most often in the colon (Fig. 24-70). Commonly, the tumor cells

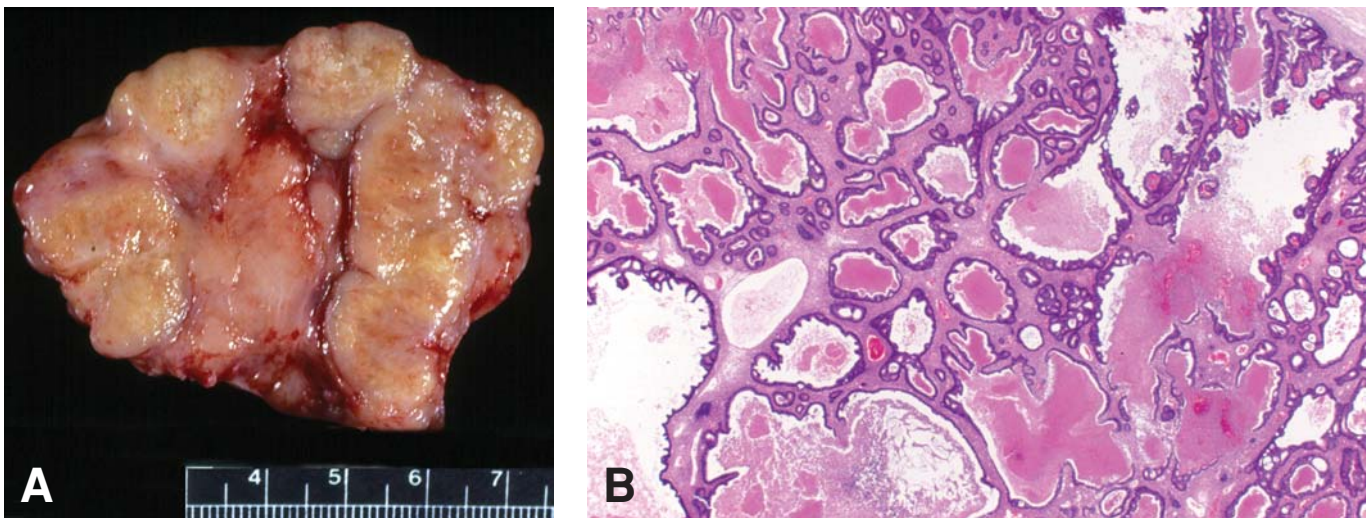

FIGURE 24-70. Metastatic adenocarcinoma from colon. A. The ovary is replaced by multinodular tumor. The sectioned surface appears solid. **B.** Microscopically, the tumor shows a garland-like glandular pattern with focal segmental necrosis and abundant necrotic debris.

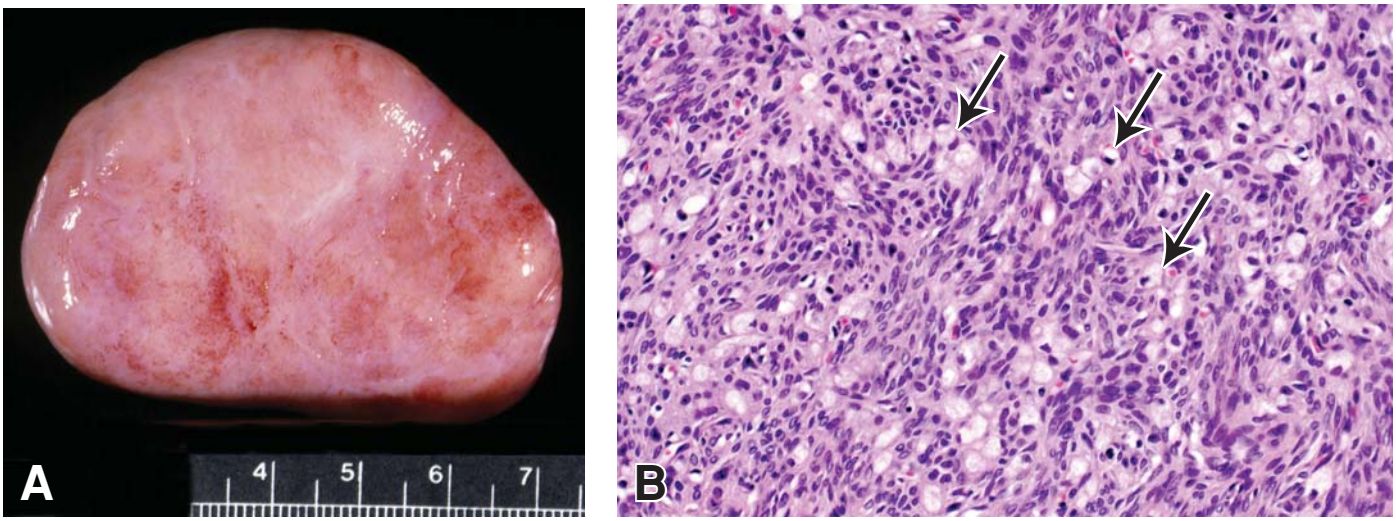

FIGURE 24-71. Krukenberg tumor. A. The ovary is enlarged and the cut surface appears solid, pale yellow and partially hemorrhagic. **B.** A microscopic section of **A** reveals mucinous (signet-ring) cells (clear cells, *arrows*) infiltrating the ovarian stroma.

stimulate ovarian stroma to differentiate into hormonally active cells (luteinized stromal cells), leading to androgenic and sometimes estrogenic symptoms.

Krukenberg tumors are metastases to the ovary, composed of nests of mucin-filled "signet-ring" cells in a cellular stroma derived from the ovary (Fig. 24-71). The stomach is the primary site in 75% of cases and most of the rest are from the colon.

Bilateral ovarian involvement and multinodularity suggest a metastatic carcinoma, and both ovaries are grossly involved in 75% of cases. Even an ovary that appears uninvolved grossly may contain surface implants or minute foci of tumor within the parenchyma. Thus, when metastasis to one ovary is documented, the other should also be removed.

Peritoneum

The peritoneum is a nearly continuous membrane that lines the peritoneal cavity and separates viscera from the abdominal wall. In men, the peritoneum is a closed system. In women, it is an "open system" interrupted in the pelvis by the fallopian tubes, which provide a final conduit for transmission of pathogens and chemicals from the genital tract to the peritoneal cavity.

The cells that line the peritoneal cavity and those that form the serosa of the ovary are both of celomic epithelial origin. ***Thus, it is not clear whether tumors and tumor-like lesions of peritoneum and ovary (i.e., müllerian epithelial lesions) are the same entity in both locations.***

Many inflammatory lesions involve the peritoneum. Granulomatous peritonitis develops as a response to foreign materials such as sutures, surgical glove powder or contrast media. Exposure to intestinal contents after perforation (e.g., in Crohn disease or diverticulitis); rupture of a mature cystic teratoma (dermoid cyst) of the ovary; and, of course, tuberculosis can also cause peritoneal inflammation. Reactive mesothelial proliferation occurs with the slightest irritation. Peritonitis is discussed in Chapter 19.

ENDOMETRIOSIS

Endometriosis is the presence of benign endometrial glands and stroma outside the uterus. It afflicts 5%–10% of women of reproductive age and regresses after natural or artificial menopause. The mean age at diagnosis is the late 20s to early 30s, although it may appear any time after menarche. Sites most frequently involved are the ovaries (>60%), other uterine adnexa (uterine ligaments, rectovaginal septum, pouch of Douglas) and the pelvic peritoneum covering the uterus, fallopian tubes, rectosigmoid colon and bladder (Fig. 24-72). Endometriosis can be even more widespread and occasionally affects the cervix, vagina, perineum, bladder and umbilicus. Even pelvic lymph nodes may contain foci of endometriosis. Rarely, distant areas such as lungs, pleura, small bowel, kidneys and bones contain lesions.

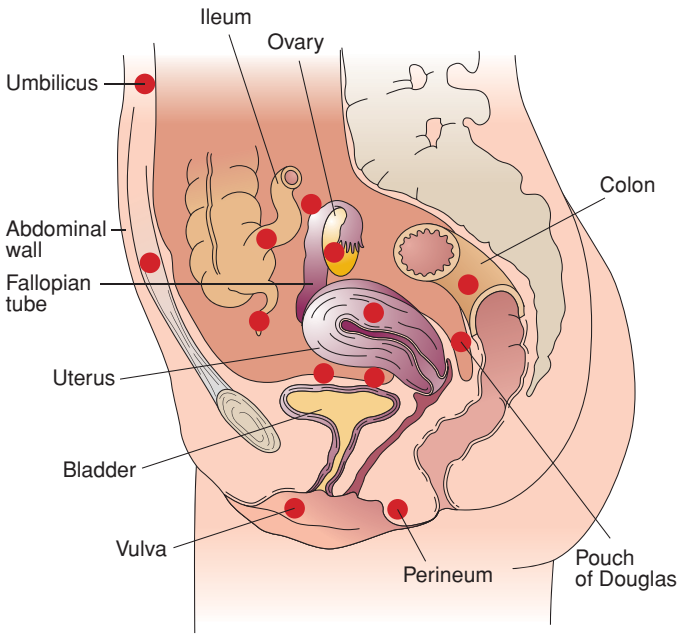

FIGURE 24-72. Sites of endometriosis.

PATHOPHYSIOLOGY: The pathogenesis of endometriosis is uncertain. Several theories, not necessarily mutually exclusive, are proposed:

1. **Transplantation** of endometrial fragments to ectopic sites
2. **Metaplasia** of the multipotential celomic peritoneum
3. **Induction** of undifferentiated mesenchyme in ectopic sites to form lesions after exposure to substances released from shed endometrium

TRANSPLANTATION: The most widely accepted theory holds that menstrual endometrium refluxes through the fallopian tubes and implants at ectopic sites. It is known that retrograde menstruation through the fallopian tubes occurs in 90% of women. A mechanism involving lymphatic and hematogenous dissemination would explain endometriosis in lymph nodes and at distant organ sites like the lungs and kidneys. The observation that pulmonary endometriosis occurs almost exclusively in women who have had uterine surgery supports this contention.

CELOMIC METAPLASIA: This theory proposes that endometriosis arises by endometrial metaplasia of peritoneal serosa or serosa-like structures. Thus, if appropriately stimulated, the pelvic peritoneum may differentiate into any type of müllerian epithelium.

INDUCTION THEORY: This concept suggests that something secreted by the endometrium makes endometrial epithelium and stroma develop in ectopic sites.

PATHOLOGY: The earliest lesions of endometriosis may be yellow-red stains, reflecting breakdown of blood products. Red lesions, which also occur early in the disease, are actively growing foci of endometriosis (Fig. 24-73). Operative specimens usually contain black lesions showing some degree of resolution. These 1–5-mm foci on the ovary and peritoneal surfaces are called "mulberry" nodules. With repeated cycles of hemorrhage and subsequent fibrosis, affected surfaces may scar and become grossly brown ("powder burns"). Over time, fibrous adhesions may become more pronounced and lead to complications, such as intestinal obstruction. Repeated hemorrhage in the ovaries may turn endometriotic foci into cysts up to 15 cm in diameter containing inspissated, chocolate-colored material ("chocolate cysts").

Endometriosis is characterized by ectopic normal endometrial glands and stroma (Fig. 24-73). Occasionally, healed foci may contain only fibrous tissue and hemosiderin-laden macrophages, which by themselves are not diagnostic. Immunohistochemical demonstration of CD-10 can be diagnostic.

CLINICAL FEATURES: Symptoms of endometriosis depend on where implants are located. Dysmenorrhea, caused by implants on uterosacral ligaments, is common. Lesions swell just before or during menstruation, producing pelvic pain. Half of women with dysmenorrhea have endometriosis. Other symptoms include dyspareunia and cyclical abdominal pain.

Infertility is the primary complaint in a third of women with endometriosis (Fig. 24-74). The hormonal milieu in a woman who does not achieve pregnancy encourages development of endometriosis. In turn, once endometriosis develops, it contributes to the infertile state and a vicious circle is established. Conversely, pregnancy may alleviate the disease. Conservative surgery to restore pelvic anatomy helps many women with endometriosis to become pregnant.

Malignancy occurs in about 1%–2% of cases of endometriosis (Fig. 24-60). Clear cell and endometrioid tumors are the most frequent forms. Adenosarcoma, although rare, is the most common sarcoma.

MESOTHELIAL TUMORS

Mesothelial tumors range from benign to multicentric aggressive malignancies.

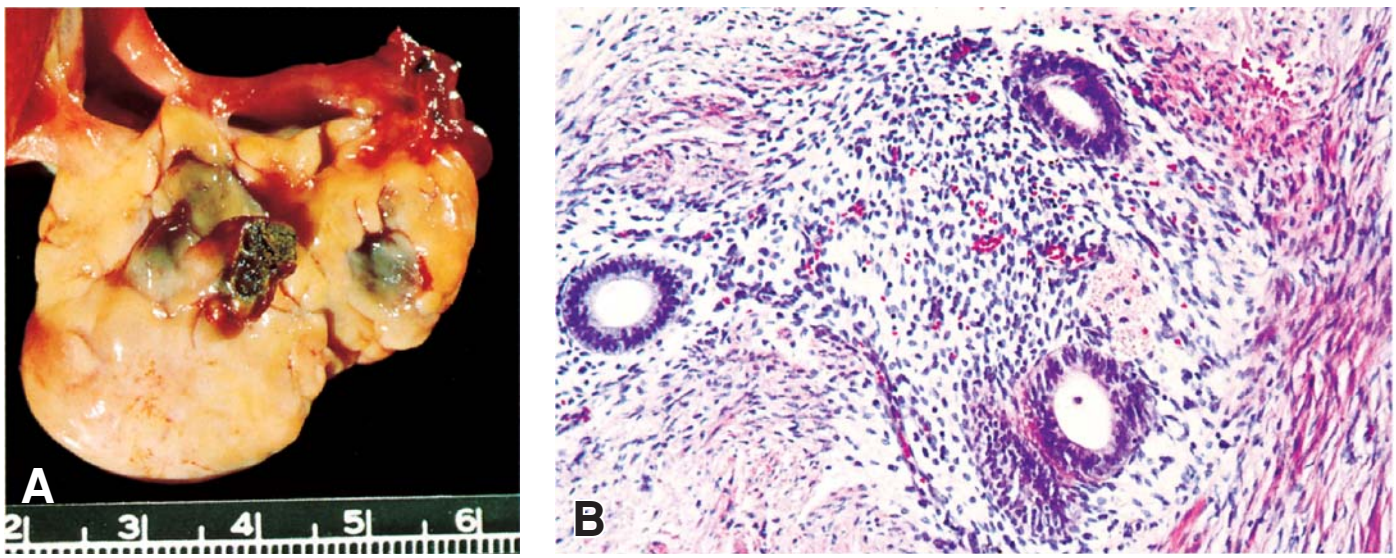

FIGURE 24-73. Endometriosis. A. Implants of endometriosis on the ovary appear as red-blue nodules. **B.** A microscopic section shows endometrial glands and stroma in the ovary.

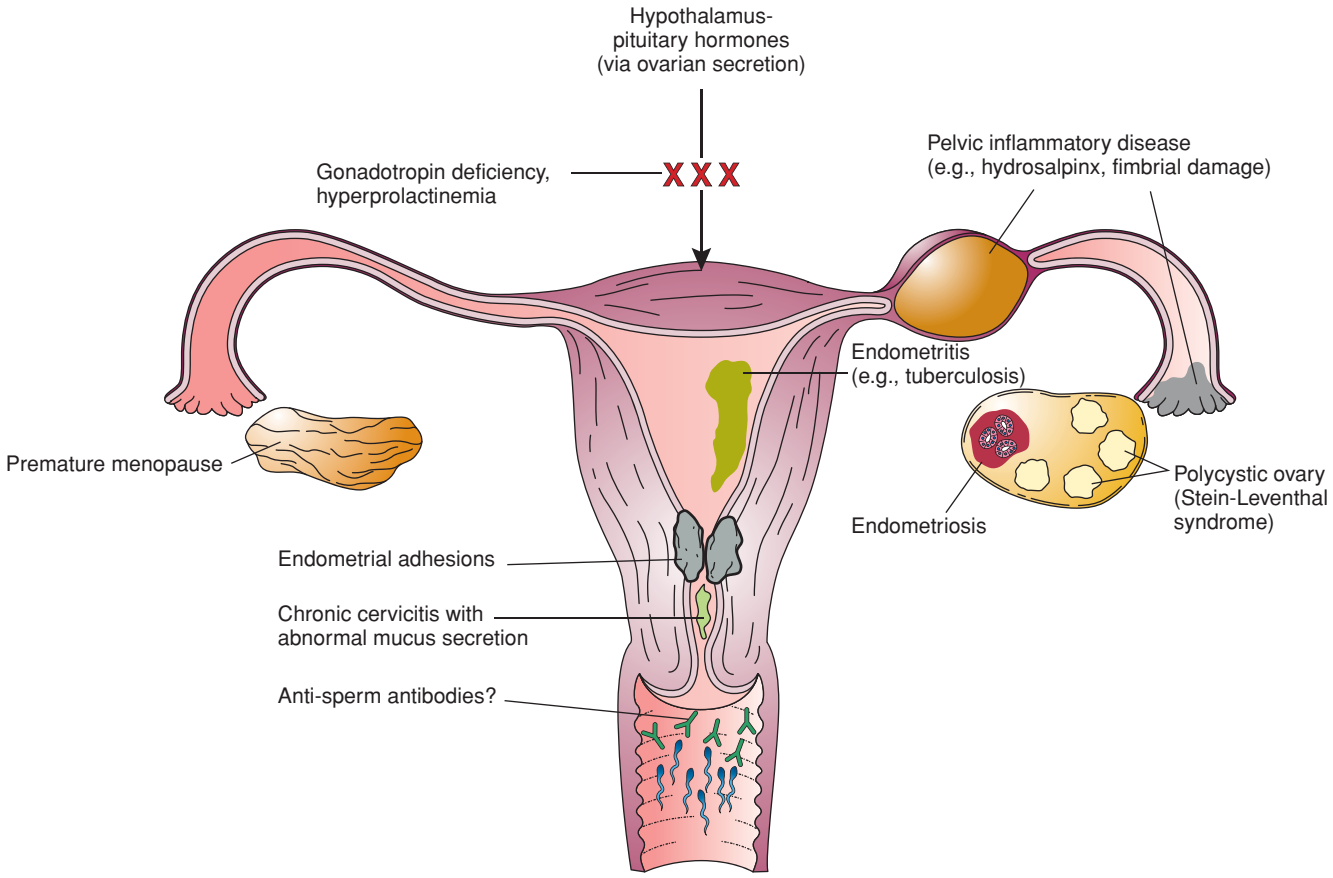

FIGURE 24-74. Causes of acquired infertility.

Adenomatoid Tumors Are Benign Mesothelial Neoplasms, Mainly of Fallopian Tubes

It is encountered in the fallopian tubes and in subserosal tissue of the uterine corpus near the fallopian tubes. It is rare elsewhere in the peritoneum.

Well-Differentiated Papillary Mesotheliomas Are Benign

Well-differentiated papillary mesotheliomas are rare in women of reproductive age. They are typically asymptomatic and usually found incidentally at operation. These tumors are solitary, small, broad-based, wart-like polypoid or nodular excrescences with a single layer of small bland cuboidal cells covering thick papillae (Fig. 24-75). They often resemble serous epithelial tumors of the ovary, but the two are treated differently.

Diffuse Peritoneal Malignant Mesotheliomas Are Invariably Fatal

These tumors arise from peritoneal mesothelium. They are rare in women and constitute only a small proportion of all malignant mesotheliomas, most of which are pleural. They must be distinguished from serous adenocarcinomas, including those arising from the peritoneal surface itself and those metastatic from the ovary, because they are treated differently and have much different survival rates. Most patients are middle-aged or postmenopausal with nonspecific symptoms such as ascites, abdominal discomfort, digestive disturbances and weight loss. Unlike pleural tumors, asbestos exposure is uncommon in women with peritoneal mesothelioma, but up to 2 million fibers per gram wet weight have been reported in some tumors.

PATHOLOGY: Diffuse malignant mesothelioma extensively involves and thickens the peritoneum and serosa of the various abdominal and pelvic

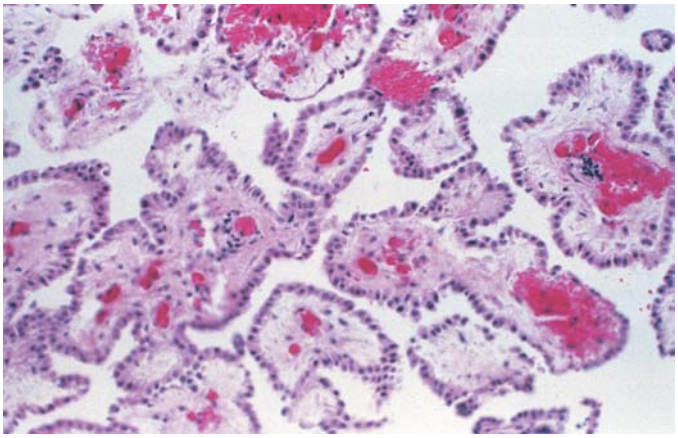

FIGURE 24-75. Well-differentiated peritoneal mesothelioma. Cuboidal epithelium lines papillae.

organs. It has a tubulopapillary to solid pattern. Unlike pleural mesothelioma, the sarcomatoid type is rare. The epithelial variant displays polygonal or cuboidal neoplastic cells with abundant cytoplasm. Thrombomodulin, calretinin, cytokeratin 5/6 and HBME-1 are markers of malignant mesothelioma, whereas CA-125, CEA and estrogen and progesterone receptors (ER and PR) are markers of ovarian epithelial tumors. No effective treatment is available.

SEROUS TUMORS (PRIMARY AND METASTATIC)

Unlike the ovary, which features a wide range of tumors, serous tumors are virtually the only type found in the peritoneum. Mucinous tumors in the peritoneum are metastases from a primary cancer of the appendix or ovary.

Serous Tumors of Borderline Malignancy Resemble the Corresponding Ovarian Neoplasms

Most serous borderline tumors in the peritoneum are metastases from the ovary, but some may be primary in the peritoneum. In the latter case, serous peritoneal tumors without invasion are usually benign; those that are invasive carry a worse prognosis.

PATHOLOGY: Whether in the ovary or the peritoneum, borderline serous tumors are characterized by papillary processes, small clusters of cells, cell stratification, detached cellular clusters, nuclear atypia and mitotic activity in the absence of invasion. Implants appear as fine granularities or small nodules with clusters of blunt papillae or glandular structures, often having complex cellular tufts (Fig. 24-76). Psammoma bodies are common and may fill the core of the papillae. Mild to severe cytologic atypia with some stratification is common but is substantially less than that seen in adenocarcinoma.

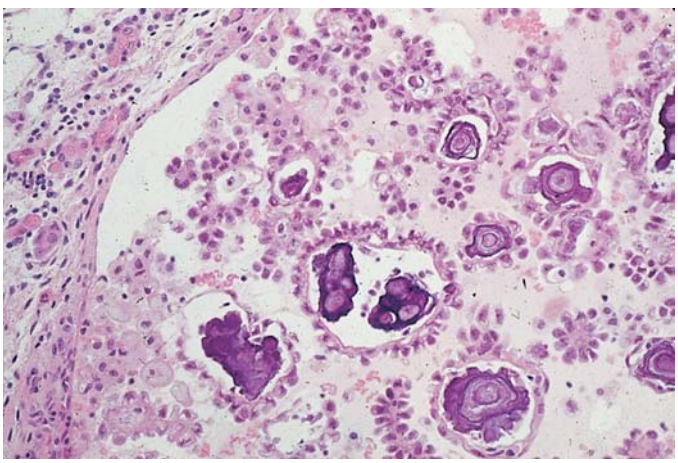

FIGURE 24-76. Noninvasive implants of borderline serous tumor on the peritoneum. The tumor exhibits epithelial tufts and psammoma bodies (compare to Fig. 24-56B).

Serous Adenocarcinoma Occurs in Women with Normal Ovaries

The frequency of serous adenocarcinoma arising de novo in the peritoneum is estimated as 10% of its counterpart in the ovary. The mean age of women with this tumor is 50–65 years. The diagnosis of a primary peritoneal tumor requires demonstration of normal ovaries. Abdominal pain and ascites are frequent presentations. Like ovarian cancer, serous adenocarcinoma primarily in the peritoneum may have a familial basis and can metastasize to distant locations.

PSEUDOMYXOMA PERITONEI

Pseudomyxoma peritonei is the accumulation of jelly-like mucus in the pelvis or peritoneum. Previously interpreted as spread from mucinous ovarian tumors, pseudomyxoma peritonei is now understood to derive largely from mucus-producing adenocarcinomas of the appendix.

PATHOLOGY: The condition may be extensive and appear as semisolid gelatin covering all abdominal structures, or there may be little more than a slightly thickened gelatinous coat over a focal area of bowel or omentum. The appendix is commonly enlarged or adherent to an omentum covered with the gelatinous material. Within the gelatin are strips of very well-differentiated, intestinal-type, mucinous epithelium (Fig. 24-77). If only isolated foci are present, the epithelium may be so well differentiated that it resembles a simple mucinous adenoma. Cribriform patterns or other histologic features of malignancy, such as signet-ring cells or glands, are seen on occasion and warrant a diagnosis of adenocarcinoma.

Low-grade tumors are usually treated for cure, which entails aggressive surgical debulking and intraperitoneal chemotherapy. The 5-year survival is under 50%.

DEVELOPMENT, ANATOMY AND PHYSIOLOGIC CHANGE

During embryologic development, the human breast first appears at about the 5th week, when ectodermal thickenings—the mammary ridges, or "milk lines"—extend from the axilla to the medial part of the thigh. Regression occurs except in the 4th intercostal space, where the breast will later develop. By the 9th week of gestation, solid epithelial cords grow from the epidermal layer into the underlying mesenchyme. From about the 20th to 32nd weeks of gestation, these solid cellular invaginations canalize and form a network of about 15–25 branching, primary, mammary ducts under the influence of maternal hormones. Near the end of gestation, the breast responds to maternal and placental steroid hormones and to prolactin. These produce secretory activity, and breast development may be transiently prominent in male and female newborns before returning to the inactive state. Further breast development accelerates at puberty, when ducts begin to elongate and branch (Fig. 25-1A). Estrogen and progesterone cause the terminal end buds and connective tissue stroma to proliferate, differentiate and remodel to form the terminal duct lobular unit (TDLU) of the adult breast (Fig. 25-1B).

The breasts are on the upper chest wall between the 2nd and the 6th ribs. They extend medially to the sternum and laterally to the anterior axillary line, although the tail may extend farther into the axilla. Each breast is composed of skin, subcutaneous adipose tissue and the functional component composed of ducts, lobules and stroma. Collecting ducts, through which milk is secreted, open at the nipple. The nipple–areolar complex is centrally placed and contains abundant sensory nerves and sebaceous and apocrine glands. The nipple consists mainly of dense fibrous tissue mixed with smooth muscle. The latter gives the nipple its erectile capability and contributes to expression of milk. Pigmentation increases in the nipple and areola at puberty and increases further during pregnancy. Stratified squamous epithelium that lines the nipple skin extends superficially into the collecting duct before it transitions abruptly to glandular epithelium. The latter contains an inner luminal secretory epithelial cell layer and an outer myoepithelial cell layer.

Just beneath the nipple, collecting ducts dilate to form lactiferous sinuses, which subdivide into 15–25 lobes with segmental and subsegmental ducts. These terminate in the TDLU, where milk is made. The TDLU consists of (1) terminal ductules or acini, whose epithelium differentiates into secretory acini in pregnant or lactating glands; (2) the intralobular collecting duct; and (3) specialized intralobular stroma (Fig. 25-1B).

The TDLU is a dynamic structure that changes cyclically during the menstrual cycle. These periodic alterations include epithelial proliferation and apoptosis, as well as changes in intralobular stroma. In the follicular phase of the menstrual cycle, terminal ducts are few and are lined by a simple, two-cell layer of epithelium with surrounding myoepithelium. After ovulation, mitoses increase in the luminal epithelium, as do acini and edema of the intralobular stroma. Myoepithelial cells become more prominent, owing to cytoplasmic accumulation of glycogen. These changes

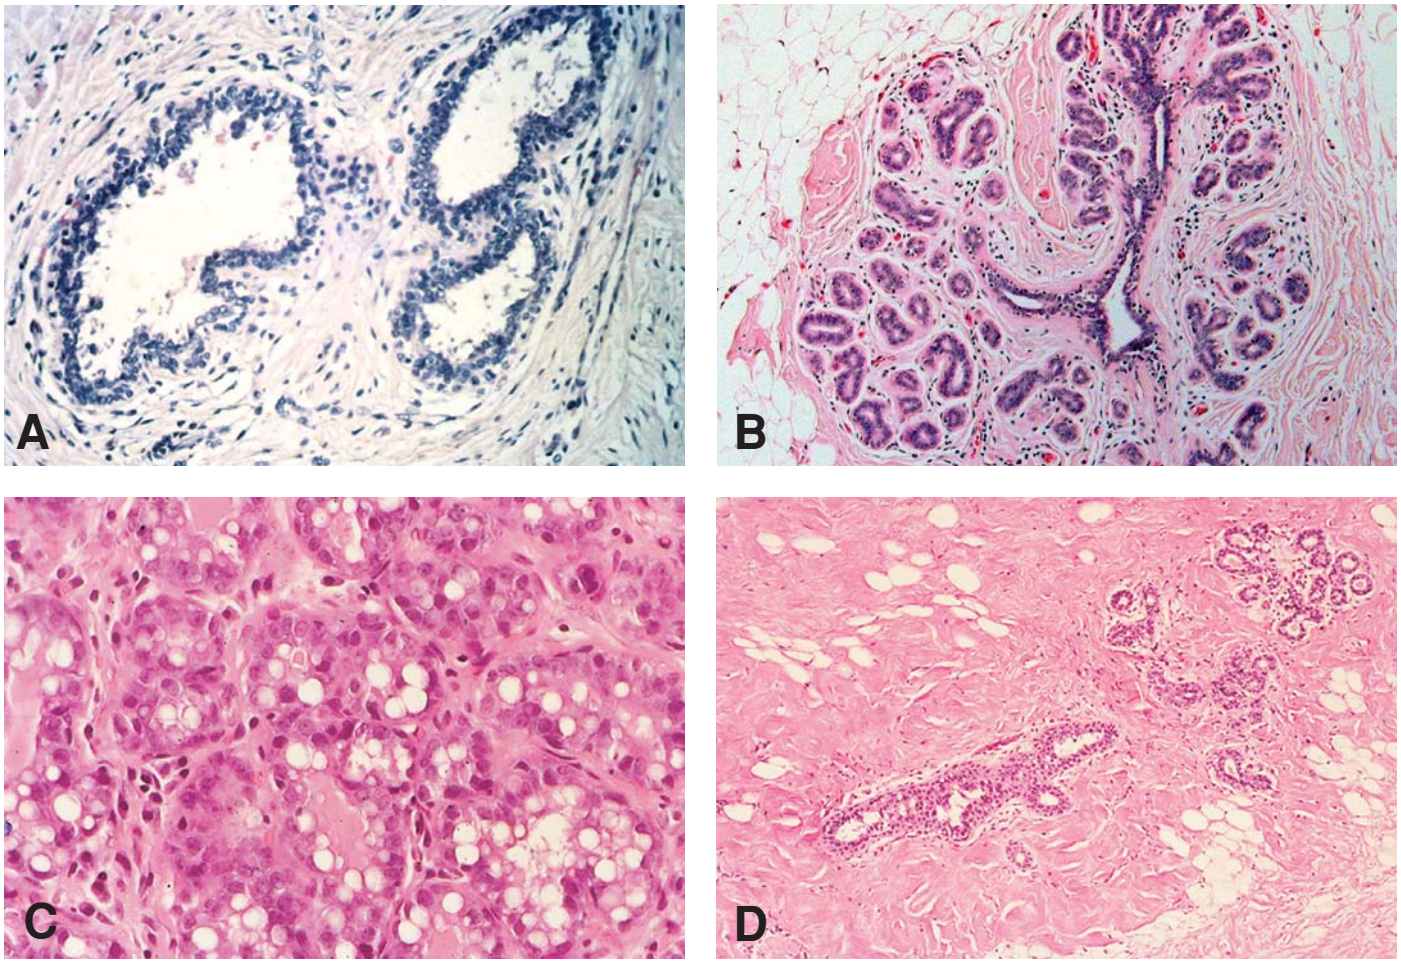

FIGURE 25-1. Normal breast architecture at various ages. A. Adolescent breast. Large and intermediate-size ducts are seen within a dense fibrous stroma. No lobular units are present. **B. Postpubertal breast.** The terminal duct lobular unit consists of small ductules arrayed around an intralobular duct. The two-cell-layered epithelium shows no secretory or mitotic activity. The intralobular stroma is dense and confluent with the interlobular stroma. **C. Lactating breast.** The terminal duct lobular units are conspicuously enlarged, with inapparent interlobular and intralobular stroma. The individual terminal ducts, now termed acini, show prominent epithelial secretory activity (cytoplasmic vacuolization). The acinar lumina contain secretory material. **D. Postmenopausal breast.** The terminal duct lobular units are absent. The remaining intermediate ducts and larger ducts are commonly dilated.

may cause progressive fullness of the breast and tenderness. The TDLUs return to their follicular phase state during menses, when declining estrogen and progesterone levels cause apoptosis. At this time, lymphocytes infiltrate the intralobular stroma.

Full functional breast development only occurs with the hormonal changes of pregnancy and lactation. In pregnancy, glandular tissue increases markedly, compared to fibrous and fatty connective tissue. Early in pregnancy the TDLU grows rapidly. Stromal vascularity and chronic inflammatory cells increase. In later pregnancy, lobular epithelial cells start to become vacuolated owing to increased secretion into distended lobular units. This effect becomes more pronounced with lactation (Fig. 25-1C). At the end of lactation, the gland involutes dramatically, as pronounced cell death and tissue remodeling eventually the breast returns to its prepregnancy state.

In menopause, TDLUs atrophy, but large and intermediate-sized ducts persist (Fig. 25-1D). Fat predominates over fibrous tissue, but the latter typically cuffs the remaining ducts. Fat increases as a percentage of total breast mass as the woman ages.

Outside of the TDLU, nonspecialized collagenous connective tissue and fat make up the bulk of the breast tissue. Intralobular stroma is more cellular than is interlobular stroma. Mucopolysaccharides in extracellular matrix are also more abundant, and a few lymphocytes, plasma cells, mast cells and macrophages are present.

The breast is very vascular and contains a complex lymphatic network, draining mainly into axillary lymph nodes, with a minority communicating with internal mammary nodes.

DEVELOPMENTAL ABNORMALITIES

Complete bilateral or unilateral absence of breast development occurs rarely, but hypoplasia is more common. Minor asymmetry between breasts occurs frequently. Less often, breasts may be markedly different in size owing to hypoplasia of one breast or unusual enlargement of the other **(juvenile hypertrophy)**. However, the latter is usually bilateral. Unless there is an underlying hormonal abnormality, juvenile breast hypertrophy regresses spontaneously.

The most common anomaly of breast development is **supernumerary nipples,** or **polythelia,** with or without associated breast tissue **(polymastia),** which results from persistent epidermal thickenings. These mostly occur along the milk line, which extends from the axilla to the groin, but other sites may rarely be involved. Congenitally **inverted nipple** is due to failure of nipple eversion in development, usually unilaterally.

INFLAMMATORY DISEASES OF THE BREAST

Acute Mastitis Is a Common Complication of Breast Feeding

Acute mastitis occurs mostly early in the postpartum period and reflects bacterial infection, usually with *Staphylococcus* or *Streptococcus.* Patients have pain, swelling or redness, often with fever and malaise. Cracks in the skin or lactational stasis predispose to infection. If minor, mastitis usually resolves with antibiotics and continued lactation. If it is severe or untreated, abscesses or systemic infection may occur.

Periductal Mastitis of Lactiferous Ducts Is Painful

The disease is unrelated to lactation, age or history of pregnancy. It presents with a painful subareolar mass and overlying erythema. The large majority of patients are cigarette smokers. Nipple ducts show keratinizing squamous metaplasia. A keratin plug can become trapped and lead to duct rupture. Keratin debris spilling into the stroma then elicits a foreign body, chronic, inflammatory response, which may become secondarily infected. Recurrences are common and can lead to fistulas. Surgical excision is curative.

Granulomatous Mastitis Has Diverse Etiologies

Granulomatous inflammation (Fig. 25-2) of the breast can be caused by mycobacteria, parasites, fungi or foreign material. **Tuberculosis** of the breast is rare in Western countries but more common in developing countries, where the infection is endemic. Patients typically present with a mass or sinus that may be mistaken clinically for invasive carcinoma. Other organisms that cause granulomas are discussed in Chapter 9. **Sarcoidosis** rarely involves the breast, but when it does, it presents as single or multiple breast masses.

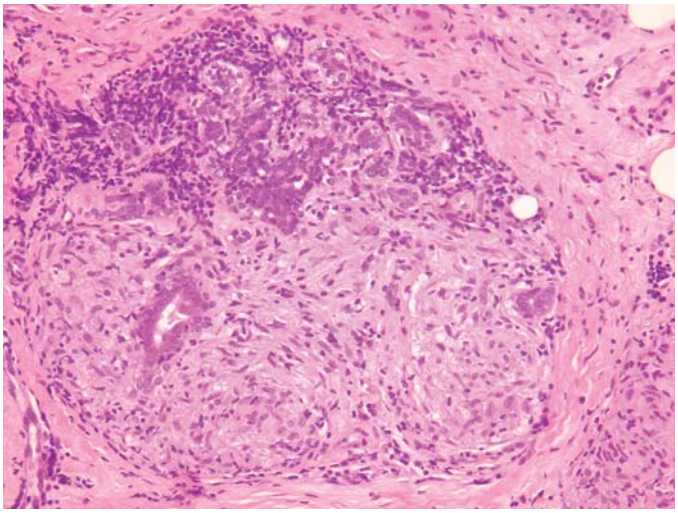

FIGURE 25-2. Breast lobule showing florid granulomatous inflammation characterized by collections of epithelioid histiocytes.

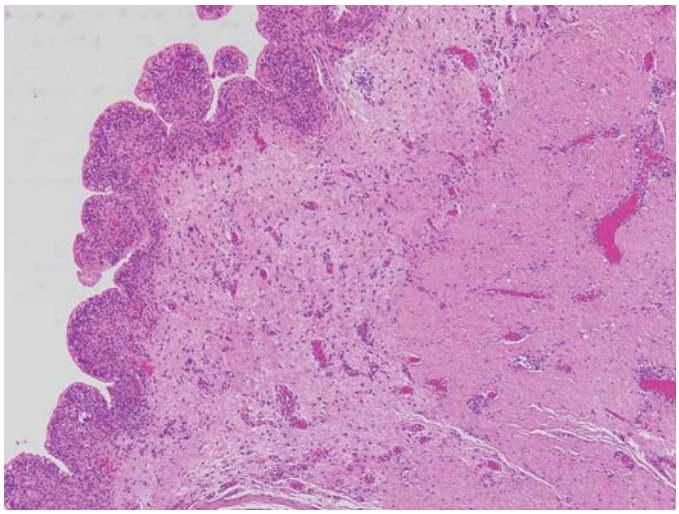

FIGURE 25-3. Capsule around breast implant showing synovial metaplasia with papillary hyperplasia and chronic inflammation.

Silicone gel can leak from breast implants and cause foreign body granulomatous inflammation, with a fibrous capsule. In severe cases, this may cause skin retraction, nipple inversion and formation of hard masses, which may simulate or obscure a malignancy. Draining lymph nodes may enlarge, owing to spread of vacuolated histiocytes containing refractile particles. The use of saline, rather than silicone, in implants has greatly reduced implant-associated granulomatous mastitis.

PATHOLOGY: On gross sectioning, the breast tissue after rupture of an implant is firm and may be gritty if calcification is present. Fat necrosis and foreign body giant cell reaction, with varying degrees of inflammation and fibrosis, are characteristic. During tissue processing, the silicone is largely lost from the tissue, leaving behind clear spaces. These spaces, and the macrophages, may contain birefringent particles. The capsule is formed by a band of frequently calcified, collagenized fibrous tissue. Some capsules around implants develop synovial metaplasia: a lining that resembles synovium, with or without papillary hyperplasia (Fig. 25-3).

Idiopathic granulomatous mastitis is rare. It typically occurs in women 20–40 years old who have recently been pregnant. It may be bilateral in up to 25% of patients. The granulomas in this setting are centered within lobules, with frequent superimposed acute inflammation and microabscesses (Fig. 25-4).

Sclerosing Lymphocytic Lobulitis Is an Autoimmune Reaction

Sclerosing lymphocytic lobulitis, also called **lymphocytic** or **fibrous mastopathy,** is uncommon. It is often associated with other autoimmune diseases, in particular type 1 diabetes mellitus and Hashimoto thyroiditis. Clinically, most

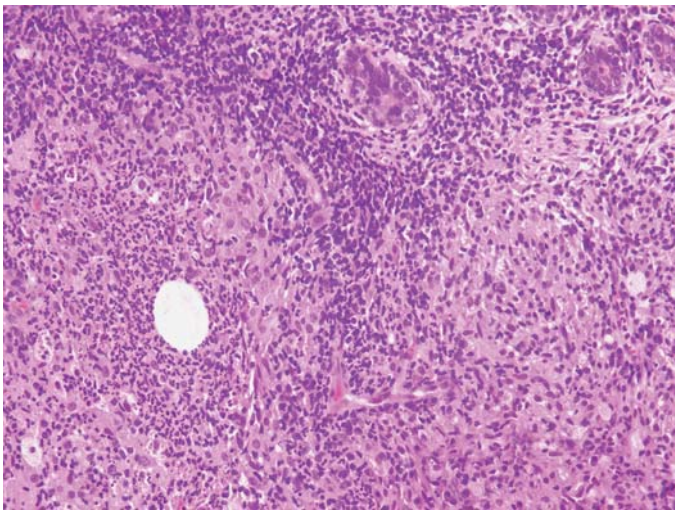

FIGURE 25-4. Granulomatous inflammation centered on a breast lobule with a prominent acute inflammatory cell infiltrate. The histologic appearances are in keeping with a diagnosis of idiopathic granulomatous mastitis.

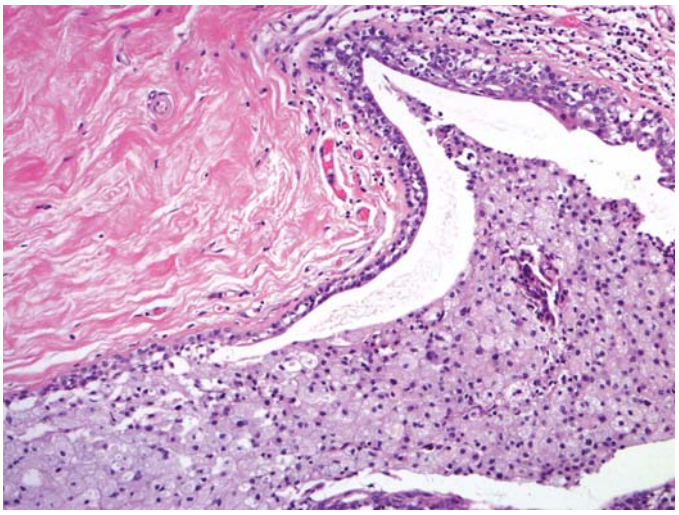

FIGURE 25-6. Duct ectasia. Dilated duct filled with foamy histiocytes. The duct epithelium is focally infiltrated by histiocytes and chronic inflammation of the periductal stroma is present.

patients exhibit a hard mass, which may be tender and sometimes bilateral. Circumscribed aggregates of small lymphocytes surround lobules, ducts and vessels, and lobular atrophy, basement membrane thickening and fibrosis are evident (Fig. 25-5). Interlobular stroma shows dense fibrosis and epithelioid myofibroblasts.

Duct Ectasia May Lead to Duct Rupture

Duct ectasia is common and is characterized by dilation and periductal inflammation, with fibrosis of large and intermediate breast ducts, which contain inspissated material. Peri- or postmenopausal women are more likely to be symptomatic, complaining of a serous or bloody discharge, mass or pain. As disease progresses, duct wall fibrosis may cause the nipple to retract. Episodes of acute inflammation are occasionally complicated by abscess or sinus formation. Dilated ducts contain amorphous debris and foamy macrophages (Fig. 25-6). The lining epithelium and periductal stroma have inflammatory cells and foamy macrophages. Duct rupture incites a chronic inflammatory response, often with foreign body granulomas. Over time, fibrosis increases, with or without obliteration of ducts.

Fat Necrosis Often Mimics Cancer

Like carcinoma of the breast, fat necrosis often presents as a hard mass, frequently with associated skin tethering. Some patients may give a history of trauma. Necrotic fat cells, acute inflammation, cholesterol clefts and hemorrhage are evident early in the course of fat necrosis. Foamy macrophages and multinucleated giant cells that engulf lipid droplets then gradually accumulate (Fig. 25-7). With time, fibrosis and dystrophic calcification develop.

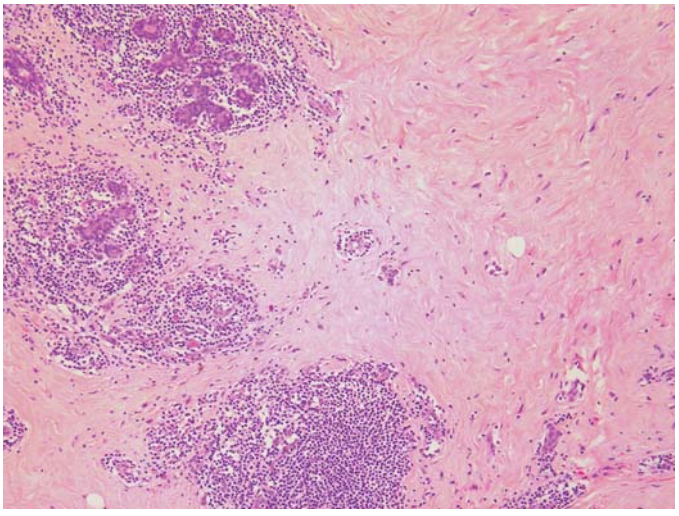

FIGURE 25-5. Prominent periductal and perivascular lymphocytic infiltration in a dense fibrous stroma, characteristic of sclerosing lymphocytic lobulitis.

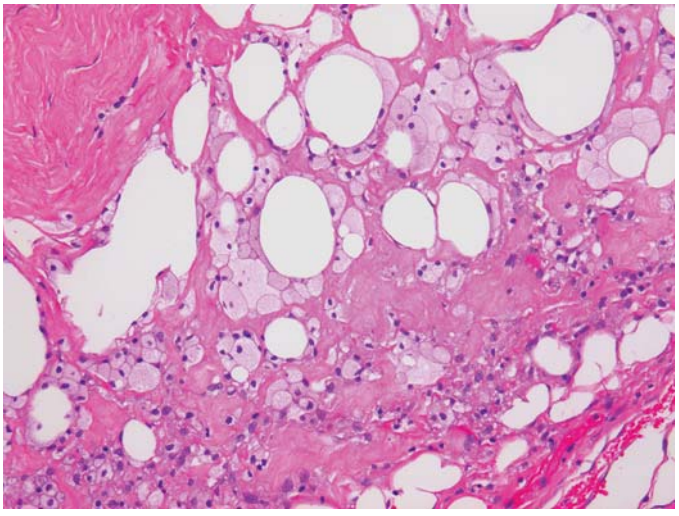

FIGURE 25-7. Fat necrosis. Necrotic fat cells with abundant foamy histiocytes.

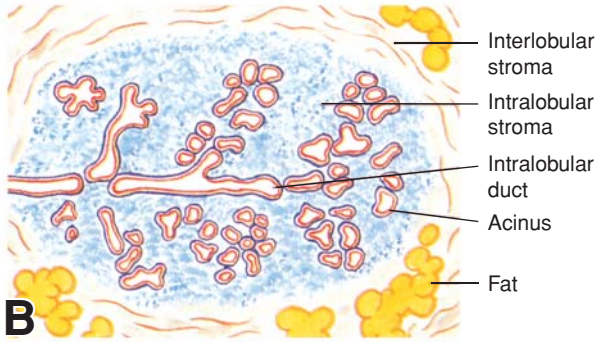
BENIGN EPITHELIAL LESIONS

Benign epithelial lesions can be classified based on their risk of subsequent cancer development. Lesions not associated with increased risk are **nonproliferative breast changes** (e.g., fibrocystic change). **Proliferative disease without atypia** entails 1.5–2-fold increased risk of developing carcinoma over 5–15 years and is classified simply as **proliferative breast disease**. **Proliferative lesions with atypia** involve even greater relative risk (4–5-fold). Such patients require close clinical monitoring. Patients at high risk may consider medical treatment options (e.g., estrogen antagonists).

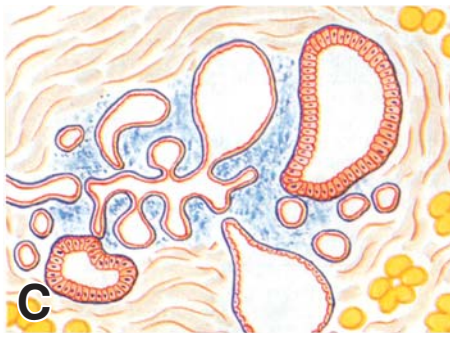
Fibrocystic Change Is an Exaggerated Physiologic Response

Fibrocystic change (FCC) is a nonproliferative change that includes gross and microscopic cysts, apocrine metaplasia, mild epithelial hyperplasia and an increase in fibrous stroma. FCC affects over one third of women 20–50 years old, then declines after menopause. Most women with FCC are asymptomatic, but some present with nodularity and, occasionally, pain. FCC is typically multifocal and bilateral.

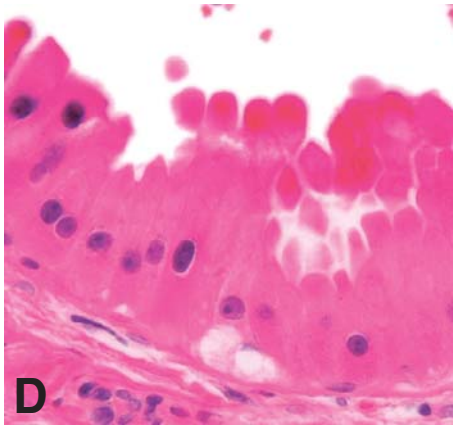
PATHOLOGY: The breast tissue in FCC consists grossly of firm fibrofatty tissue within which are multiple clear cysts or "blue dome" cysts (Fig. 25-8A). The latter contain a dark, thin fluid that imparts a blue color to unopened cysts. Cysts vary from 1 mm to several centimeters and may lack epithelial lining or be lined by attenuated epithelium and myoepithelium (Fig. 25-8C). Their lining may include apocrine-type cells, which are large and have abundant, granular, eosinophilic cytoplasm and a basally located nucleus (Fig. 25-8D). Surrounding stroma is often sclerotic. Inflammation may be due to cyst rupture. Mild "usual" ductal hyperplasia (see below) is frequent, with no

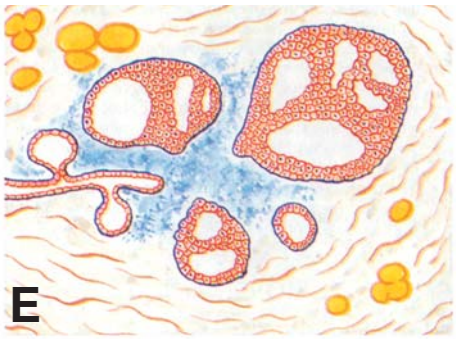


Terminal duct lobular unit



Nonproliferative fibrocystic change





Proliferative breast disease

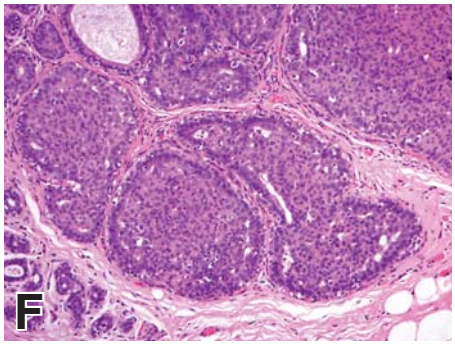


FIGURE 25-8. Fibrocystic change. A. Cysts of various sizes are dispersed in dense, fibrous connective tissue. Some of the cysts are large and contain old blood-tinged proteinaceous debris. **B. Normal terminal duct lobular unit. C. Nonproliferative fibrocystic change** combines cystic dilation of the terminal ducts with varying degrees of apocrine metaplasia of the epithelium and increased fibrous stroma. **D. Apocrine metaplasia.** Epithelial cells have apocrine features with eosinophilic cytoplasm. **E. Proliferative breast disease.** Terminal duct dilation and intraductal epithelial hyperplasia are present. **F. Florid epithelial hyperplasia of usual type.** The epithelium within the ducts proliferates and almost fills the duct lumen, with residual "secondary" spaces remaining as peripheral slit-like spaces. Cytoplasmic borders are indistinct and the nuclei appear round to oval and frequently overlap, resulting in a streaming pattern.

more than 3–4 cell layers above the basement membrane (Fig. 25-8C). Acini are increased in number and size, lined by columnar cells and frequently contain calcifications.

Proliferative Breast Disease Variably Increases Risk of Cancer

Usual Epithelial Hyperplasia

Usual epithelial hyperplasia within ducts or lobules is typified by increased cellularity, relative to the basement membrane (Fig. 25-8E, F). There may be more than 4 cell layers, often bridging across duct lumens. Nuclei may be so oriented as to present a streaming pattern. Secondary spaces are slit-like, irregular and typically peripheral in location. Both luminal and basal epithelial cells proliferate, the latter expressing high–molecular-weight ("basal") cytokeratins. Usual epithelial hyperplasia does not show consistent genetic alterations, and the characteristic alterations seen in atypical duct hyperplasia and low-grade ductal carcinoma in situ are absent (see below).

Sclerosing Adenosis

In sclerosing adenosis (SA), the TDLU shows disordered epithelial, myoepithelial and stromal components. Lesions vary from microscopic foci to masses that may be palpable and that may be mistaken clinically and radiologically for carcinoma. SA often calcifies and may be targeted for core biopsies. It is not a precursor of invasive cancer but is grouped with proliferative lesions without atypia for risk assessment purposes.

PATHOLOGY: SA lesions show disorderly proliferation of ducts, tubules and intralobular stromal cells, resulting in distortion and expansion of lobules and obliterating duct spaces (Fig. 25-9). A lobulocentric architecture is maintained. In cases that are difficult to distinguish from invasive carcinoma, immunohistochemistry can highlight the preservation of myoepithelial cells around distorted ducts.

Radial Scar/Complex Sclerosing Lesion

Radial scar is a benign sclerosing lesion with a central fibroelastotic scar and peripheral radiating ducts and lobules. If over 1 cm, they are called complex sclerosing lesions. Larger lesions may be seen mammographically as stellate or spiculated structures with radiolucent central areas that may be difficult to distinguish from cancer.

PATHOLOGY: Radial scars are characterized by central fibroelastotic cores, within which are found entrapped and distorted small ducts (Fig. 25-10). At the edges, radiating ducts and lobules show diverse benign alterations. Occasionally, atypical hyperplasia or carcinoma may be present.

CLINICAL FEATURES: Radial scars carry a twofold increase in breast cancer risk, which is even greater in women with coexisting proliferative disease, with and without atypia. This increased risk pertains to both ipsilateral and contralateral breasts, indicating that radial scars are markers of generally increased susceptibility to breast cancer. Since cancer can occur in radial scars, surgical excision is recommended.

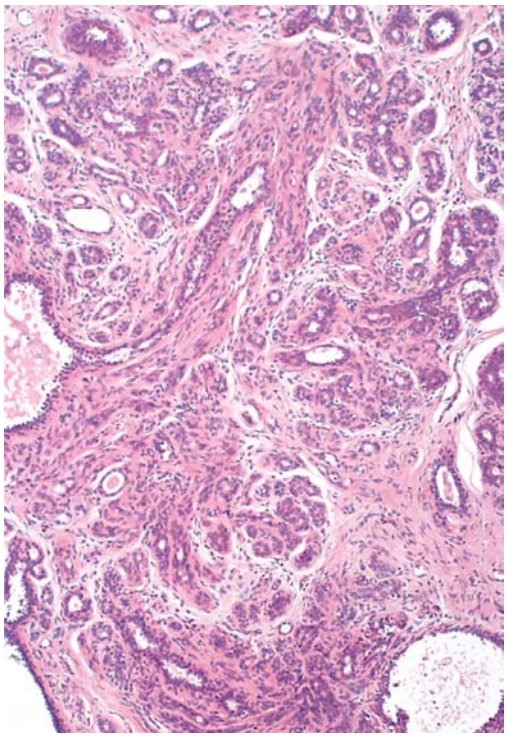

FIGURE 25-9. Sclerosing adenosis. This lesion is characterized by the proliferation of small, abortive, duct-like structures, and myoepithelial cells expand and distort the lobule in which it arises. The lesion is well circumscribed, in contrast to a cancerous lesion.

Intraductal Papilloma

Papillomas are divided into central and peripheral groups. Central papillomas arise in large lactiferous ducts and tend to be solitary. Peripheral papillomas originate in terminal duct lobular units and are usually multiple. Patients may present with a mass lesion or an often bloody nipple discharge. On mammography, central papillomas are well-circumscribed masses; peripheral papillomas are identified often as clustered calcifications or small nodular masses. Ultrasound often

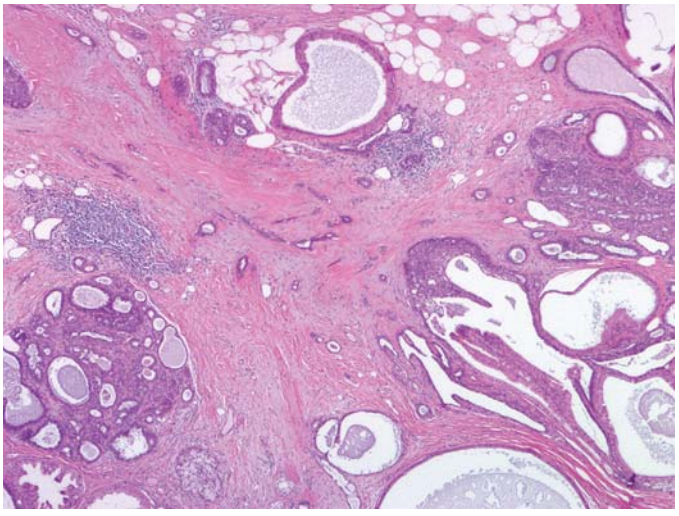

FIGURE 25-10. Radial scar. Angulated glands in a fibroelastotic center are surrounded by a radial distribution of benign ducts and apocrine cysts.

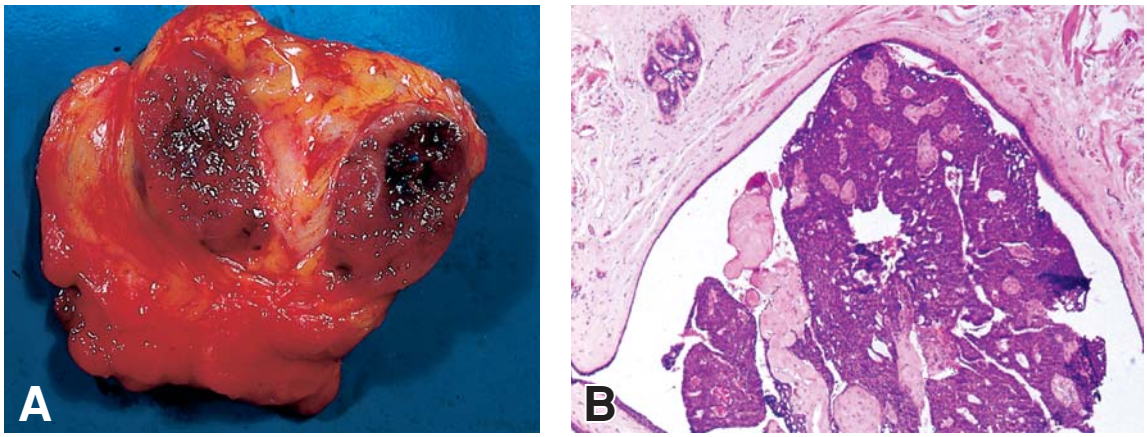

FIGURE 25-11. Intraductal papilloma. A. A large papillary mass is seen within dilated ducts. **B.** A photomicrograph shows a benign papillary growth in a subareolar duct.

shows larger lesions as well-defined hypoechoic masses, with solid and cystic components, near dilated ducts.

PATHOLOGY: Papillomas vary from microscopic foci to masses several centimeters across (Fig. 25-11A). Larger lesions frequently show foci of hemorrhage or necrosis. Dilated duct spaces contain multiple branching papillae with fibrovascular cores. These are lined by a layer of myoepithelium, on which one or more layers of epithelium lie (Fig. 25-11B). Florid epithelial hyperplasia of usual type or atypical ductal hyperplasia may be present (Fig. 25-12). Papillomas often contain areas of apocrine change and, less often, squamous metaplasia. Sclerosis of papillae or duct walls is variable, but it may be marked and can entrap and distort benign epithelium at the periphery, mimicking an invasive process.

CLINICAL FEATURES: Peripheral papillomas are more often associated with concurrent or subsequent breast cancer. The relative risk of a malignancy is 2-fold in patients with central papillomas and 3-fold if papillomas are peripheral. If there is atypia within these lesions, relative risks are 5- and 7-fold, respectively. If a papilloma is found on core biopsy, excision is generally recommended because atypia or carcinoma may coexist in areas not sampled in the biopsy.

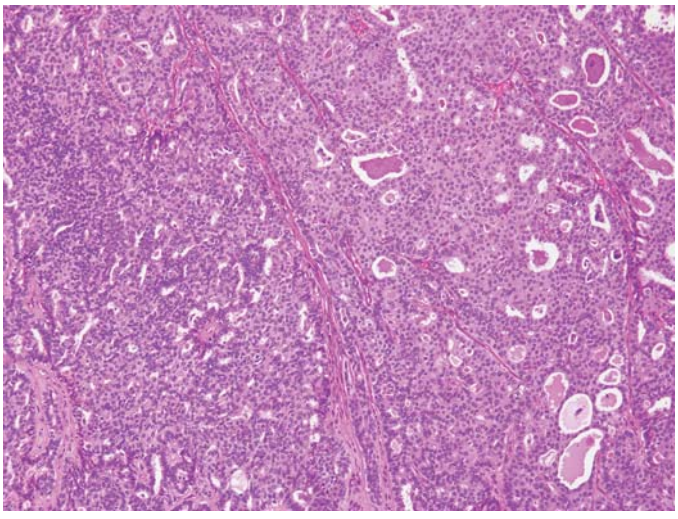

FIGURE 25-12. Intraductal papilloma with focus (on right of image) showing low-grade cytologic atypia and architectural atypia in keeping with atypical ductal hyperplasia occurring within a papilloma (atypical papilloma).

Proliferative Disease with Atypia Is Composed of a Heterogeneous Group of Breast Lesions

Atypical Ductal Hyperplasia

PATHOLOGY: Atypical ductal hyperplasia (ADH) is an intraductal epithelial proliferation with a dual population of low-grade neoplastic epithelial cells and benign cells. The benign population may comprise normal lining cells or proliferating cells showing epithelial hyperplasia of usual type. The neoplastic population consists of monomorphic small cells that are evenly spaced, with well-defined cytoplasmic borders and round, hyperchromatic, uniform nuclei. These form architecturally complex structures, such as micropapillae, rigid bridges, bars, solid sheets or cribriform arrays (Fig. 25-13). If the duct is completely filled by neoplastic cells, and if two duct spaces extending at least 2 mm are involved, the lesion is considered low-grade ductal carcinoma in situ (DCIS). If these criteria are not met, most pathologists would designate the lesion ADH.

MOLECULAR PATHOGENESIS: One third to 1/2 of ADH lesions show no genetic changes. The others, however, show alterations that overlap with low-grade DCIS. Common patterns of genetic alterations in proliferative breast lesions are summarized in Table 25-1.

In patients with ADH, the relative risk of subsequent breast cancer is increased 4–5-fold compared to age-matched controls. Cancers occur in ipsilateral and contralateral breasts equally frequently. This raises the important question as to the extent to which these lesions are precursors of invasive malignancies, or whether they may on occasion represent nonprogressing lesions that are products of similar processes that also produce invasive cancers. Hormonal therapy may be used to reduce the risk of developing breast cancer.

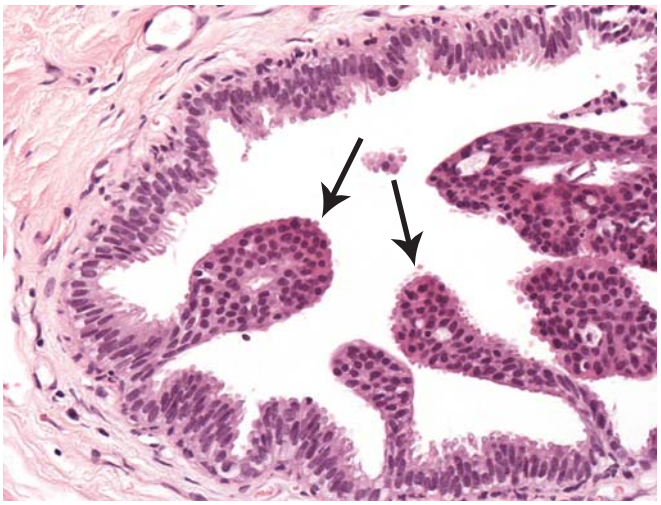

FIGURE 25-13. Atypical ductal hyperplasia (ADH). Micropapillae (*arrows*) project into the duct lumen and consist of cells with an increased nuclear-to-cytoplasmic ratio and nuclear hyperchromasia. Residual benign columnar cells are seen lining the duct.

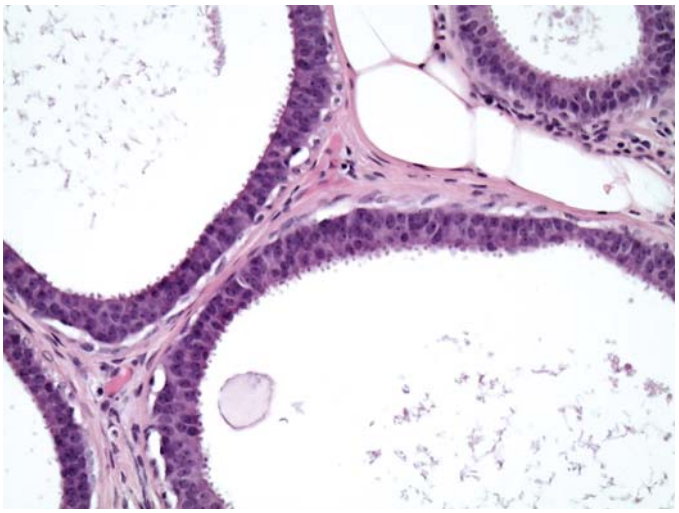

FIGURE 25-15. Flat epithelial atypia. The terminal duct lobular unit (TDLU) is enlarged as a result of dilatation of the lobular acini. These are lined by one to two layers of epithelial cells showing low-grade cytologic atypia. Nuclei appear round with variably conspicuous nucleoli, and loss of their basal location (loss of polarity) is seen. Architectural complexity is not a feature.

Atypical Lobular Hyperplasia

Atypical lobular hyperplasia (ALH) is usually an incidental finding in a biopsy or excision performed for something else. In ALH, cells are indistinguishable from those seen in lobular carcinoma in situ (LCIS; see below), but the degree of involvement of the TDLU is less in ALH than in LCIS; fewer acini are involved and less than 50% within the lobule are distended (Fig. 25-14A). As in LCIS, cells of ALH can spread in a pagetoid fashion to involve ducts (Fig. 25-14B). ALH morphology and associated risk of subsequent breast cancer are discussed below.

Flat Epithelial Atypia

Flat epithelial atypia (FEA) describes a lesion of TDLUs in which acini are variably dilated, lined by one or several layers of epithelial cells, with low-grade cytologic atypia. It presents as round, nonbranching mammographic microcalcifications.

PATHOLOGY: Variably distended acini lined by cuboidal to columnar epithelial cells distend the TDLU (Fig. 25-15). Cells show uniform round nuclei and a slight increase in the nuclear-to-cytoplasmic ratio. Cell polarity is lost, and nucleoli are variably prominent. Architectural complexity, such as micropapillae, bridges, bars or cribriform structures, is absent.

FEA may coexist with ADH, DCIS, ALH/LCIS and invasive carcinoma, particularly tubular carcinoma. The cells of FEA are similar in morphology to coexisting in situ and invasive carcinoma. Furthermore, loss of heterozygosity (LOH) is present in most cases, in patterns that are shared with

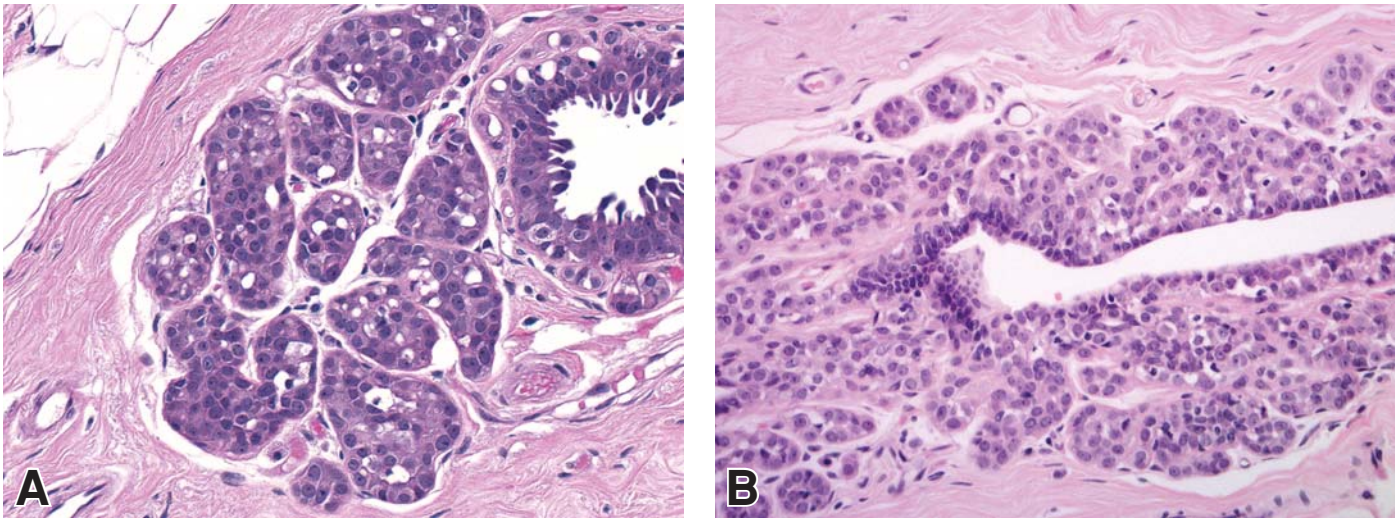

FIGURE 25-14. A. Atypical lobular hyperplasia (ALH). There is minimal distension of the lobular acini by a uniform population of cells with intracytoplasmic lumina and round nuclei containing small nucleoli. **B. Pagetoid spread** of lobular neoplastic cells into the terminal duct. Here the atypical cells lie beneath an attenuated surface layer of luminal epithelial cells.

TABLE 25-1
COMMON GENETIC ALTERATIONS ASSOCIATED WITH BREAST LESIONS

Lesion Type	Other	Alteration
ADH	Loss	16q
	Gain	17p
Phyllodes tumors	Gain	1q
	Loss	13
Familial adenomatous polyposis	Mutation	*APC*, β-catenin
	Loss	5q
Familial breast cancer, high penetrance		*BRCA1, BRCA2*
	Li-Fraumeni	*TP53*
	Cowden	*PTEN*
	Hereditary diffuse gastric cancer	*CDH1*
	Peutz-Jeghers	*STK11*
Familial breast cancer, low penetrance	Ataxia telangiectasia	*ATM*
	Li-Fraumeni variant	*CHEK2*
Low-grade DCIS	Gain	1q
	Loss	16q
High-grade DCIS	Gain	17q, 8q, 5p
	Loss	11q, 14q, 8p, 13q
	Amplifications	17, 6, 8, 11
Encapsulated papillary carcinoma		LOH, 16q, 1q
Lobular neoplasia	Gain	1q, 6q
	Loss	16p, 16q (especially 16q22.1), 17p, 22q
Pleomorphic LCIS	Gains and losses	Same as lobular neoplasia
	Amplification	8q24, 17q12
	LOH	16q22.1, p53, *HER2, BRCA1*
Invasive ductal NST, low grade	Loss	16q
	Gain	1q, 16p
Invasive ductal NST, high grade		Heterogeneous and aneuploid
Invasive lobular carcinoma	Loss	16q
	Gain	1q, 16p
Invasive lobular carcinoma, high grade		Same as invasive lobular carcinoma
	Amplification	8q24, 17q12, 20q13
Tubular carcinoma	Loss	16q (8p, 3p, 11q)
	Gain	1q, 16p
Medullary carcinoma	Mutations (acquired)	*TP53, BRCA1*
	Epigenetic inactivation	*BRCA1*
Micropapillary	Gain	8q, 17q, 20q
	Loss	6q, 13q
Metaplastic carcinoma	Mutations	*TP53*
Male breast cancer	Inherited mutations	*BRCA2*
	Acquired mutations	*TP53, PTEN, CHEK2*

ADH = atypical ductal hyperplasia; DCIS = ductal carcinoma in situ; LCIS = lobular carcinoma in situ; LOH = loss of heterozygosity; NST = no specific type.

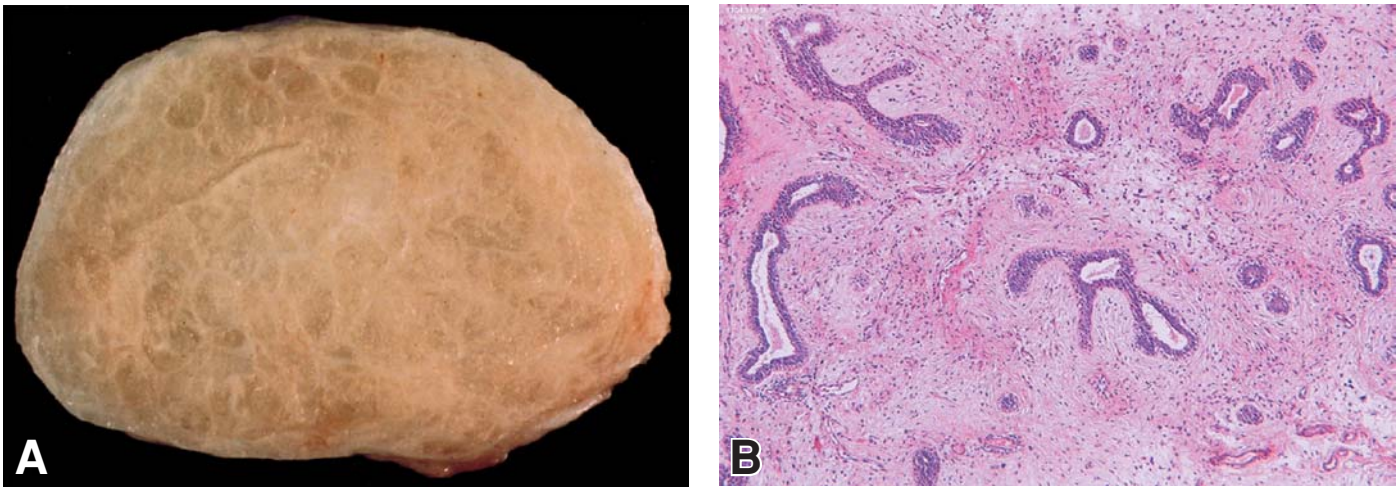

FIGURE 25-16. Fibroadenoma. A. Surgical specimen. This well-circumscribed tumor was easily enucleated from the surrounding tissue. The cut surface is characteristically glistening tannish-white and has a septate appearance. **B.** Microscopic section. Elongated epithelial duct structures are situated within a loose, myxoid stroma.

coexistent DCIS or invasive carcinoma. The characteristic 16q loss seen in low-grade DCIS and invasive carcinoma is the most frequently detected recurrent change in FEA.

Limited clinical outcome data in patients with FEA suggest that local recurrence and progression to invasive carcinoma are uncommon.

FIBROEPITHELIAL LESIONS

These arise from intralobular stroma and contain both stromal and epithelial elements.

Fibroadenomas Have Benign Epithelium and Stroma

Fibroadenomas are common, mobile, painless, breast lumps that most often affect 20- to 35-year-old women. Clinically silent lesions are particularly common and are usually identified by mammography. These are typically well-defined solitary masses, which may be calcified. However, they can be multiple and bilateral, most often in Afro-Caribbean women.

PATHOLOGY: Fibroadenomas are round or ovoid and rubbery (Fig. 25-16A) and are sharply demarcated from surrounding breast tissue. Most are less than 3 cm, but they can rarely be much larger (up to 20 cm) in young women or adolescents. Fibroadenomas have two components: stroma and epithelium (Fig. 25-16B). The stroma typically contains spindle cells and shows variable, but usually low, cellularity. In younger women, the stroma is often myxoid. With age, stroma may be denser and can calcify. The epithelial component is formed from normal TDLU constituents; epithelial and myoepithelial layers are preserved. The relationship of the stroma to the epithelium is typically uniform throughout. Two patterns are known. In the **intracanalicular** pattern, stromal growth compresses ducts into curvilinear slits. The **pericanalicular** pattern is characterized by ducts that maintain a tubular configuration, surrounded by stromal proliferation. These growth patterns have no prognostic import.

The epithelial component of a fibroadenoma often shows hyperplasia, especially in young women. Rarely, atypical ductal hyperplasia, lobular neoplasia or DCIS can occur within fibroadenomas. Complex fibroadenomas show benign changes, including epithelial calcifications, sclerosing adenosis (Fig. 25-17), papillary apocrine change or cysts greater than 3 mm.

Variants of fibroadenoma include **tubular adenoma,** in which small tubular structures are surrounded by a loosely cellular vascularized stroma (Fig. 25-18), and **juvenile fibroadenoma,** which are most common in adolescents (Fig. 25-19). These grow rapidly and may reach 20 cm, causing clinical concern. Juvenile fibroadenomas resemble fibroadenomas histologically, but with more cellular stroma.

Fibroadenomas are surgically excised if they are of clinical or radiologic concern. They can recur, but not often. There is no risk of subsequent breast cancer in the vast majority of cases.

Phyllodes Tumor

These tumors make up less than 1% of breast tumors. They have epithelial and stromal components, the latter being neoplastic. The name is derived from the Greek word *phyllos,* meaning "leaf," because they show a leaf-like growth

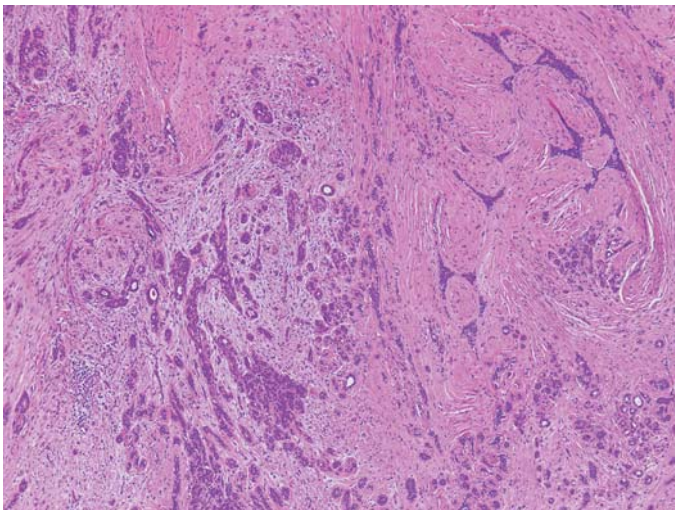

FIGURE 25-17. Fibroadenoma involved by sclerosing adenosis.

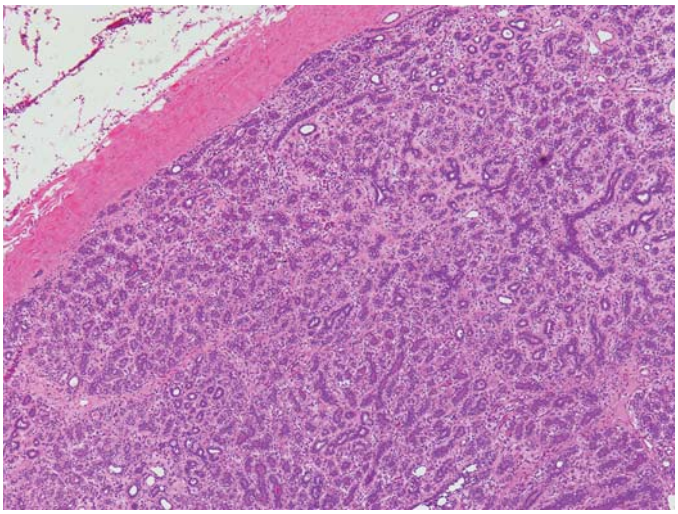

FIGURE 25-18. Tubular adenoma. Well-circumscribed fibroepithelial lesion with closely packed round tubules showing little intervening stroma.

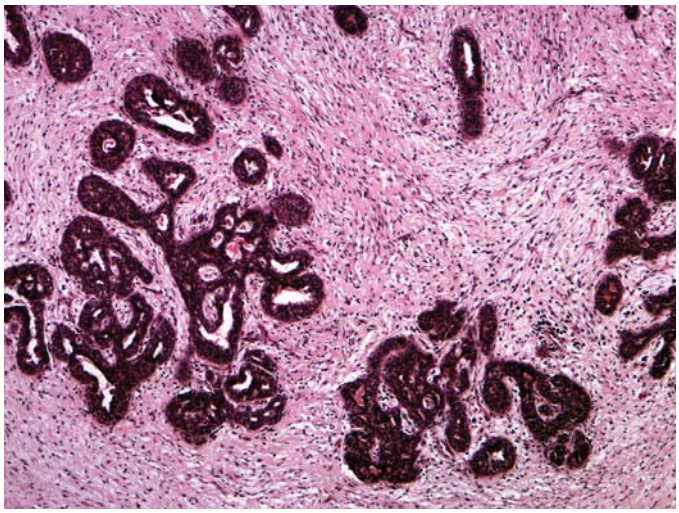

FIGURE 25-19. Juvenile fibroadenoma. The stroma shows hypercellularity, although mitoses and cellular atypia are not features. Epithelial hyperplasia of usual type is present in the glands.

pattern. They can occur at any age but are most common in the 6th decade. Phyllodes tumors present as rapidly growing breast masses and on mammography are well circumscribed or lobulated. Ultrasound may show internal hyperechoic areas in a hypoechoic mass.

PATHOLOGY: Phyllodes tumors vary in size from a few centimeters across to 20 cm. **Benign** phyllodes tumors are sharply circumscribed. Their cut surfaces are firm, glistening and grayish white. Clefts may be prominent. Malignant lesions often show infiltrative margins. On microscopy, fronds of hypercellular stroma lead to formation of leaf-like structures, which project into cystic spaces (Fig. 25-20). These spaces are lined by a dual layer of benign epithelium and myoepithelium. The stroma ranges from benign and hypercellular to frankly sarcomatous. Most phyllodes tumors are benign and have mild or moderately hypercellular stroma with mild cytologic atypia and few mitoses. In **malignant** phyllodes tumors, stroma is very hypercellular, with considerable pleomorphism, abundant mitoses (>10 per 10 HPFs) and stromal overgrowth. Malignant heterologous elements, such as bone, cartilage or fat, may be present. Those tumors that are not clearly benign or malignant are called **borderline**.

MOLECULAR PATHOGENESIS: The epithelium in phyllodes tumors appears to influence stromal growth. The tumors upregulate transcriptionally active β-catenin and downstream effectors such as cyclin D1 via the Wnt pathway. Altered karyotypes may occur with malignant progression (Table 25-1).

The main risk of benign phyllodes tumors is local recurrence, which happens 20% of the time, rather than metastasis. The best predictor of recurrence is completeness of excision; thus, a rim of normal tissue should be excised with these tumors. Recurrence is more common with malignant lesions. Metastases are rare overall, but up to 25% of high-grade malignant phyllodes tumors may disseminate. ***Only stromal components are seen in metastases.*** Axillary lymph node metastases are very rare.

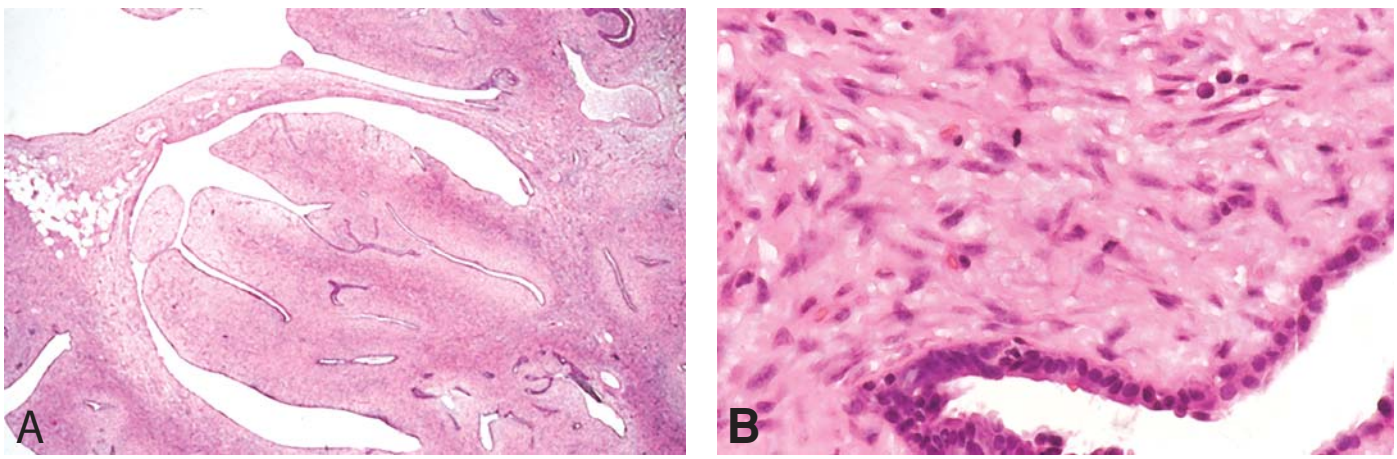

FIGURE 25-20. Phyllodes tumor. A. A polypoid tumor with a leaf-like pattern expands a duct. **B.** The stromal component adjacent to ductal epithelium is similar to a fibroadenoma, but is more cellular. The residual ductal structure is benign.

STROMAL LESIONS

Stromal lesions arise from nonspecialized interlobular stroma. Mesenchymal lesions that occur outside the breast, such as lipomas or vascular tumors, can occur here. Stromal lesions specific to the breast, such as pseudoangiomatous stromal hyperplasia and myofibroblastoma, are also found.

Pseudoangiomatous Stromal Hyperplasia Mimics a Vascular Lesion

Pseudoangiomatous stromal hyperplasia (PASH) is a benign process that is usually found incidentally in biopsies done for other reasons. It occasionally presents as a painless, circumscribed mass with a homogeneous cut surface. It commonly occurs in gynecomastia. Most female patients are premenopausal, suggesting that hormonal factors may play a role in PASH development and growth.

PATHOLOGY: PASH lesions are circumscribed, with homogeneous tan cut surfaces. They vary from 1 to 7 cm. Interanastomosing spaces, which rarely contain red blood cells, are seen in dense collagenous stroma (Fig. 25-21). Myofibroblasts close to these spaces mimic endothelial cells. True vascular channels may occur in the stroma.

Fibromatosis Consists of Fibroblasts and Myofibroblasts

Fibromatosis can be locally aggressive but does not metastasize. The lesions present predominantly as unilateral, painless, firm to hard masses. Most patients are in their 40s, but any age group may be affected. Mammography shows a stellate mass, mimicking carcinoma.

MOLECULAR PATHOGENESIS: Fibromatosis is usually sporadic but is rarely seen in association with familial adenomatous polyposis (FAP) and Gardner syndrome. FAP is caused by mutations in the adenomatous polyposis coli (*APC*) gene, which negatively regulates nuclear translocation of β-catenin. Sporadic and FAP-associated lesions show genetic alterations in APC or β-catenin, affecting the APC/β-catenin pathway (Table 25-1). Breast fibromatosis may also occur during pregnancy, but hormonal factors are not thought to contribute to the pathogenesis.

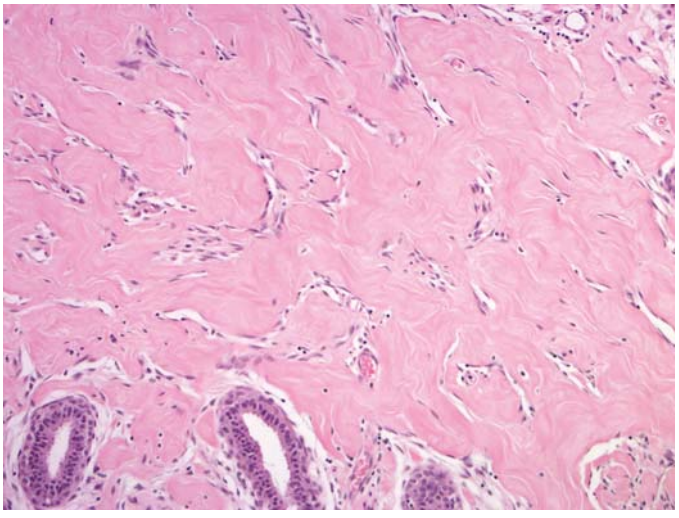

FIGURE 25-21. Pseudoangiomatous stromal hyperplasia. Slit-like spaces within a collagenized stroma are seen. Myofibroblasts are distributed singly at the margins of the spaces, resembling endothelial cells. True capillaries are also evident.

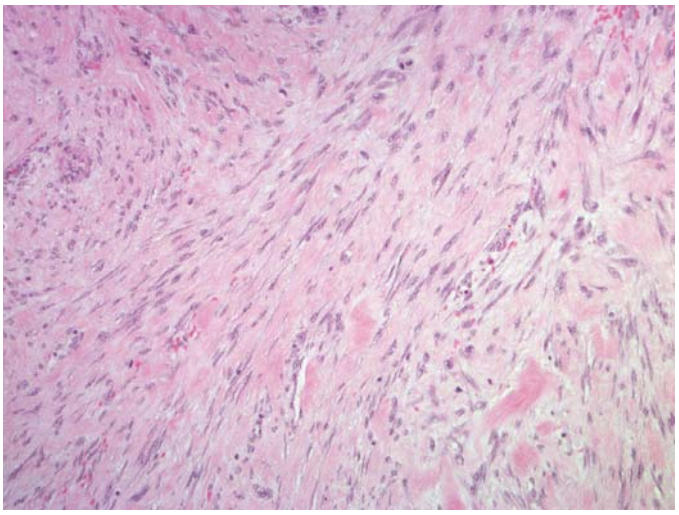

FIGURE 25-22. Fibromatosis. Interlacing bundles of spindle cells, without nuclear atypia, are present with focal bands of collagen.

PATHOLOGY: Grossly, fibromatosis is poorly defined and firm, with infiltrative margins. Sizes vary from less than 1 cm to greater than 10 cm. Broad sweeping fascicles and interlacing bundles of bland-appearing spindle or oval cells characterize fibromatosis (Fig. 25-22). Collagen may be prominent. Adjacent normal breast tissue is infiltrated by proliferating spindle cells, and collections of lymphocytes are common at the periphery. There is no cellular atypia, and mitotic figures are rare (<3 per 10 HPFs).

CARCINOMA OF THE BREAST

Breast cancer is the most common malignancy of women in the United States; its mortality is second only to lung cancer.

EPIDEMIOLOGY: The incidence of breast cancer has slowly increased over the past 50 years. Women in the United States have a 1 in 9 risk of developing breast cancer; however, as this represents lifetime risk, it overestimates actual risk for an individual woman. One in 5 women with breast cancer will die from it. Age-specific incidence rates increase dramatically after age 40. In industrialized countries with high rates of breast cancer, incidence continues to increase with age, finally plateauing at 75–80 years. In some populations, including Hispanic and black women, that plateau is reached at a younger age. Breast cancer is uncommon before the age of 35 in all populations. The incidence of estrogen receptor (ER)–negative cancers increases rapidly until age 50, after which it flattens or decreases. By contrast, ER-positive breast cancer continues to rise after that

age. Thus, peak ages of onset for ER-negative and ER-positive breast cancers are 50 and 70, respectively.

Breast cancer occurs 4–5 times more commonly in Western industrialized countries than in the developing world. Risks in daughters and granddaughters of women who migrated from countries of low incidence to Western countries increase with successive generations.

Widespread use of screening mammography in the 1980s led to a sharp increase in the proportion of diagnoses of noninvasive breast lesions (i.e., DCIS). The frequency of small invasive cancers has also increased. However, although widespread screening mammography greatly increased detection of early breast cancers, it has not appreciably decreased the incidence of late-stage breast cancers. Overall mortality has declined from 30% to 20%, and stage-specific mortality has also improved. Improved therapies have contributed greatly to the decline in breast cancer mortality.

ETIOLOGIC FACTORS: Multiple risk factors for breast cancer have been identified, some of which cannot be modified and some of which are amenable to change (Table 25-2). Women can be stratified by level of breast cancer risk. Those who carry a germline *BRCA* mutation (see below) or who have a history of chest radiation are considered high risk; women who have had multiple family members with breast cancer or who have multiple risk factors are at moderate risk.

Nonmodifiable risk factors include age, race (greatest in non-Hispanic white population), family history, genetic factors (germline mutations in *BRCA1* or *BRCA2*), breast density and early age at menarche. Modifiable risk factors are late age at first live birth, diet, high body mass index, alcohol consumption and use of exogenous hormones.

SPORADIC BREAST CANCER: Only about 25% of sporadic breast cancers have identifiable risk factors. Factors affecting the hormonal milieu modify breast cancer risk.

- ***The majority of breast cancers are stimulated by estrogen.*** Cumulative lifetime exposure to estrogen determines the level of this risk. As such, early menarche (younger than 11 years), late menopause and older age at first term pregnancy increase risk. Pregnancy before age 20 is protective; nulliparity and deferring childbearing until after 35 years of age are associated with a two- to threefold increased relative risk. Longer lactation reduces risk of breast cancer. Oophorectomy before age of 35, but not afterward, dramatically lowers risk of breast cancer. Antiestrogens, including tamoxifen and aromatase inhibitors, decrease the development of ER-positive breast cancer. Oral contraceptives do not increase breast cancer risk, although hormone replacement therapy (HRT) increases risk slightly, 1.2–1.7 times.
- **Radiation** increases risk of breast cancer, as documented in survivors of the atomic bomb and in women who received irradiation for Hodgkin lymphoma. Irradiation earlier in life (i.e., in childhood or adolescence) poses the greatest risk; exposure after the age of 40 years has not been shown to increase incidence.
- The influence of **dietary fat** on breast cancer risk has been extensively studied, and there are limited data to suggest that total fat may increase risk of breast cancer after menopause. However, the risk, if existent, is likely to be small. The effect is postulated to occur through modifying levels of circulating estrogens. Prospective studies of the effects of carbohydrates have not shown consistent associations with breast cancer risk.
- **Alcohol consumption** consistently predicts higher breast cancer rates. Results from the Nurses' Health Study showed that even low levels of alcohol consumption (3–6 drinks per week) were associated with a minute increase in breast cancer risk (relative risk 1.15). The most relevant measure was cumulative average alcohol consumption over long periods of time, and both drinking earlier and later in adult life were independently associated with breast cancer risk. An association with binge drinking was also found.
- Postmenopausal women who are **overweight** or **obese** are at greater risk for breast cancer. Central adiposity has been positively associated with risk. Interestingly, obesity appears to have an opposite effect on breast cancer risk among premenopausal women.
- **Smoking.** Active smoking, particularly if begun at an early age and continuing for a long time, confers increased risk for development of breast cancer. The magnitude of that increased risk is approximately 20%. This risk is strongly associated with a polymorphism at the *NAT2* gene site (N-acetyltransferase 2). One phenotype determined by this locus (slow acetylator) is associated with greater risk of smoking-related breast cancer. Risk of breast cancer associated with environmental smoking is less well established, but some agencies have concluded that younger, mainly premenopausal, nonsmoking women with significant exposure for extended times may have increased risk of breast cancer.
- Mammographic breast density reflects the proportions of stroma and epithelium rather than fat in breasts. Patients with **denser breasts** (i.e., ≥75% density) have a four- to fivefold greater risk of breast cancer. Density is influenced by age, parity, body mass index and menopausal status, although genetic factors may also play a role.
- Higher levels of **physical activity** are associated with a reduction in breast cancer risk, with most studies showing evidence of a dose-response relationship. The benefit of activity is independent of race or ethnicity.

TABLE 25-2
RISK FACTORS FOR BREAST CANCER DEVELOPMENT

Not Modifiable	Modifiable
Age	Body mass index
BRCA germline mutations	Diet
Family history	Alcohol
Chest radiation	Exogenous estrogen
Race/ethnicity	Exercise
Height	Smoking
Age at menarche	Reproductive history
Age at menopause	Age at first full-term delivery
Breast density	Lactation
Atypia on prior breast biopsy	

- Prior breast biopsies showing **atypical hyperplasia** or **nonatypical proliferative breast disease** increase relative risk of 4 to 5 times and 1.5 to 2 times, respectively (see above). Women with a previous breast cancer have a 10-fold increased risk of developing a second primary tumor in the ipsilateral or contralateral breast. Hormonal treatment with antiestrogens decreases this risk.

MOLECULAR PATHOGENESIS:

FAMILIAL BREAST CANCER: The strongest association with increased risk for breast cancer is a family history of breast cancer at a young age in first-degree relatives. The risk is greater if the relative was affected at a young age or had bilateral breast cancer. Familial disease accounts for 10% of breast cancers. Two high-risk breast cancer susceptibility genes, *BRCA1* and *BRCA2*, account for 20%–50% of familial tumors. Some inherited breast cancer susceptibility is part of more generalized familial cancer susceptibility syndromes (Table 25-1). Common inherited polymorphisms have been identified through genome-wide association studies, but the 20 common low-risk alleles identified thus far account for less than 5% of familial risk.

BRCA1 and *BRCA2* are tumor suppressor genes that display an autosomal dominant pattern of inheritance with variable penetrance. *BRCA1*, on chromosome 17q21, is involved in DNA repair, transcriptional regulation, chromatin remodeling and protein ubiquitination. Germline mutations in *BRCA1* confer a lifetime breast cancer risk of between 37% and 85% by age 70 years, with over half of the cancers occurring before age 50. In women older than 70 years, *BRCA1* germline mutations account for less than 2% of cancers; however, 30% of cancers in women under 45 years of age occur in mutation carriers. Carriers are also at significantly increased risk of other cancers, most notably ovarian cancer, with a lifetime risk of 15%–40%. Incidence of cancers of the cervix, endometrium, fallopian tube and stomach is elevated, and prostate cancer is more common in male carriers. About 0.1% of the population has *BRCA1* germline mutations, but rates are higher in Ashkenazi Jews and French Canadians. Breast cancers that develop in patients with germline mutations are typically high-grade, ductal carcinomas, of no special type; however, they show many of the features present in medullary-like cancers, with pushing margins, prominent inflammatory responses, absent tubule formation, high mitotic counts and significant nuclear pleomorphism (Fig. 25-23). In *BRCA1* carriers, the majority of cancers are negative for ER, progesterone receptor (PR) and human epidermal growth factor receptor 2 (HER2), and p53 mutations are more common. Young age at onset is typical.

Germline mutations in *BRCA2*, located on chromosome 13q12, are associated with a 30%–40% lifetime risk of developing breast cancer and an increased risk of ovarian cancer. Moreover, there is an increased incidence of uveal tract and skin melanomas and cancers of the pancreas and biliary tract. Male carriers of *BRCA2* mutations are also at risk for breast and prostatic cancers. Women mostly develop high-grade invasive ductal tumors of no special type. Unlike *BRCA1*-associated cancers, *BRCA2*-related cancers are more commonly ER and PR than are BRCA1 cancers. HER2 gene amplification is rare.

MAMMARY STEM CELLS: Self-renewal of mammary stem cells involves a diverse network of regulatory pathways including Notch, Hedgehog, Wnt/β-catenin, epidermal growth factor receptor (EGFR), transforming growth factor-β (TGF-β), integrins and ER/PR, among others. Current anticancer therapies mostly fail to eradicate stem cell clones and instead favor expansion of the stem cell pool or select for resistant clones. Eradicating these cells may greatly influence breast cancer survival.

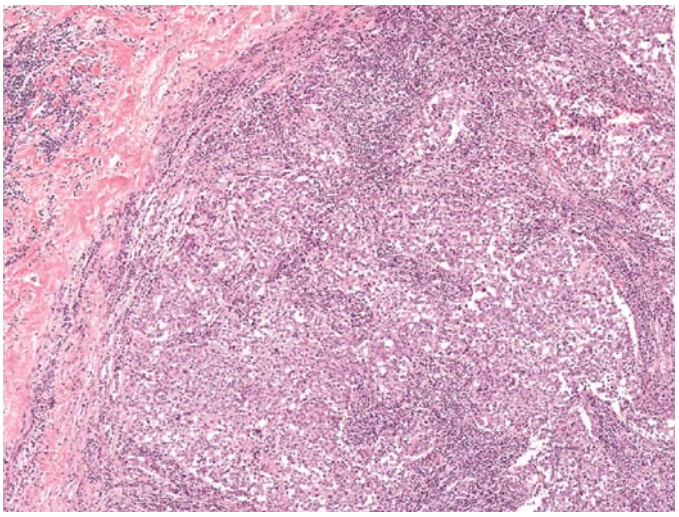

FIGURE 25-23. *BRCA1*-associated breast cancer. High-grade invasive ductal carcinoma, no special type, characterized by pushing margins and a prominent lymphocytic infiltrate.

Carcinoma In Situ May Be a Non-obligate Precursor of Invasive Cancer

Carcinoma of the breast may be **in situ** (confined by the gland's basement membrane) or **invasive,** in which the malignant cells have infiltrated through the basement membrane into adjacent breast stroma. Further subclassification is based on morphology, immunohistochemistry and molecular profiling. Of women with biopsy-proven DCIS who received no further therapy, 20%–30% subsequently developed invasive cancer.

Ductal Carcinoma In Situ

DCIS identifies a heterogeneous group of lesions that vary in their architectural and cytologic features, as well as in their natural history. These abnormalities are considered nonobligate precursors of invasive carcinoma, the chance of progressing to invasion varying with the histologic subtype, grade and extent. The incidence of DCIS has soared with the advent of widespread screening mammography in the mid-1980s. It once represented about 5% of breast cancers beforehand, and now accounts for 25% of breast cancers in screened populations. Because this increased detection of DCIS has not been associated with decreased incidence of advanced breast cancers, the link between the lesions categorized as DCIS and invasive breast cancer is unclear.

MOLECULAR PATHOGENESIS: In some cases, DCIS may be a precursor of invasive breast carcinoma. Thus, DCIS is often seen together with invasive carcinomas. In those cases, noninvasive tumors and

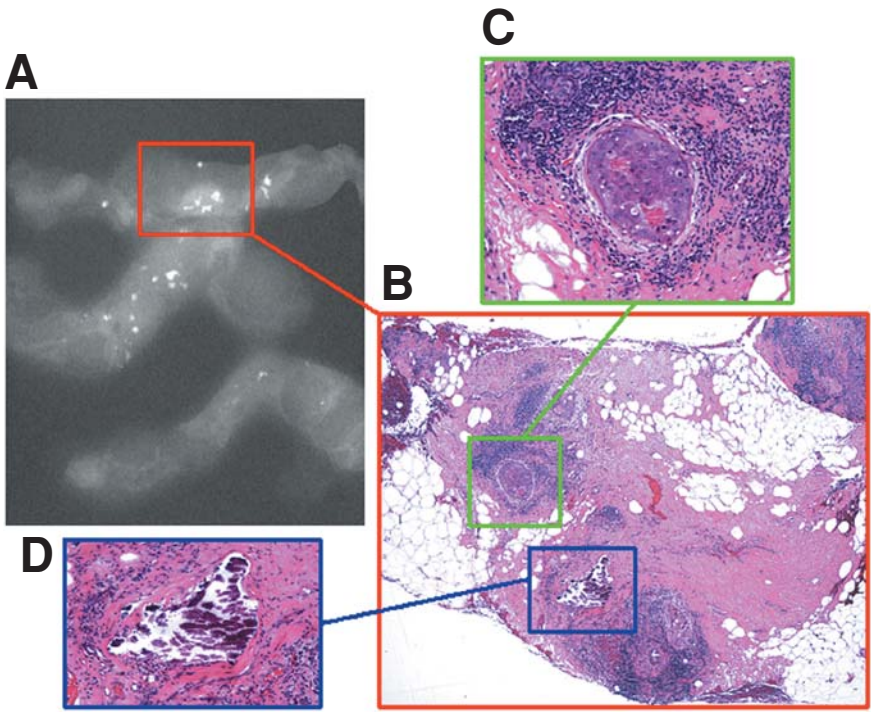

FIGURE 25-24. Ductal carcinoma in situ. A. Specimen radiograph of core biopsy shows linear and punctate atypical calcifications that are highly suspicious for cancer. **B.** Low-power photomicrograph showing high-grade in situ ductal carcinoma. **C.** High-power image of a duct expanded by in situ ductal carcinoma. **D.** High-power photomicrograph of tissue calcification.

their invasive counterparts may show similar cytologic appearance and nuclear grade. Also, DCIS and invasive carcinoma share distinct molecular and cytogenetic alterations. The mechanisms governing any such suggested progression of DCIS to invasive carcinoma, however, are poorly understood.

Further, molecular analyses have shown differences in the numbers and types of chromosomal changes in low- and high-grade DCIS (Table 25-1). Intermediate-grade DCIS shares alterations of both groups. Invasive carcinomas occurring in association with DCIS share grade and molecular alterations. Low-grade and high-grade DCIS are therefore fundamentally distinct entities, and one does not appear to evolve into the other. The same appears to be true for low- and high-grade invasive cancer. ***Multiple pathways of carcinogenesis and progression are likely.***

PATHOLOGY: DCIS predominantly involves ducts but can extend into lobules and is characterized by a proliferation of malignant epithelial cells showing a range of histologic features (Fig. 25-24). Growth patterns may be cribriform, micropapillary, papillary, solid and comedo types, and multiple architectural patterns can coexist in one lesion. More important prognostically is the nuclear grade: low, intermediate and high, although heterogeneity in grade is not uncommon.

- **High-grade DCIS** is composed of large, pleomorphic cells with marked variation in size and shape. The cells have abundant cytoplasm, irregular nuclei with prominent nucleoli and coarse chromatin. They proliferate rapidly. Intraductal necrosis is common (Fig. 25-25) and appears grossly as distended ducts with white necrotic material resembling comedos, hence the term **comedo necrosis**. The cellular necrotic debris often undergoes dystrophic calcification, which may be seen on mammography as linear, branching calcifications. The cells remain in duct spaces, but periductal chronic inflammation and formation of new vessels may be present. DCIS spreads through the duct system and often extends beyond clinically detected borders, making clear margins difficult to obtain. Cells with high nuclear grade can be seen with any of the above growth patterns.
- **Low-grade DCIS:** At the other end of the histologic spectrum, in low-grade DCIS cells are uniform, small and evenly spaced, with round, regular hyperchromatic nuclei (Fig. 25-26). Mitoses are infrequent. Micropapillary or cribriform growth predominates, and solid growth patterns are less common. Although necrosis is uncommon, foci of either punctate or comedo necrosis can be seen.

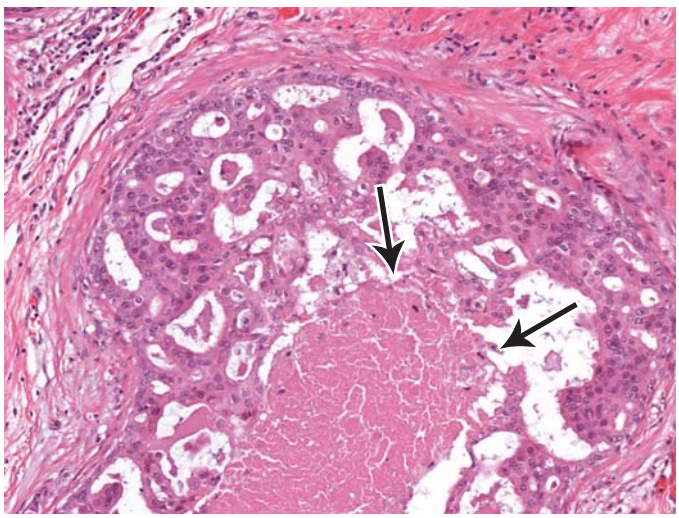

FIGURE 25-25. Ductal carcinoma in situ (DCIS) with comedo necrosis. Intraductal carcinoma with a cribriform architecture and central comedo necrosis (*arrows*).

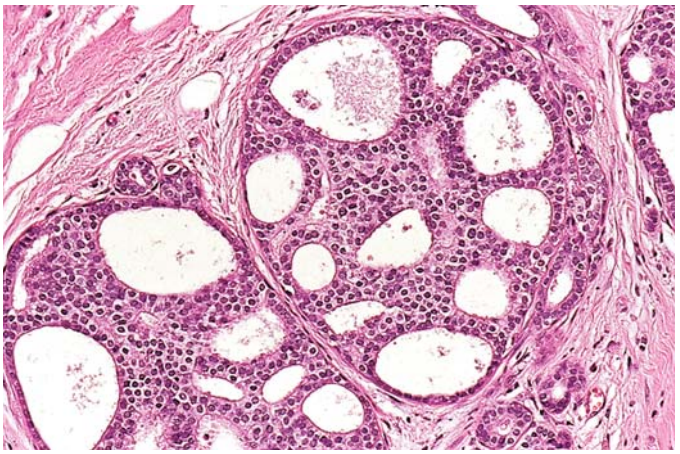

FIGURE 25-26. Ductal carcinoma in situ noncomedo type. A cribriform arrangement of tumor cells is evident.

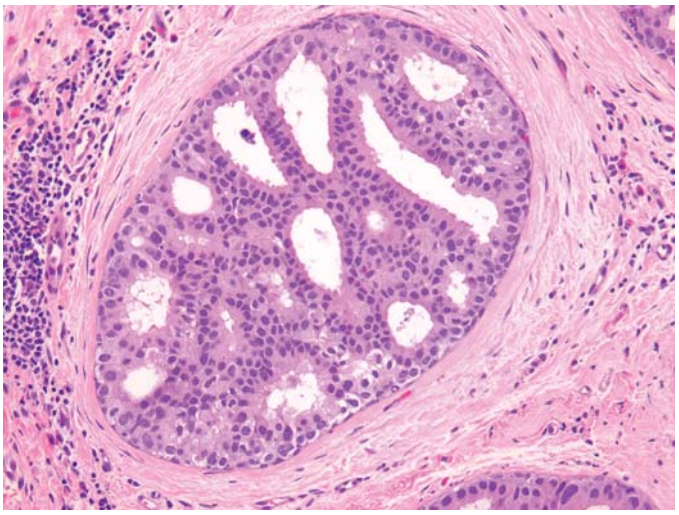

FIGURE 25-27. Intermediate-grade ductal carcinoma in situ with moderate nuclear pleomorphism and some polarization of cells around secondary spaces.

- **Intermediate-grade DCIS:** Intermediate-grade DCIS falls between high- and low-grade DCIS. Cells show moderate pleomorphism but maintain some degree of polarization (Fig. 25-27). Solid or cribriform growth is typical.
- **Microinvasive carcinoma:** This pattern is defined as one or more foci of invasive carcinoma, none of which exceed 1 mm in diameter (Fig. 25-28). ***This lesion typically occurs in the setting of high-grade DCIS.***

Immunohistochemistry may occasionally be required to aid in the diagnosis of DCIS. DCIS is distinguished from epithelial hyperplasia of usual type because, in contrast to the latter, DCIS lacks high–molecular-weight cytokeratin staining. Still, some high-grade DCIS may express "basal," high–molecular-weight cytokeratins. Stains for myoepithelial cell markers (smooth muscle myosin heavy chain, calponin, p63, etc.) will confirm that the lesion is in situ and help in cases with foci suspicious for microinvasion.

Low- and intermediate-grade DCIS typically show strong diffuse staining for ER. High-grade lesions show less frequent ER staining but often overexpress HER2 (up to 60% of cases). This frequency is greater than what is seen in invasive carcinoma. Currently, ER is the only biomarker assessed in routine clinical practice.

CLINICAL FEATURES: DCIS is most often visualized on mammography as calcifications. A small proportion of women present symptomatically with a mass lesion, a nipple discharge or Paget disease of the nipple (see below).

DCIS is treated by surgical excision. Breast-conserving surgery is possible in many cases, and adjuvant radiation reduces the risk of recurrence. When tumors recur, they do so at the site of the previous surgery and are invasive carcinomas 50% of the time. Lymph node metastases occur in less than 1% of patients with DCIS. In such cases, foci of invasion may have been missed when examining the

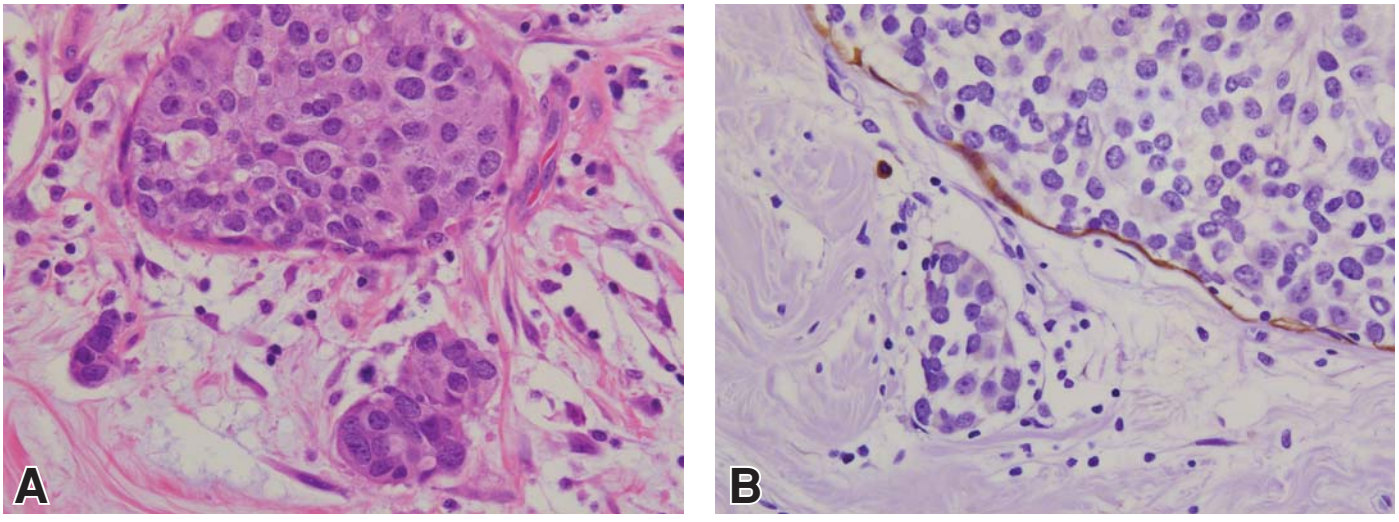

FIGURE 25-28. Ductal carcinoma in situ (DCIS) **(A)** with focus of microinvasive carcinoma. **(B)** Immunohistochemical staining with smooth muscle myosin heavy chain confirms the absence of a myoepithelial cell layer around the small stromal cluster.

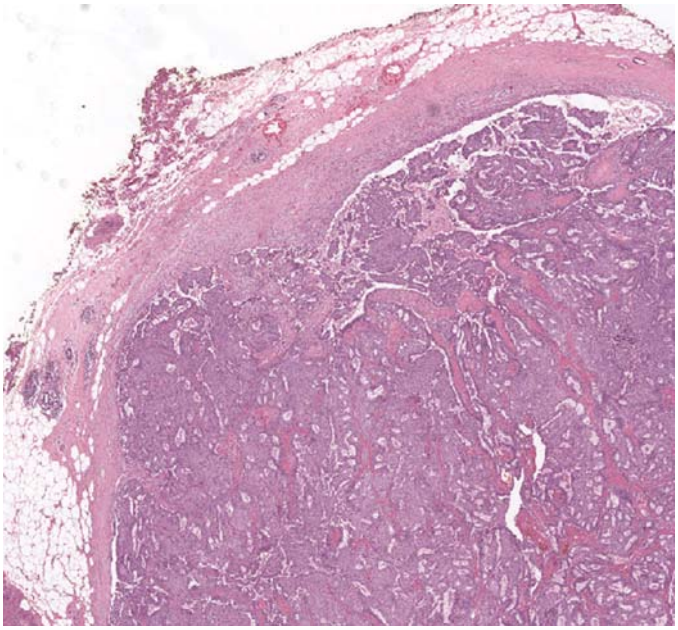

FIGURE 25-29. Encapsulated papillary carcinoma. Fibrovascular cores lined by malignant epithelial cells, without an intervening myoepithelial cell layer. The edge of the tumor has a pushing front, without evidence of stromal invasion.

primary lesions. Antihormone therapy reduces the risk of recurrence or progression for DCIS, which may be the case for hormone receptor–positive cases only. In all, the critical prognostic factors for patients with DCIS include lesion size, nuclear grade, the presence of comedo necrosis and margin status. Cancer-specific mortality is extremely low, with 1.0%–2.6% dying from invasive cancer 8–10 years after diagnosis of DCIS.

Encapsulated Papillary Carcinoma Is an Indolent Tumor

Encapsulated papillary carcinoma covers lesions previously called intracystic or encysted papillary carcinoma. These lesions have no myoepithelial cells at their periphery, and their true nature (i.e., whether they are truly in situ or, perhaps, invasive) is unclear. They are well-circumscribed, partially cystic, frequently hemorrhagic, solid masses. A capsule surrounds fibrovascular cores that are lined by one or more layers of malignant epithelial cells, with no intervening myoepithelial cell layer (Fig. 25-29). The cells are usually low to intermediate grade. At its edge, the tumor has a smooth pushing border, although frank stromal invasion can be present; this is typically invasive carcinoma of no special type.

Limited data show that these tumors have genetic alterations involving LOH at 16q and 1q. These tumors are not aggressive and metastases are rare. While controversial, the current approach is to stage them as Tis disease. If there is a component of conventional invasive carcinoma, the tumor stage should be based on the extent of the invasive component.

Paget Disease of the Nipple Reflects Extension of DCIS or Invasive Cancer

In Paget disease of the nipple, malignant glandular cells penetrate the epidermis of the nipple and areola. It is invariably associated with underlying DCIS, with or without invasive ductal carcinoma. This disease is rare, occurring in 1%–4% of breast cancers.

Paget disease presents as erythema or an eczematous change to the nipple and areola (Fig. 25-30A), sometimes with nipple retraction. Half of patients have palpable masses.

Malignant glandular epithelial cells are present in the epidermis, singly or in small groups (Fig. 25-30B). They

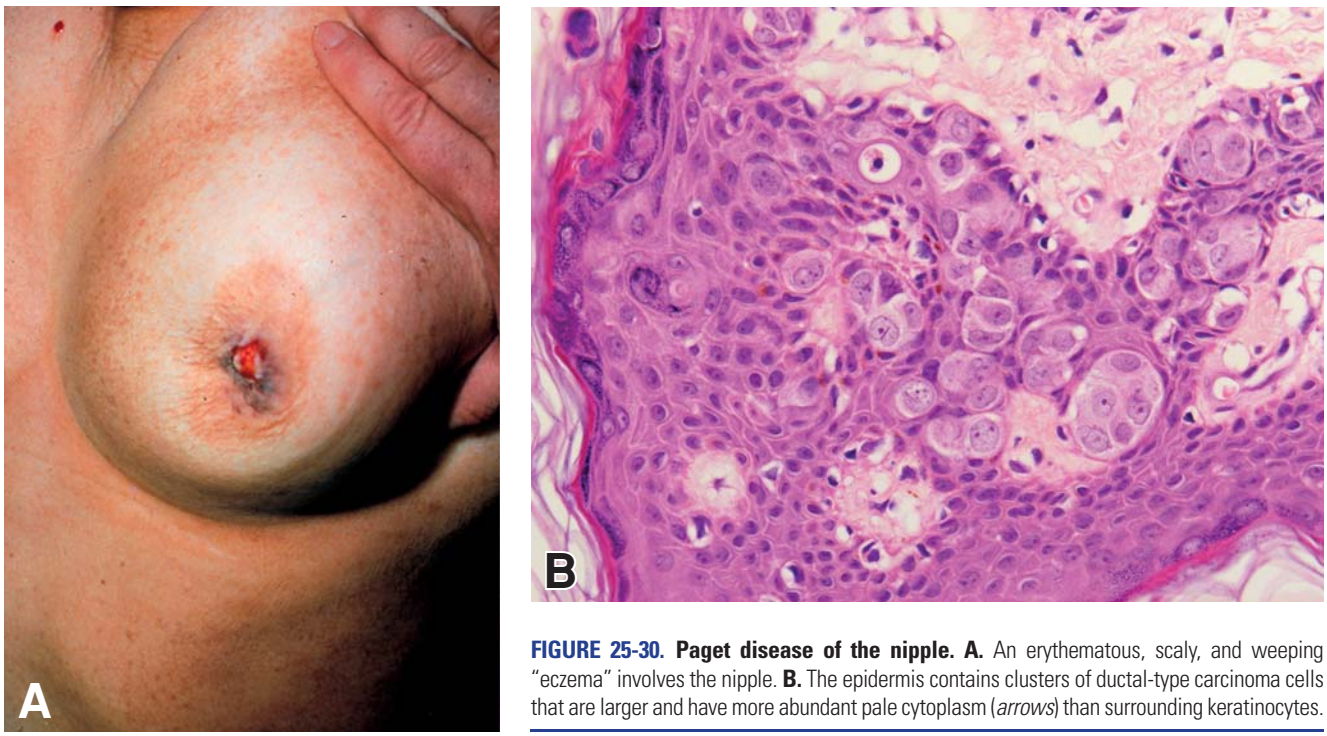

FIGURE 25-30. Paget disease of the nipple. A. An erythematous, scaly, and weeping "eczema" involves the nipple. **B.** The epidermis contains clusters of ductal-type carcinoma cells that are larger and have more abundant pale cytoplasm (*arrows*) than surrounding keratinocytes.

are large, with abundant cytoplasm that contains mucin globules, and pleomorphic nuclei with prominent nucleoli. These cells express epithelial membrane antigen (EMA) and low–molecular-weight cytokeratins. They almost always overexpress HER2. ER and PR are also positive in 40% and 30% of cases, respectively. Paget cells genetically resemble underlying tumor cells in the vast majority of cases. Prognosis is a function of the stage of the underlying breast cancer and not the presence of Paget cells.

Lobular Neoplasia Encompasses LCIS and ALH

Both ALH and LCIS (see above) reflect the same atypical proliferations of loosely cohesive epithelial cells, but they differ in the relative risk of developing breast cancer.

EPIDEMIOLOGY: Since LCIS is generally asymptomatic, its true incidence is unknown. Estimated incidence is 1%–4%. It is bilateral in up to 30% of patients and multicentric in 85%. ALH and LCIS are best considered to be risk factors: the cancers that develop are typically not at the same site as these lesions and may be in the contralateral breast. Relative risk of subsequent cancer is 3–5.5-fold for ALH and 7–10-fold for LCIS. For LCIS, this means an absolute risk of 1%–2% per year and a lifetime risk of 30%–40%. Some evidence supports a precursor role for these lesions, albeit not an obligate one: a disproportionately high number of tumors that develop are invasive lobular carcinoma, and 2/3 occur in the ipsilateral breast. Furthermore, coexistent LCIS and invasive lobular carcinomas often show the same genetic changes, suggesting that at least some LCISs are precursors to invasive carcinoma.

MOLECULAR PATHOGENESIS: Studies have identified genetic and karyotypic abnormalities in LCIS and ALH (Table 25-1). These studies have identified recurrent 16q22.1 loss in LCIS, ALH and invasive lobular carcinoma, for which the target gene encodes E-cadherin. This protein plays an essential role in cell adhesion and in cell cycle regulation through the β-catenin/Wnt pathway. Patients with germline mutations in this gene are at a high risk of developing lobular breast carcinoma and gastric signet ring cell carcinoma. Pleomorphic LCIS shares recurrent genomic alterations with classic LCIS (Table 25-1) but also harbors greater genomic instability.

PATHOLOGY: LCIS rarely appears grossly or with mammography: associated calcifications may present in nonneoplastic luminal epithelial cells. Also, rare variants, such as pleomorphic LCIS and classic LCIS with comedo necrosis, and dystrophic calcification with central necrosis, are detectable on mammography.

The cells of LCIS are monotonous and small, with round regular nuclei and minute nucleoli, although larger cells with conspicuous nucleoli occasionally dominate (Fig. 25-31). Cytoplasmic mucin vacuoles may be surrounded by a distinct halo. Unlike DCIS, the cells of LCIS do not form complex patterns but rather make solid clusters that pack and distend lobular acini. The growth pattern is loosely cohesive or dishesive. Gaps between individual cells reflect loss of cell–cell adhesion (see above). Pagetoid spread of lobular neoplastic cells is common in LCIS, where the cells track along beneath ductal luminal epithelial cells.

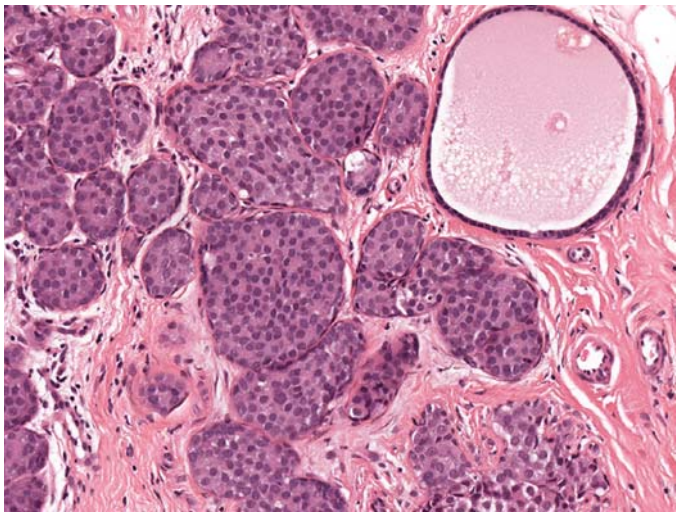

FIGURE 25-31. Lobular carcinoma in situ. The lumina of the terminal duct lobular units are distended by tumor cells, which exhibit round nuclei and small nucleoli. Cytoplasmic mucin vacuoles are present.

ALH and LCIS are diagnosed by the degree of filling and distention of acini. In LCIS, at least 50% of acini in a lobular unit are completely involved and distended by the atypical cell population, in contrast to less than 50% in ALH. LCIS rarely shows comedo necrosis, but when it does, the comedo necrosis greatly distends the involved spaces. Constituent cells retain the cytologic features of classic LCIS (Fig. 25-32).

Pleomorphic LCIS shows moderate to marked variation in nuclear size and shape and nuclear hyperchromasia. Nucleoli and mitotic figures are variably prominent (Fig. 25-33). Central comedo necrosis, often with microcalcifications, is typical. These are rare in classic LCIS.

Distinguishing LCIS from low-grade solid DCIS may be difficult. The absence of immunostaining for E-cadherin in LCIS and ALH may help make that distinction (Fig. 25-34), as DCIS cells retain cell membrane staining for E-cadherin.

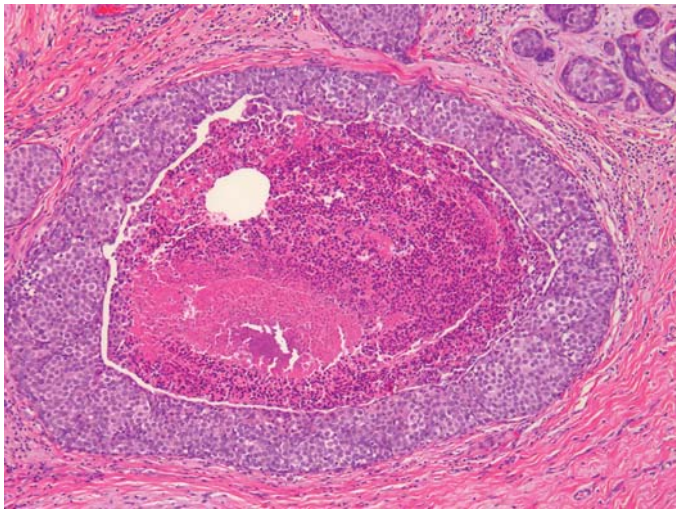

FIGURE 25-32. Lobular carcinoma in situ showing classic nuclear features but central expansile comedo necrosis.

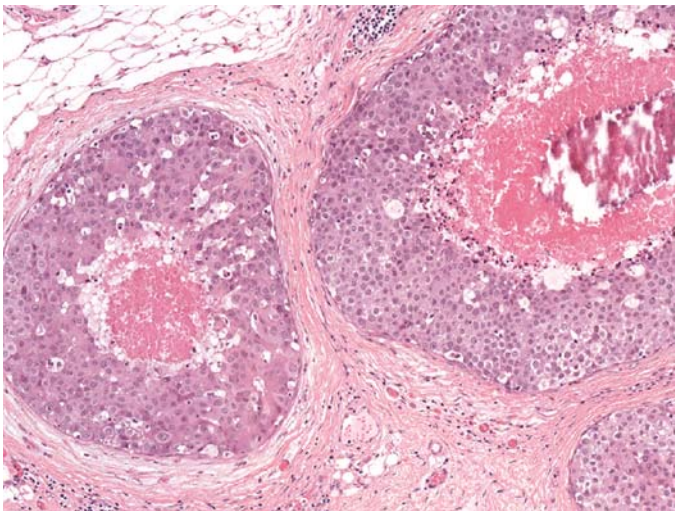

FIGURE 25-33. Pleomorphic lobular carcinoma in situ (PLCIS). A dyshesive population of markedly atypical epithelial cells with central comedo necrosis fill and distend the ducts. Dissociation of the neoplastic cells gives rise to spaces that may be misinterpreted as secondary spaces. E-cadherin expression was absent.

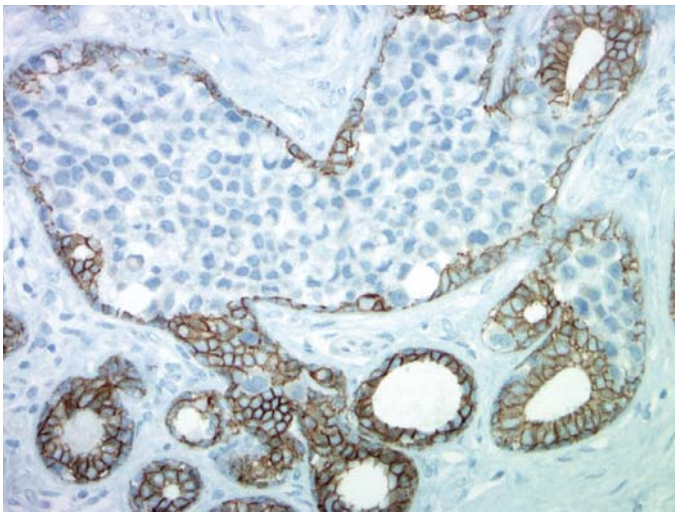

FIGURE 25-34. E-cadherin in lobular carcinoma in situ (LCIS). Membranous E-cadherin expression is seen in residual luminal epithelial cells, but the lobular neoplastic cells should show loss of staining.

CLINICAL FEATURES: The management of a patient with LCIS is controversial. For classic LCIS, many authorities would opt for no further surgical management. However, adjuvant hormonal therapy may be considered, and lifelong follow-up is required. Variant LCIS (pleomorphic, or classic LCIS with comedo necrosis), may require surgical excision with clear margins, plus, possibly, adjuvant radiation therapy.

Invasive Breast Carcinoma Is Derived from the TDLU

Breast cancer can occur anywhere in the breast but is most common in the upper outer quadrant. Patients most often have an ill-defined breast mass, which may be adherent to the skin or underlying muscle. Nonpalpable asymptomatic tumors are usually detected by mammography. These mostly appear radiologically as a spiculated mass or architectural distortion, with or without associated microcalcifications.

Most breast cancers are classified as carcinomas of no special type (NST). The remainder are special types of carcinomas or have mixed morphologic features.

Invasive Ductal Carcinoma, No Special Type

Of invasive breast cancers, 50%–70% fall in this category. These tumors are a heterogeneous group that do not show characteristics of a specific or "special" histologic type. The term "invasive carcinoma of no special type (ductal NST)" is preferred by the World Health Organization (WHO) Working Group.

Ductal NSTs present as irregular, dense masses on mammography or ultrasound (Fig. 25-35A). They are usually moderately or poorly defined, are nodular or stellate, and have firm to hard cut surfaces (Fig. 25-35B). Tumor cells form trabeculae, sheets, nests and glands (Fig. 25-35C). Nuclear pleomorphism and mitotic counts vary. Surrounding stroma varies from desmoplastic to collagenous. Higher-grade lesions may show

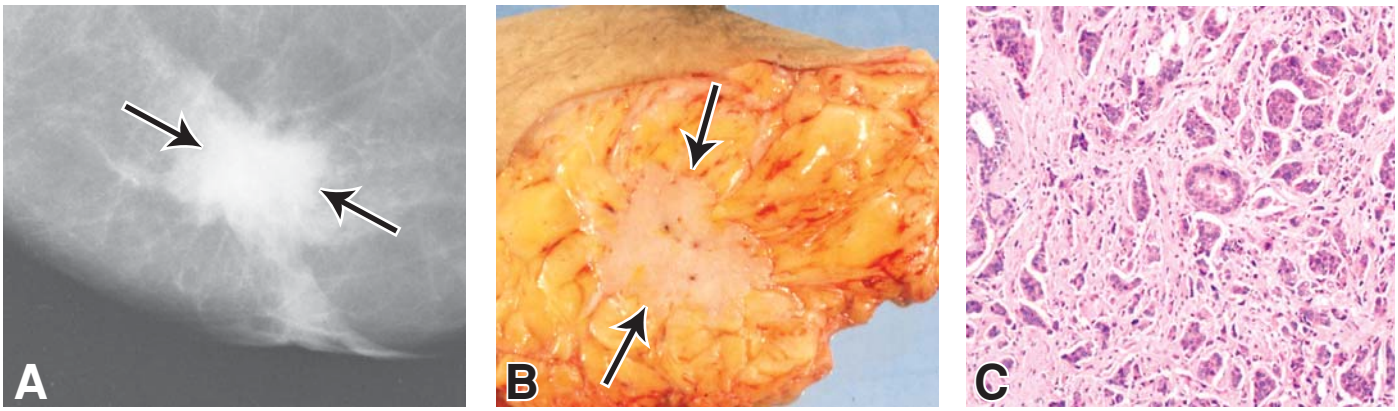

FIGURE 25-35. Carcinoma of the breast. A. Mammogram. An irregularly shaped, dense mass (*arrows*) is seen in this otherwise fatty breast. **B.** Mastectomy specimen. The irregular white, firm mass in the center is surrounded by fatty tissue. **C.** Photomicrograph showing irregular cords and nests of invasive ductal carcinoma cells invading stroma.

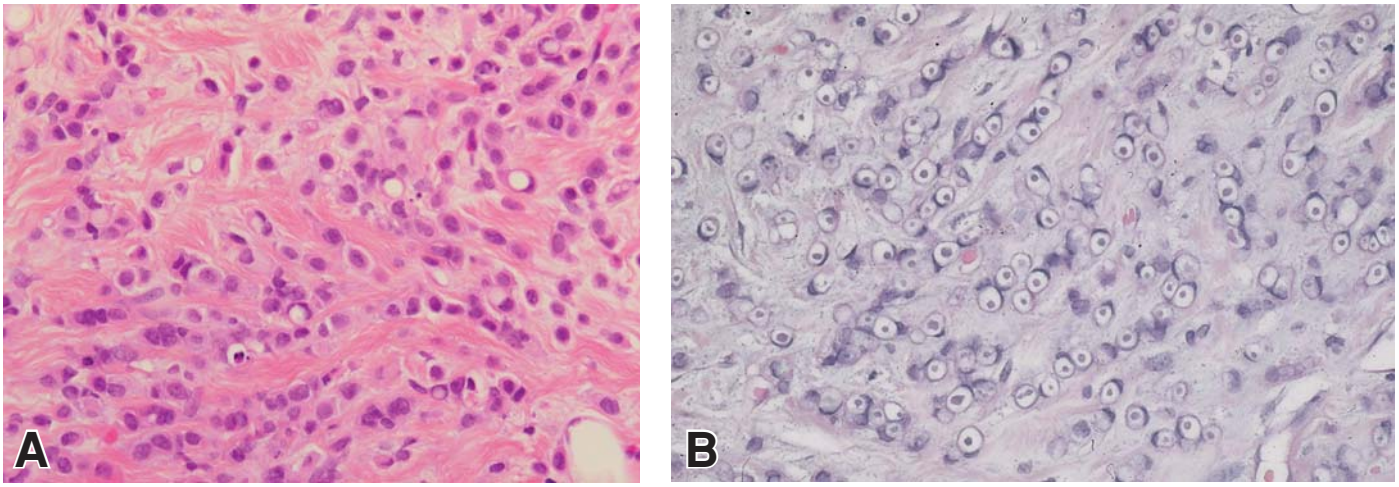

FIGURE 25-36. Lobular carcinoma. A. Invasive lobular carcinoma. In contrast to invasive ductal carcinoma, the cells of lobular carcinoma tend to form single strands that invade between collagen fibers in a diffuse pattern. The tumor cells are similar to those seen in lobular carcinoma in situ. **B. Signet ring carcinoma.** The tumor cells contain large amounts of clear mucin.

tumor necrosis. If a special-type component makes up over 50% of the tumor, the tumor is considered mixed (i.e., ductal with special-type features). DCIS is present in up to 80% of cases and is typically of the same nuclear grade as the invasive component.

Most ductal NSTs (75%) are ER positive, and 15% are HER2 positive. Specific genetic lesions or alterations are associated with a particular histologic type or grade in some cases. Low-grade invasive NSTs are usually diploid or near diploid, with trends in chromosomal variations (Table 25-1), while high-grade tumors tend to be less easily categorized. Since deletions of 16q are found in only about 1/3 of low-grade NSTs, progression from low- to high-grade cancer is probably relatively uncommon.

Overall, 35%–50% of patients with ductal NSTs survive 10 years, varying according to grade, tumor and lymph node stage and the presence of lymphovascular invasion.

Invasive Lobular Carcinoma

Invasive lobular carcinoma is the second most common form of invasive breast cancer, accounting for 5%–15% of all invasive carcinomas. Because stromal desmoplasia and fibrosis may be minimal, patients often have clinically silent disease grossly and by mammography, or may present with a poorly defined thickening of the breast. Lobular cancers characteristically show dishesive malignant epithelial cells that infiltrate the stroma diffusely (Fig. 25-36). They often line up in a row and may show a periductal "targetoid" arrangement. They do not form ducts, but rather solid sheets, trabeculae or nests. Neoplastic cells typically contain intracytoplasmic lumina and eccentric nuclei and resemble the cells of LCIS.

Invasive lobular carcinomas are more often ER positive than are ductal NSTs, although high-grade lobular cancers may lack ER and overexpress HER2. E-cadherin expression is usually low or absent, reflecting biallelic loss of the tumor suppressor gene that encodes this protein. Patterns of genetic changes in invasive lobular carcinoma differ from those in ductal carcinomas (Table 25-1).

These carcinomas tend to spread to the peritoneum, retroperitoneum, ovary and uterus, leptomeninges and gastrointestinal tract (Fig. 25-37). Matched for grade and stage, their prognosis is similar to that of ductal NST cancers.

Tubular Carcinoma

Tubular carcinomas represent 1%–2% of invasive breast cancers. Mammography detects this tumor disproportionately frequently. Tubular carcinomas are well-defined stellate masses whose cellular composition is almost entirely open and angulated tubules, lined by a single layer of mildly atypical epithelial cells (Fig. 25-38A). Over 95% of tubular carcinomas are ER positive and HER2 negative. Tubular carcinomas share some patterns of karyotypic changes with other tumor types (Table 25-1). Lymph node metastases are rare, and patients with tubular carcinomas have an excellent prognosis.

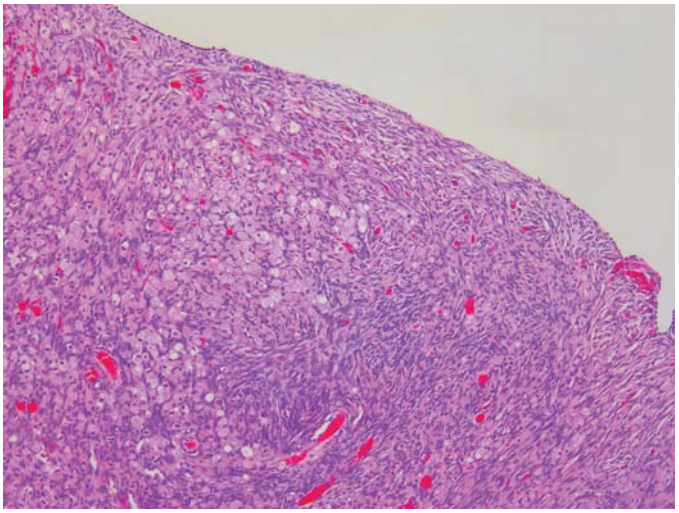

FIGURE 25-37. Ovary showing metastatic lobular carcinoma characterized by dyshesive cells with eccentric nuclei and intracytoplasmic lumens.

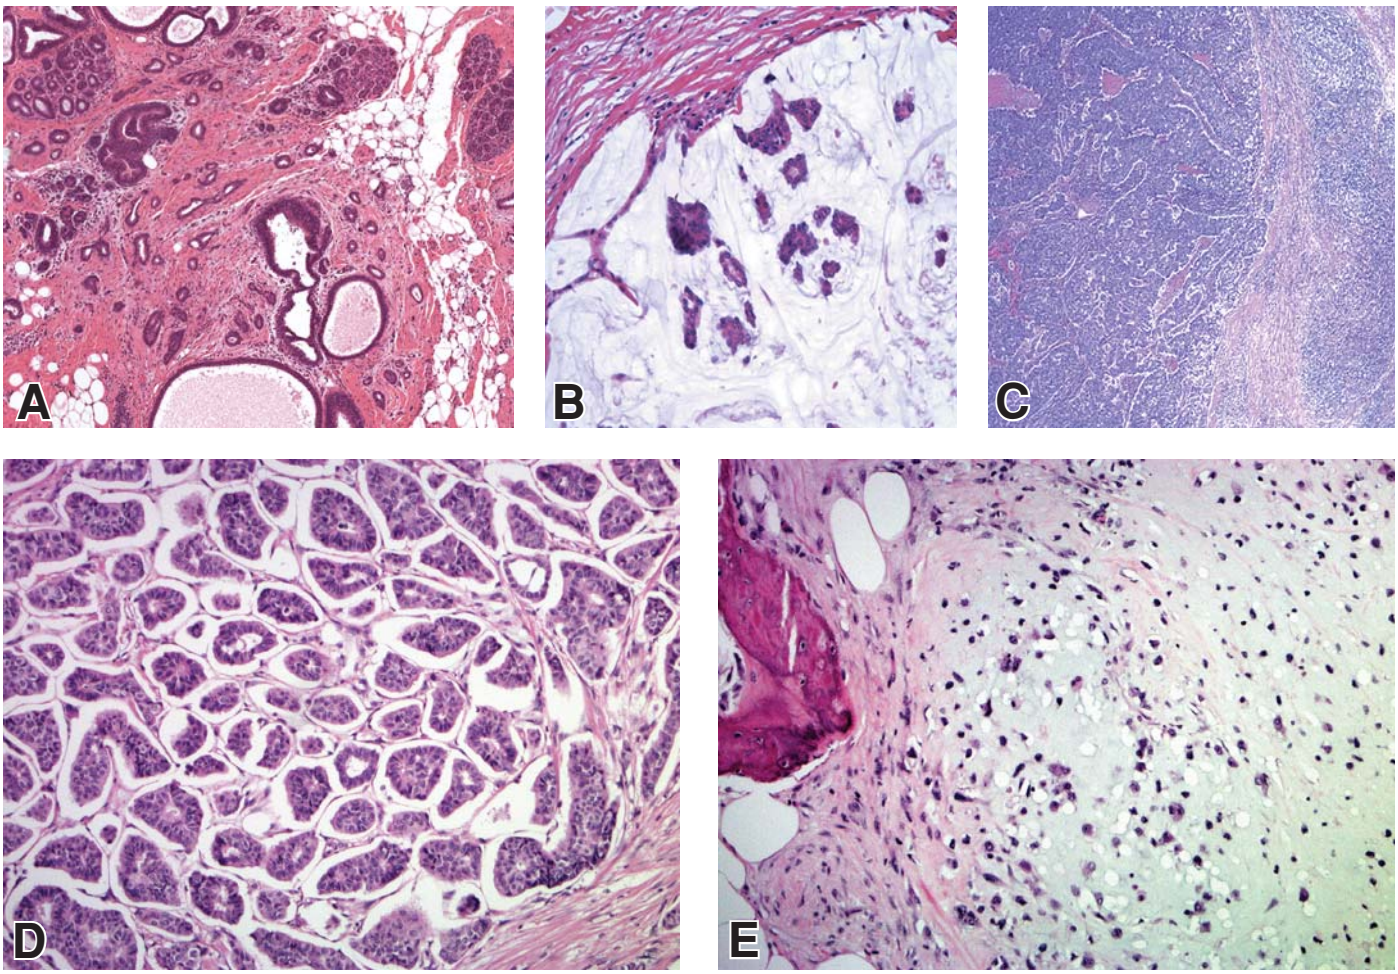

FIGURE 25-38. Patterns of breast carcinoma. A. Tubular carcinoma. Open and angulated malignant glands are dispersed between normal lobules and show extension into fat. A single layer of epithelium lines the tubules, and myoepithelial cells are absent. **B. Mucinous carcinoma.** Clusters of malignant cells float in large pools of extracellular mucin. **C. Medullary carcinoma.** The malignant cells are pleomorphic and grow in solid sheets, forming a blunt margin. There is no gland formation. Numerous mitoses are present. The tumor is surrounded by a dense lymphocytic infiltrate. **D. Micropapillary carcinoma.** Sponge-like pattern of empty spaces containing glands and small clusters of malignant epithelium. Focal serration of the outer borders of the glands is seen. **E. Metaplastic carcinoma.** Cartilaginous and osseus matrix in a metaplastic carcinoma with heterologous elements. Elsewhere, foci of poorly differentiated adenocarcinoma were seen.

Mucinous Carcinoma

Patients with mucinous carcinoma are typically older than those with other tumor types. These tumors, which make up 1%–6% of breast cancers, are well circumscribed, with a gelatinous texture. Low-grade malignant epithelial cells form acini, nests or trabeculae, which appear to float in pools of extracellular mucin (Fig. 25-38B). The malignant epithelial cells do not invade stroma directly. Pure mucinous carcinomas show little genomic instability or recurrent amplifications. They are uniformly of low histologic grade. Most are ER positive and HER2 negative. Patients with pure mucinous carcinoma have an excellent prognosis.

Carcinomas with Medullary Features

Classic medullary carcinomas are exceptionally rare, although other types of carcinoma may show medullary features. Almost 1/2 of patients are younger than 50. Medullary tumors are well circumscribed and soft, and include all of the following: (1) grade 2–3 nuclei; (2) circumscribed, pushing margins; (3) syncytial growth pattern in greater than 75% of the tumor; (4) a moderate or marked lymphoplasmacytic infiltrate; and (5) no tubule formation (Fig. 25-38C). DCIS is an uncommon concomitant. Medullary cancers are typically ER, PR and HER2 negative ("triple negative") and have characteristic patterns of genetic changes (Table 25-1). While tumors arising in patients with *BRCA1* germline mutations often show medullary features, only 13% of tumors with medullary features are associated with this mutation.

The prognosis for pure medullary carcinoma is better than for high-grade ductal NST tumors, and lymph node metastases occur less frequently. Most women who die from their disease do so within 5 years of diagnosis.

Micropapillary Carcinoma

Pure micropapillary carcinoma occurs rarely, but micropapillary areas are more often admixed with ductal NST carcinoma. In these tumors, malignant epithelial nests or acini are surrounded by a clear space (Fig. 25-38D). As micropapillary tumors invade lymphatic vessels and metastasize to lymph

nodes readily, recognizing even a minor component of micropapillary carcinoma is important. The high frequency of lymph node metastases notwithstanding, it is unknown if micropapillary tumors have an inherently poorer prognosis.

The vast majority of micropapillary carcinomas are ER and PR positive. Up to 1/3 show HER2 positivity. Common genetic changes seen in these tumors are shown in Table 25-1.

Metaplastic Carcinoma

Metaplastic carcinomas are heterogeneous tumors with malignant spindle cells, squamous cell carcinoma or heterologous elements, such as bone or cartilage (Fig. 25-38E). Adenocarcinoma may be absent, but cytokeratin immunostains are at least focally present. These tumors typically cluster with the basal molecular subgroup on gene expression profiling (see below).

Metaplastic tumors are usually ER and HER2 negative and show complex patterns of chromosomal gains and losses (Table 25-1).

Subtypes of metaplastic carcinomas are associated with better or worse prognosis when compared with ductal NSTs. Low-grade, fibromatosis-like, metaplastic carcinoma and low-grade adenosquamous metaplastic carcinoma are associated with a favorable outcome. Other metaplastic subtypes respond poorly to adjuvant chemotherapy and fare worse than other forms of triple-negative breast cancer.

PROGNOSTIC FACTORS

Breast Cancer Staging

Breast cancer survival is strongly influenced by tumor stage, expressed as the TNM classification (tumor [T], regional lymph nodes [N] and distant metastasis [M] (Table 25-3). Breast cancer spreads by direct extension (e.g., to chest wall); via lymphatics to axillary, internal mammary and infra- and supraclavicular lymph nodes; and hematogenously to distant sites.

TABLE 25-3
PATHOLOGIC TUMOR STAGING

pTis	Carcinoma in situ (ductal or lobar) or Paget disease without invasive carcinoma
pT1mic	Microinvasion (≤1 mm)
pT1a	Invasive tumor >1 mm but ≤5 mm
pT1b	Invasive tumor >5 mm but ≤1 cm
pT1c	Invasive tumor >1 cm but ≤2 cm
pT2	Invasive tumor >2 cm but ≤5 cm
pT3	Invasive tumor >5 cm
pT4	Edema or tumor ulcerating through skin or satellite skin nodules and/or chest wall invasion[a] or inflammatory breast carcinoma

[a]Does not include invasion of the pectoralis muscle.
Data from Edge SB, Byrd DR, Compton CC, et al., eds. AJCC Cancer Staging Manual, 7th ed. New York: Springer, 2009.

Tumor Size

Prognosis varies with tumor size (T in the TNM protocol): patients with larger tumors show poorer survival. In assessing tumor size, only the invasive part is considered. Some locally advanced tumors are staged T4, based on skin or chest wall invasion, regardless of tumor size.

"Inflammatory breast cancer" has a particularly poor prognosis. This tumor features edema, erythema, induration, warmth and tenderness of overlying skin, resulting in an orange peel–like ("peau d'orange") appearance. Arm edema and pain may also occur, probably because of lymphatic obstruction by tumor. These findings correspond to tumor invasion of dermal lymphatic vessels.

Lymph Node Status

The presence or absence of axillary lymph node metastases is a key prognostic indicator for patients with breast cancer and requires pathologic evaluation of surgically resected lymph nodes. Axillary dissection risks significant postoperative morbidity (i.e., lymphedema and nerve damage). Sentinel lymph node (SLN) biopsy reduces this risk. This procedure requires injection of a dye and radioactive isotope and involves intraoperative lymphatic mapping of the draining or "sentinel" lymph node, the node most likely to contain breast cancer metastases. If it is negative, axillary dissection can safely be avoided. Immunohistochemical staining may help to identify cytokeratin-positive epithelial cells that may not be seen otherwise. Such detailed SLN evaluation has improved detection of micrometastases (>0.02 cm, <0.2 cm or >200 cells) and isolated tumor cells. The actual impact on prognosis of small metastases is small compared with node-negative women. Thus, there is a general consensus that there is little value in performing additional levels or immunohistochemical studies on SLNs.

Distant Metastases

Distant metastases portend a poor prognosis. Breast cancers metastasize to bone, which is where metastatic disease presents in 25% of cases. Of women who die from their disease, 70% eventually develop bone involvement. Smaller percentages of patients have other metastases, usually to lung, liver, central nervous system (CNS), skin and adrenal glands.

Tumor Grade

Histopathologic grading of breast tumors is one of the critical components of decision making. The Nottingham grading system, also called the modified Bloom and Richardson method, is most widely used. It combines scores for tubule formation, nuclear pleomorphism and mitotic count into a final grade of 1, 2 or 3 for low-, intermediate- and high-grade carcinomas, respectively (Fig. 25-39). Patients with grade 1 tumors have significantly better survival than those with grade 2 or grade 3 tumors.

Other Prognostic Features

- **Lymphovascular invasion (LVI):** Finding tumor cells within lymphovascular spaces correlates well with lymph node metastases (Fig. 25-40) and is a poor prognostic sign. If both LVI and nodal metastases are present, prognosis is worse than either alone. Furthermore, LVI is present in

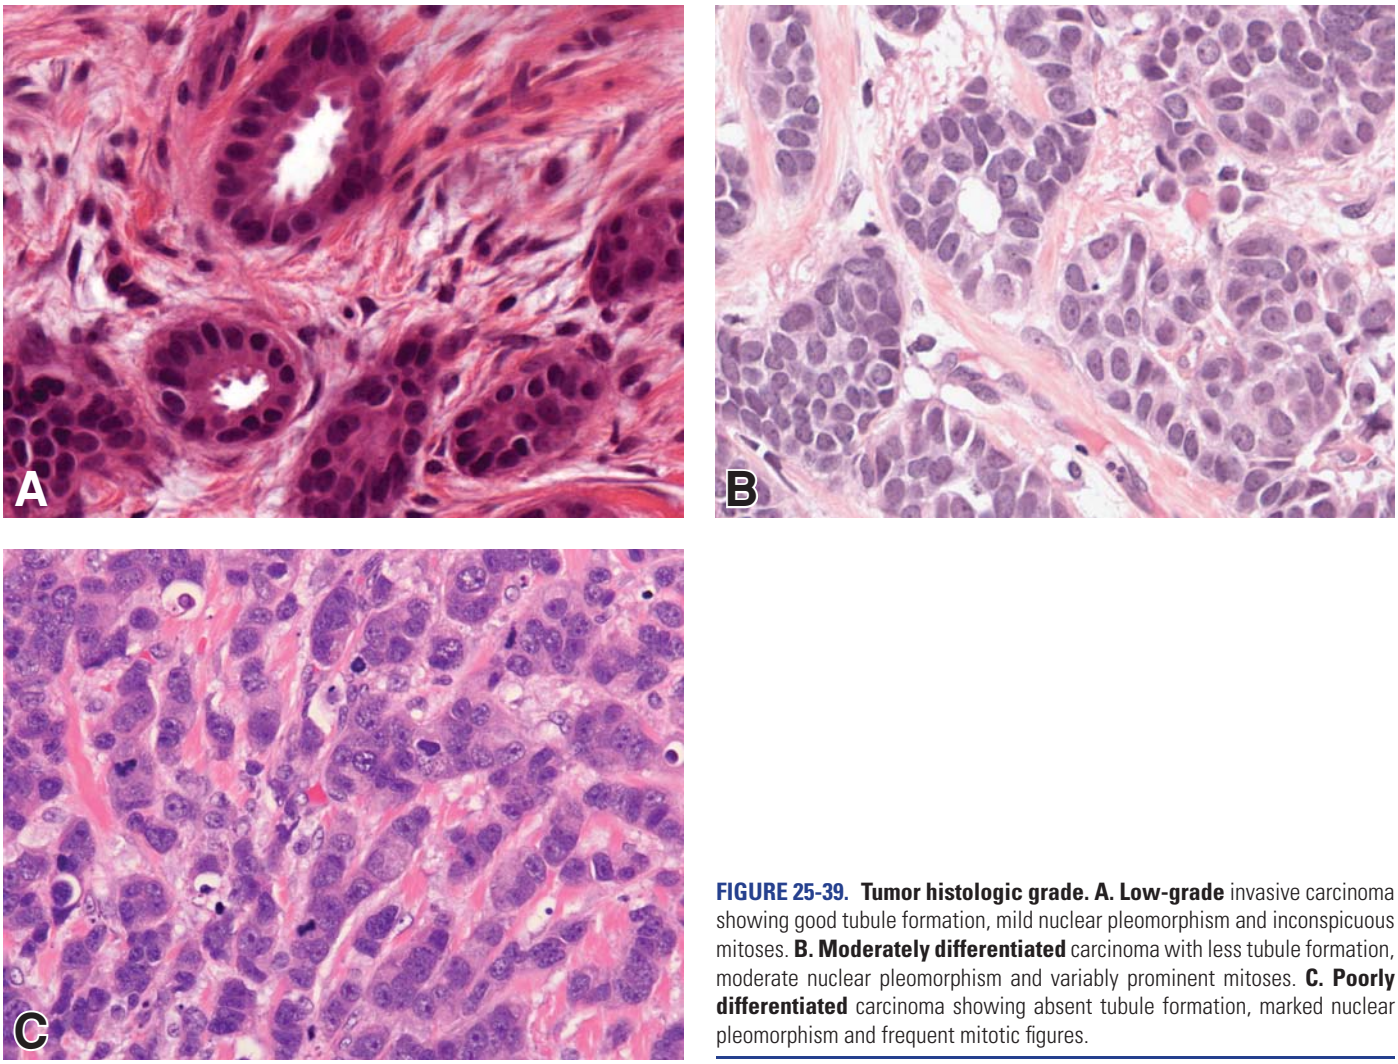

FIGURE 25-39. Tumor histologic grade. A. Low-grade invasive carcinoma showing good tubule formation, mild nuclear pleomorphism and inconspicuous mitoses. **B. Moderately differentiated** carcinoma with less tubule formation, moderate nuclear pleomorphism and variably prominent mitoses. **C. Poorly differentiated** carcinoma showing absent tubule formation, marked nuclear pleomorphism and frequent mitotic figures.

15% of patients without axillary nodal metastases and is a more important prognostic factor in this group.

- **Proliferative index and ploidy:** Tumors with high proliferative indices have worse prognoses. Several parameters are used to assess proliferation in breast cancers, including (1) mitotic index, assessed histologically; (2) the proportion of cells in S phase of the cell cycle by flow cytometry; (3) immunohistochemical staining for proteins (Ki67) expressed by actively proliferating cells (Fig. 25-41); and (4) thymidine labeling index. Cell cycle analysis can also

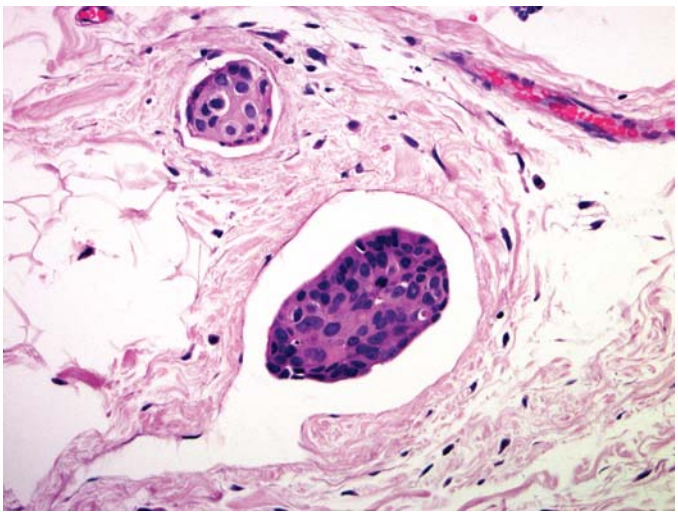

FIGURE 25-40. Lymphovascular invasion. Endothelial cell–lined lymphatic channels containing tumor emboli.

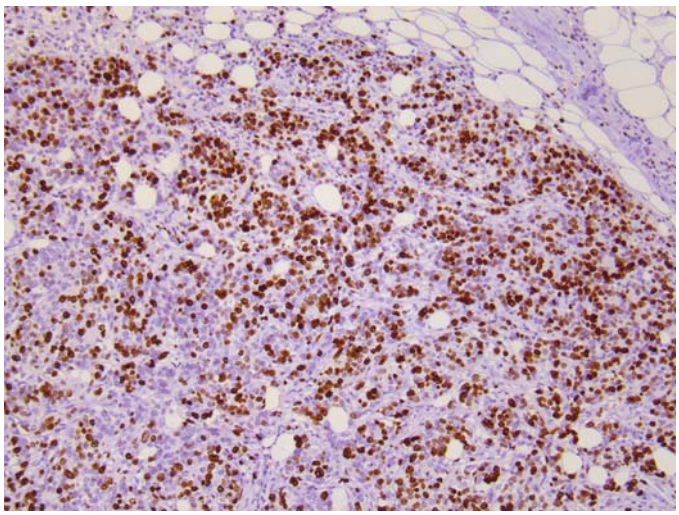

FIGURE 25-41. Ki67 staining (using MIB1 clone) in invasive carcinoma. This example shows a high percentage of cell nuclei staining.

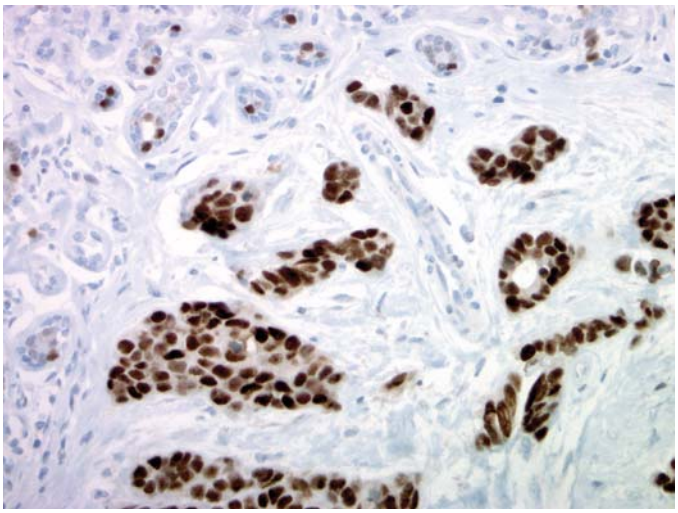

FIGURE 25-42. Estrogen receptor (ER). Strong nuclear positivity for estrogen receptor in this moderately differentiated invasive ductal carcinoma (immunohistochemical stain). Staining in normal breast lobules is seen in the upper left-hand corner.

detect aneuploidy, which occurs in 2/3 of breast cancers and confers a poorer prognosis. Notably, much of the prognostic impact of multigene predictor signatures (discussed below) comes from proliferation genes.

- **Response to neoadjuvant therapy:** In patients who receive systemic treatment before surgery (neoadjuvant therapy), the response to the therapy is a strong prognostic factor. Patients who show complete pathologic responses (i.e., who lack pathologic evidence of residual breast or nodal disease) have an excellent long-term survival. Poorly differentiated tumors with high proliferation indices are more likely to respond to neoadjuvant treatment than low-grade cancers. A pathologically complete response occurs in 10%–30% of patients, little or no response in 10%–15% of patients and partial response in the remainder.
- **Estrogen and progesterone receptors:** Steroid receptor proteins are expressed by benign breast epithelium and 70%–80% of breast cancers (ER > PR). ER and PR status is determined by immunohistochemistry, which uses antibodies to detect these nuclear receptors (Fig. 25-42). Hormone receptor positivity is defined as greater than or equal to 1% staining tumor cells. ER and PR bind their respective ligands (estrogen and progesterone) and stimulate cell growth. The greatest value of assessing hormone receptor status in breast cancer is its predictive ability. Patients with ER/PR-negative tumors are unlikely to respond to hormonal therapies with antiestrogens. On the other hand, ER/PR-positive tumors show a greater probability of response.
- **HER2:** Overexpression or gene amplification (see Chapter 5) of HER2 occurs in 15%–20% of newly diagnosed breast cancers. HER2 positivity is an adverse prognostic factor irrespective of lymph node status. However, these patients may be treated with monoclonal antibodies or tyrosine kinase inhibitors that target HER2. As with hormone receptor status, many patients who express HER2 show de novo or eventual resistance to such drugs. Immunohistochemistry detects cell membrane expression of the protein, and in situ hybridization identifies gene amplification (Fig. 25-43).

Molecular Subtypes

Microarray gene expression profiling and other techniques have identified a set of genes, an "intrinsic gene list," of which several molecular subgroups (Table 25-4) appear to predict clinical outcome and response to therapy.

- **Luminal A:** The luminal groups (A and B) are characterized by gene expression patterns similar to normal breast luminal epithelial cells, including low–molecular-weight cytokeratins 8/18, ER and ER-associated genes. Luminal A tumors are typically low grade and have an excellent prognosis.
- **Luminal B** tumors also express ER and ER-associated genes but are usually higher grade than are luminal A tumors. They exhibit higher proliferative indices and have a poorer prognosis. Although they respond better to chemotherapy than do luminal A tumors, both luminal subtypes generally give poor responses.

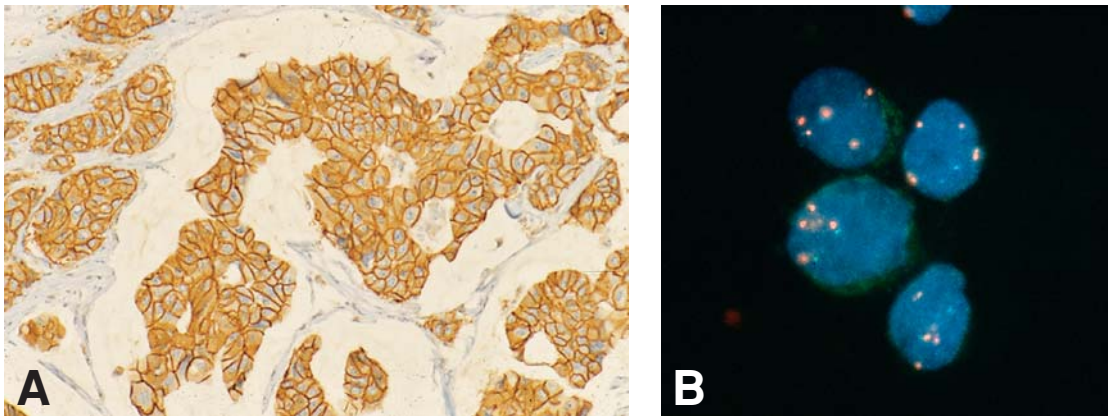

FIGURE 25-43. HER2/neu abnormalities in a breast cancer. A. Immunoperoxide staining of an invasive ductal carcinoma shows overexpression of the *HER2* (erbB-2) protein. **B.** Fluorescence in situ hybridization (FISH) methodology identifies the gene copies of *HER2* (erbB-2) in cancer cells. The *HER2* probe is red, and a normal cell should have two copies. More than two copies indicates *HER2* gene amplification. The green probe identifies the centromeric region of chromosome 17.

TABLE 25-4
MOLECULAR SUBTYPES OF BREAST CANCER

Molecular Subgroup	ER	PR	HER2	Proliferation Index	Other	Prognosis	Treatment
Luminal A	+	+	–	Low	CK8/18	Excellent	Hormonal
Luminal B	+	+	–/+	Moderate	CK8/18	Intermediate	Hormonal and chemotherapy
HER2+	–	–	+	High	AR	Poor	Trastuzumab Anthracyclines
Basal	–	–	–	Very high	CK5/6, CK14, vimentin, EGFR, c-kit	Poor	Platinum- and anthracycline-based chemo-therapy ?PARP inhibitors

+ positive; – negative; –/+ sometimes positive; AR = androgen receptor; ER = estrogen receptor; PARP = poly(adenosine diphosphate-ribose) polymerase; PR = progesterone receptor.

- **HER2:** Tumors that overexpress HER2 express genes in the HER2 pathway and with ER negativity. These tumors behave aggressively, but targeting HER2 with an antibody, trastuzumab, has significantly increased patient longevity.
- **Basal-like cancers:** These highly aggressive tumors constitute 10%–20% of invasive breast carcinomas. They are mainly ER and HER2 negative. Their name derives from their consistent expression of genes in the basal or myoepithelial cells of the breast, including high–molecular-weight cytokeratins 5/6, 14 and 17; caveolins 1 and 2; nestin; p63; and EGFR. These tumors are distinctive, with high nuclear grade, many mitoses, pushing margins, central areas of necrosis or fibrosis and a lymphocytic infiltrate. Cancers with medullary features and metaplastic carcinomas are typically basal-like. Most cancers arising in patients with germline *BRCA1* mutations are basal-like.

Additional subtypes of ER-negative breast cancers have also emerged: **molecular apocrine, claudin low** and **interferon rich**. **Molecular apocrine** tumors are androgen receptor positive and frequently HER2 positive. They demonstrate prominent apocrine features, with abundant eosinophilic cytoplasm and prominent nucleoli. **Claudin-low** tumors show high levels of expression of genes involved in epithelial-to-mesenchymal transition, including vimentin, Snail and TWIST, and down-regulation of genes involved in cell adhesion (E-cadherin, claudins 3, 4 and 7). These tumors also display stem cell–like features. Tumors of the **interferon-rich** subtype express high levels of interferon-regulated genes, including *STAT1*. The clinical importance of these additional subgroups has yet to be elucidated.

Gene Expression Profiling Prognostic Assays

A large proportion of patients with breast cancer are treated with adjuvant chemotherapy; yet not all will benefit from this therapy. In recent years, gene expression profiling prognostic assays have been developed. Commercially available approaches quantify messenger RNA (mRNA) levels for a panel of genes. One example is the **21-gene recurrence score,** which is based on the mRNA levels of 21 genes and performed using formalin-fixed, paraffin-embedded tumor tissue. The genes evaluated include 16 cancer-related genes and 5 reference genes. Analysis of respective gene expression levels leads to a "recurrence score," which is reported as reflecting low, high or intermediate risk of developing distant recurrence at 10 years after 5 years of tamoxifen (antiestrogen) therapy. The test has been shown to predict benefit from tamoxifen for patients with cancers with low- or intermediate-risk recurrence scores and benefit from chemotherapy for patients with high-risk recurrence scores.

The **70-gene prognostic signature** is a microarray-based multigene assay requiring fresh or frozen tumor samples. It is used to assess prognosis in invasive breast cancer based on expression levels of 70 cancer-related genes and 1800 reference genes. Results are reported as low or high risk for distant metastases at 10 years without adjuvant treatment and, thus, identify patients in whom withholding chemotherapy may be warranted. Importantly, *in guiding treatment decisions and evaluating prognosis, these tools complement, but do not replace, histopathology and clinical analyses.*

Genetic analysis has demonstrated that breast cancers are markedly heterogeneous, and only a few gene mutations are actually present in a high percentage of tumors (see Chapter 5). These include *PTEN, PIK3CA* and *TP53.* Analysis of matched primary and metastatic tumors shows that tumors are largely mosaics of subclones of cancer cells, and metastases may derive from genetically distinct subpopulations in the primary tumor (see Chapter 5).

Primary Therapy of Breast Cancer Almost Always Involves Surgery

Breast-conserving surgery (i.e., lumpectomy or quadrantectomy) is often used. Wider excision may be needed in patients with bulky disease. As indicated above, sentinel lymph node sampling often replaces more extensive axillary lymph node chain removal, and axillary lymph node dissection is reserved for patients in whom the SLN is positive for tumor. Postoperative radiation therapy is commonly used as well.

Systemic therapies (i.e., hormonal, chemotherapy and targeted molecular modalities) are often considered essential in managing patients with breast cancer. Patients with the worst prognoses usually gain most from such systemic therapies. Targeted therapies rely on the presence of particular targets in the tumor (e.g., ER, PR and HER2).

THE MALE BREAST

Gynecomastia Is Enlargement of the Male Breast

Male breast tissue has receptors for androgens, estrogens and progesterone. Estrogen stimulates duct development and

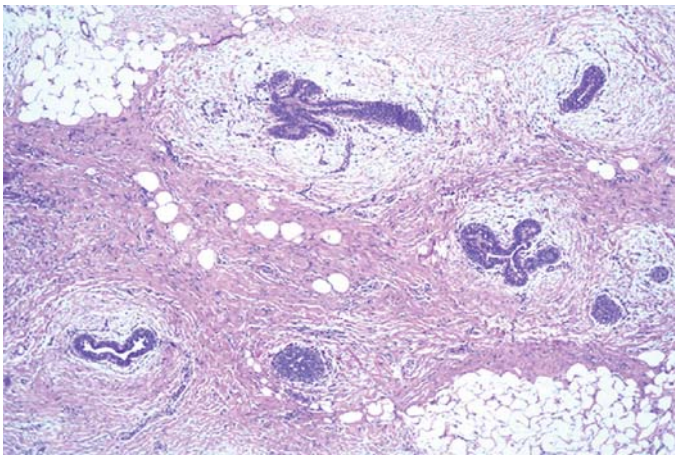

FIGURE 25-44. Gynecomastia. There is proliferation of branching, intermediate-sized ducts. The ductal epithelium is hyperplastic, and mitoses are present. A concomitant increase in the surrounding fibrous tissue causes a palpable mass.

progesterone stimulates lobular development in the presence of luteinizing hormone, follicle-stimulating hormone and growth hormone. Androgens antagonize the effects of estrogen. Testosterone can be converted to estradiol by the enzyme aromatase, which is especially present in adipose tissue.

Physiologic gynecomastia occurs in most neonates, owing to circulating maternal and placental estrogen and progesterone. Transient gynecomastia also affects over half of boys during puberty, because estrogen production peaks earlier than that of testosterone. With increasing age, free testosterone decreases and adipose tissue expands, increasing the prevalence of breast enlargement.

Gynecomastia is benign enlargement of the male breast, with proliferation of ductal and stromal elements. It is due to relatively decreased androgens or increased estrogen effect. Breast enlargement due to adipose tissue is called **pseudogynecomastia**. Nonphysiologic gynecomastia results from drugs or disorders associated with low testosterone levels, high conversion of testosterone to estrogens, elevated estrogen levels and increased sex hormone–binding globulin levels that lower free testosterone. It may occur in patients with hyperthyroidism, cirrhosis, renal failure, chronic lung disease and certain hormone-producing tumors, including Leydig and Sertoli cell tumors, testicular germ cell tumors and cancers of the liver and lung. Drugs implicated in gynecomastia include digitalis, cimetidine, spironolactone, marijuana and tricyclic antidepressants. Klinefelter syndrome is the most common chromosomal disorder associated with gynecomastia.

Gynecomastia presents as a rubbery discrete mass or ill-defined area of induration that may display either a florid or fibrous phase (Fig. 25-44). The florid phase typically occurs early, within 6 months of onset. It is characterized by epithelial hyperplasia with flat or micropapillary architecture. Periductal stroma is hypercellular and edematous, with increased vascularity and chronic inflammation.

The fibrous phase is seen after 1 year or more. It lacks epithelial proliferation, and the stroma is more collagenous. Mixtures of both phases may be seen. Pseudoangiomatous stromal hyperplasia may be seen in either phase.

Male Breast Cancers Often Reflect Hyperestrogen States

EPIDEMIOLOGY: These tumors make up 1% of breast cancers in the United States. In sub-Saharan Africa, they make up 7%–14% of breast cancers, the difference possibly reflecting endemic diseases causing liver damage and hence hyperestrogenism. In the United States, rates are highest in black men, intermediate in non-Hispanic white men and Asian-Pacific Islanders and lowest in Hispanic men. The mean age at presentation is 65.

The risk of breast cancer is greater in high-estrogen states. Men with Klinefelter syndrome have a 58-fold higher risk than normal men and an absolute risk of up to 3%. Male–female transsexuals following castration and high-dose estrogen and men treated with estrogen for prostate cancer also are at greater risk.

Men with breast cancer inherit germline mutations in *BRCA2* and show other gene mutation patterns that are similar to some observed in breast cancers in women (Table 25-1). Ionizing radiation has been implicated, being seen in Japanese men after nuclear fallout and in patients treated with therapeutic chest irradiation at a young age.

PATHOLOGY: Most breast cancers in males are invasive carcinoma, NST; however, papillary carcinoma is disproportionately represented in men. Lobular carcinoma is rare. Ninety percent of cancers are ER and PR positive. Androgen receptor positivity is frequently seen.

CLINICAL FEATURES: Most patients present with a painless lump. Nipple involvement, including retraction, discharge or ulceration, is an early event. Paget disease is a presenting feature in 1% of affected men.

Management of men with breast cancer largely reflects results of clinical studies done in women: simple mastectomy and sentinel lymph node biopsy or axillary dissection. Postoperative radiation may be given for large tumors or for close margins. Hormonal therapy with tamoxifen is frequently administered. There is limited experience in the treatment of male breast cancer with aromatase inhibitors. Adjuvant chemotherapy with or without trastuzumab may be indicated, depending on the aggressiveness of the disease and HER2 status, respectively.

EMBRYOLOGY

The origin of hematopoietic stem cells (HSCs) is controversial, but they likely arise in the mesoderm of the intraembryonic aorta/gonad mesonephros region and/or the yolk. Blood cell formation shifts from the yolk sac to the fetal liver around the 3rd month of embryogenesis. HSCs and erythroid precursors make up most of the hematopoietic tissue during the early stages of blood cell formation in the fetal liver, but production of megakaryocytes and mature neutrophils soon follows. A switch from the production of red blood cell embryonic hemoglobins to fetal hemoglobins also occurs during the hepatic phase of erythropoiesis.

Hematopoietic stem cells migrate from the liver to the bone marrow around the 4th month of embryogenesis, and by the 26th week of intrauterine life, the bone marrow has become the main hematopoietic organ. At birth, hematopoiesis becomes fully established in the marrow and virtually ceases in the liver.

From birth to puberty, all skeletal bone marrow is densely packed with hematopoietic tissue (red marrow) that can produce all blood cell types. Red marrow is subsequently largely confined to the proximal epiphyseal regions of humeri and femurs and the flat bones (skull, scapula, clavicles, sternum, ribs, vertebrae, pelvis). In adults, adipose tissue (inactive "yellow marrow") occupies most available space in medullary cavities of the skeleton. The bone marrow in the axial skeleton continues to be active until old age, when resorption of cancellous bone enlarges marrow cavities and leads to further fatty replacement. Remarkably, in healthy individuals, peripheral blood counts are maintained normally even as amounts of red marrow decline.

Local expansion of hematopoietic progenitors in red (cellular) marrow and reactivation of peripheral yellow marrow allow the hematopoietic system to meet physiologic demands for increased blood cell formation. If the hematopoietic system cannot respond to stress/demand, there is probably an abnormality of one or more hematopoietic lineages. Reactivation of hepatic and splenic hematopoiesis rarely occurs in adult life. ***Significant extramedullary hematopoiesis in adulthood usually suggests a clonal (malignant) disorder, rather than a reactive process.***

BONE MARROW

Hematopoietic Cells Derive from Multipotent Stem Cells

Bone marrow consists of a complex network of solid cords separated by sinusoids (Fig. 26-1). These cords contain stromal and hematopoietic cells, knitted together by extracellular matrix. A semipermeable barrier between sinusoids and cords consists of an endothelial cell layer, a thin basement membrane and an outer layer of interrupted reticular adventitial cells. The latter branch extensively throughout

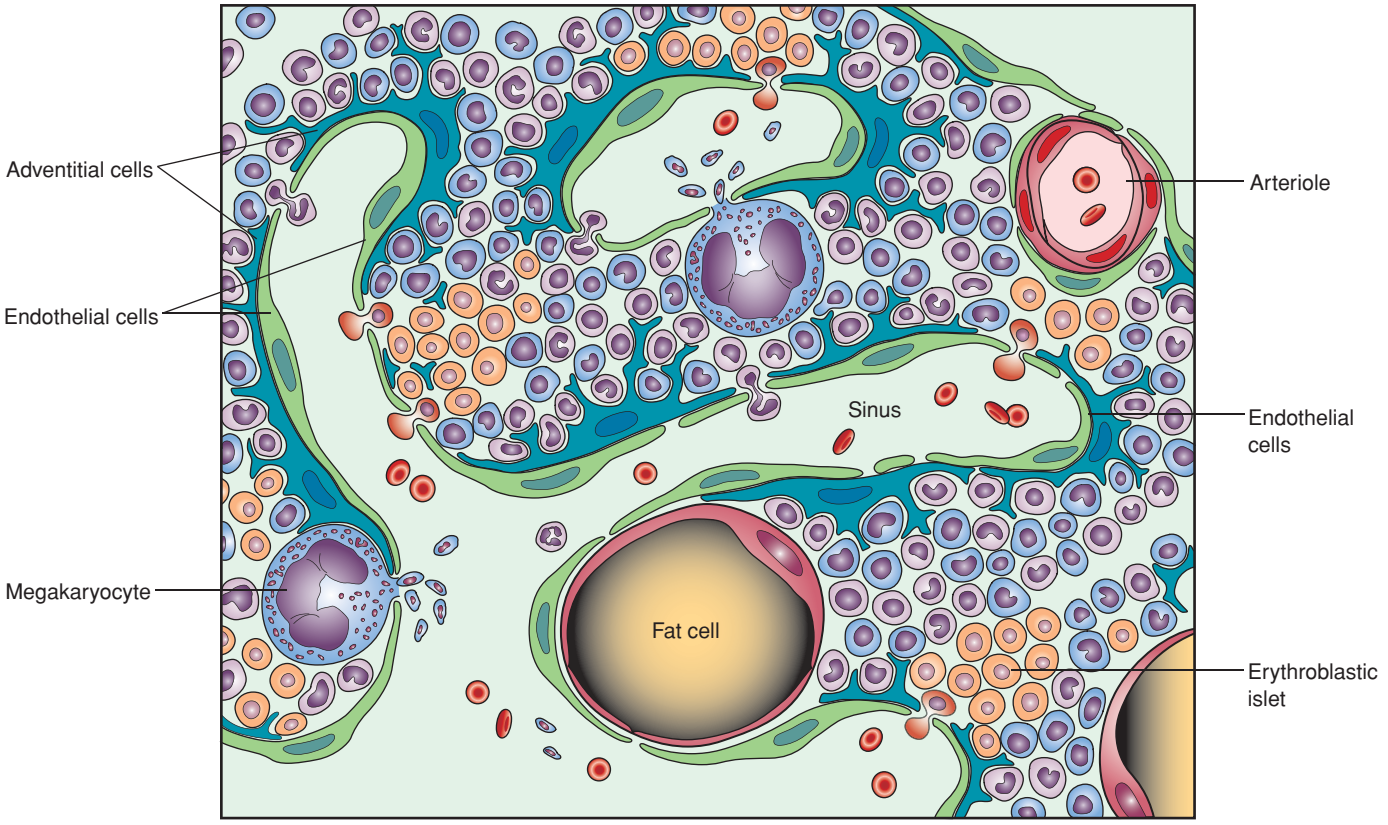

FIGURE 26-1. Structure of normal bone marrow. The sinusoids represent the major point of egress of hematopoietic cells from the bone marrow. Note that the bone marrow does not have lymphatic channels.

the cords and help anchor stromal and hematopoietic cells. Bone marrow stromal cells include macrophages, endothelial cells, lymphocytes and fibroblasts.

Islands of erythroblasts, usually in concentric rings around a macrophage that stores excess iron, are present within the cords. The erythroid islands lie close to sinusoid walls, as do megakaryocytes. Granulocyte precursors are deeper in the cords, adjacent to the bony trabeculae.

STEM CELLS: Pluripotent HSCs are a self-perpetuating pool, in which self-renewal balances differentiation and exit (Fig. 26-2). These stem cells are admixed with progenitor and more mature hematopoietic cells, with HSCs representing only a small proportion of total hematopoietic cell mass. They are small, mononuclear and difficult to identify by microscopy. HSCs are semidormant (noncycling) cells that differentiate to progenitor cells of specific lineages as needed. When marrow elements are injected into irradiated mice, stem cells form visible colonies in the spleen **("colony-forming unit, spleen" [CFU-S])**. In bone marrow cultures, stem cells form colonies containing **multipotential cells** called granulocyte, erythroid, macrophage and megakaryocyte elements **(CFU-GEMM)** and lymphoid precursor cells **(CFU-L)**.

PROGENITOR CELLS: Like stem cells, progenitor cells are small to medium-sized mononuclear cells that resemble mature lymphocytes. In culture, they give rise to colonies of differentiated progeny. Progenitor cells committed to red blood cell production forms luxuriant burst-shaped colonies **("burst-forming unit, erythroid" [BFU-E])**. Each subsequent generation of BFU-E makes smaller colonies, until a final progenitor cell, the "colony-forming unit, erythroid" **(CFU-E),** produces only a small clone of mature erythroblasts.

Granulocytic and **monocytic** cell lines derive from a single progenitor cell. This cell, named "colony-forming unit, granulocyte-monocyte" **(CFU-GM),** makes a colony with both granulocytic and monocytic cells. As the cell matures, its progeny are increasingly committed to polymorphonuclear leukocytes **(CFU-G)** or monocyte/macrophages **(CFU-M)**. **Eosinophils** and **basophils** also have specific progenitor cells (**CFU-Eo** and **CFU-Ba,** respectively). "Megakaryocytic progenitor cells" **(CFU-Meg)** produce colonies in vitro consisting of four to eight megakaryocytes.

GROWTH FACTORS: Bone marrow hematopoiesis responds to fluctuating needs for blood cells and maintains the size of the circulating blood cell mass. Growth factors mediate this responsiveness by regulating the rate of cellular proliferation, primarily in the progenitor cell compartment (Fig. 26-2).

- **Stem cell factor** (SCF, or c-KIT ligand) and **Flt3 ligand** (Flt3L) support survival and proliferation of pluripotent stem cells, CFU-GEMM and various progenitor cells.
- **Interleukin (IL)-3** and **granulocyte-macrophage colony-stimulating factor (GM-CSF)** are important for proliferation of CFU-GEMM and multiple CFUs.
- **Granulocyte colony-stimulating factor (G-CSF) and macrophage colony-stimulating factor (M-CSF)** promote granulocyte and monocyte maturation from CFU-G and CFU-M, respectively.
- **Erythropoietin (EPO),** released by renal interstitial peritubular cells in response to hypoxia, activates erythroid progenitor cells.
- **Thrombopoietin (TPO)** facilitates production and maturation of megakaryocytes.
- ***Deficiencies in one or more blood cell populations (e.g., postchemotherapy pancytopenia, especially neutropenia, stem cell mobilization prior to bone marrow transplantation, renal failure; see below) respond to treatment with several growth factors, mainly GM-CSF, G-CSF and EPO. EPO and other factors stimulate the EPO receptor and are used illicitly to enhance performance for endurance sports.***

PRECURSOR CELLS: Progenitor cells mature into precursor cells, or **blasts**. ***Starting at the precursor stage, and continuing beyond, cells are morphologically recognizable in terms of their lineage.*** Maturation of precursor cells to mature cells entails progressive nuclear changes and cytoplasmic maturation to reflect cellular functions (e.g., oxygen carriage in red blood cells, cytotoxic enzymes in neutrophils). In parallel, lineage-related cell surface proteins/antigens appear. The latter help to identify both cell types and stages of maturation.

- **Erythroid precursor cells:** The **proerythroblast** is the first stage in red blood cell maturation. Like other committed blast cells, proerythroblasts are relatively few in number, compared to the more mature red cell forms. Proerythroblasts have intensely basophilic (blue) cytoplasm with a large round nucleus, fine open chromatin and visible nucleoli. Maturation in the erythroid series is marked by a progressive decrease in nuclear size, increased nuclear chromatin density and progressive hemoglobinization of the cytoplasm. In the process, the cytosol gradually changes from blue to pink. All erythrocytes express glycophorin, which helps to define erythroid lineage. **Orthochromatic erythroblasts** then banish their nuclei to create **reticulocytes,** whose cytosol has mitochondria and hemoglobin-producing polyribosomes. These reticulocytes represent the final stage of erythroid cell maturation in the bone marrow. After they leave the bone marrow, reticulocytes lose the capacity for aerobic metabolism and hemoglobin synthesis, and become mature erythrocytes within 1–2 days.
- **Granulocytic precursors: Myeloblasts** have round to oval nuclei with delicate chromatin, multiple visible nucleoli and a blue-gray cytoplasm. **Promyelocytes,** the next stage, have similar nuclei, but their cytoplasm contains primary (azurophilic) granules. Maturation from **promyelocytes** to mature **neutrophils** involves (1) progressive nuclear chromatin condensation, (2) increasing nuclear lobulation and (3) the appearance of secondary (specific) granules. **Basophils** and **eosinophils** derive from specific progenitor and precursor cells and are distinguished by their secondary granules. Granulocyte precursors express CD13 and CD33 and progressively lose CD34 as they mature.
- **Monocytic precursor cells:** Parallel formation of monocytes from monoblasts also involves a nuclear condensation process, but with less nuclear lobation. Cytoplasm becomes gray, with only a few pink or purple granules. ***After monocytes leave the blood, they join the mononuclear phagocyte system.*** They may evolve further, depending on tissue location, function as a **phagocyte** (fixed or wandering) or immunoregulatory activity (dendritic reticulum cells, Langerhans cells).
- **Megakaryocytic precursors:** Marrow megakaryocytes mature into big multilobed cells by endomitotic division. After reaching a certain ploidy, the cytosol becomes

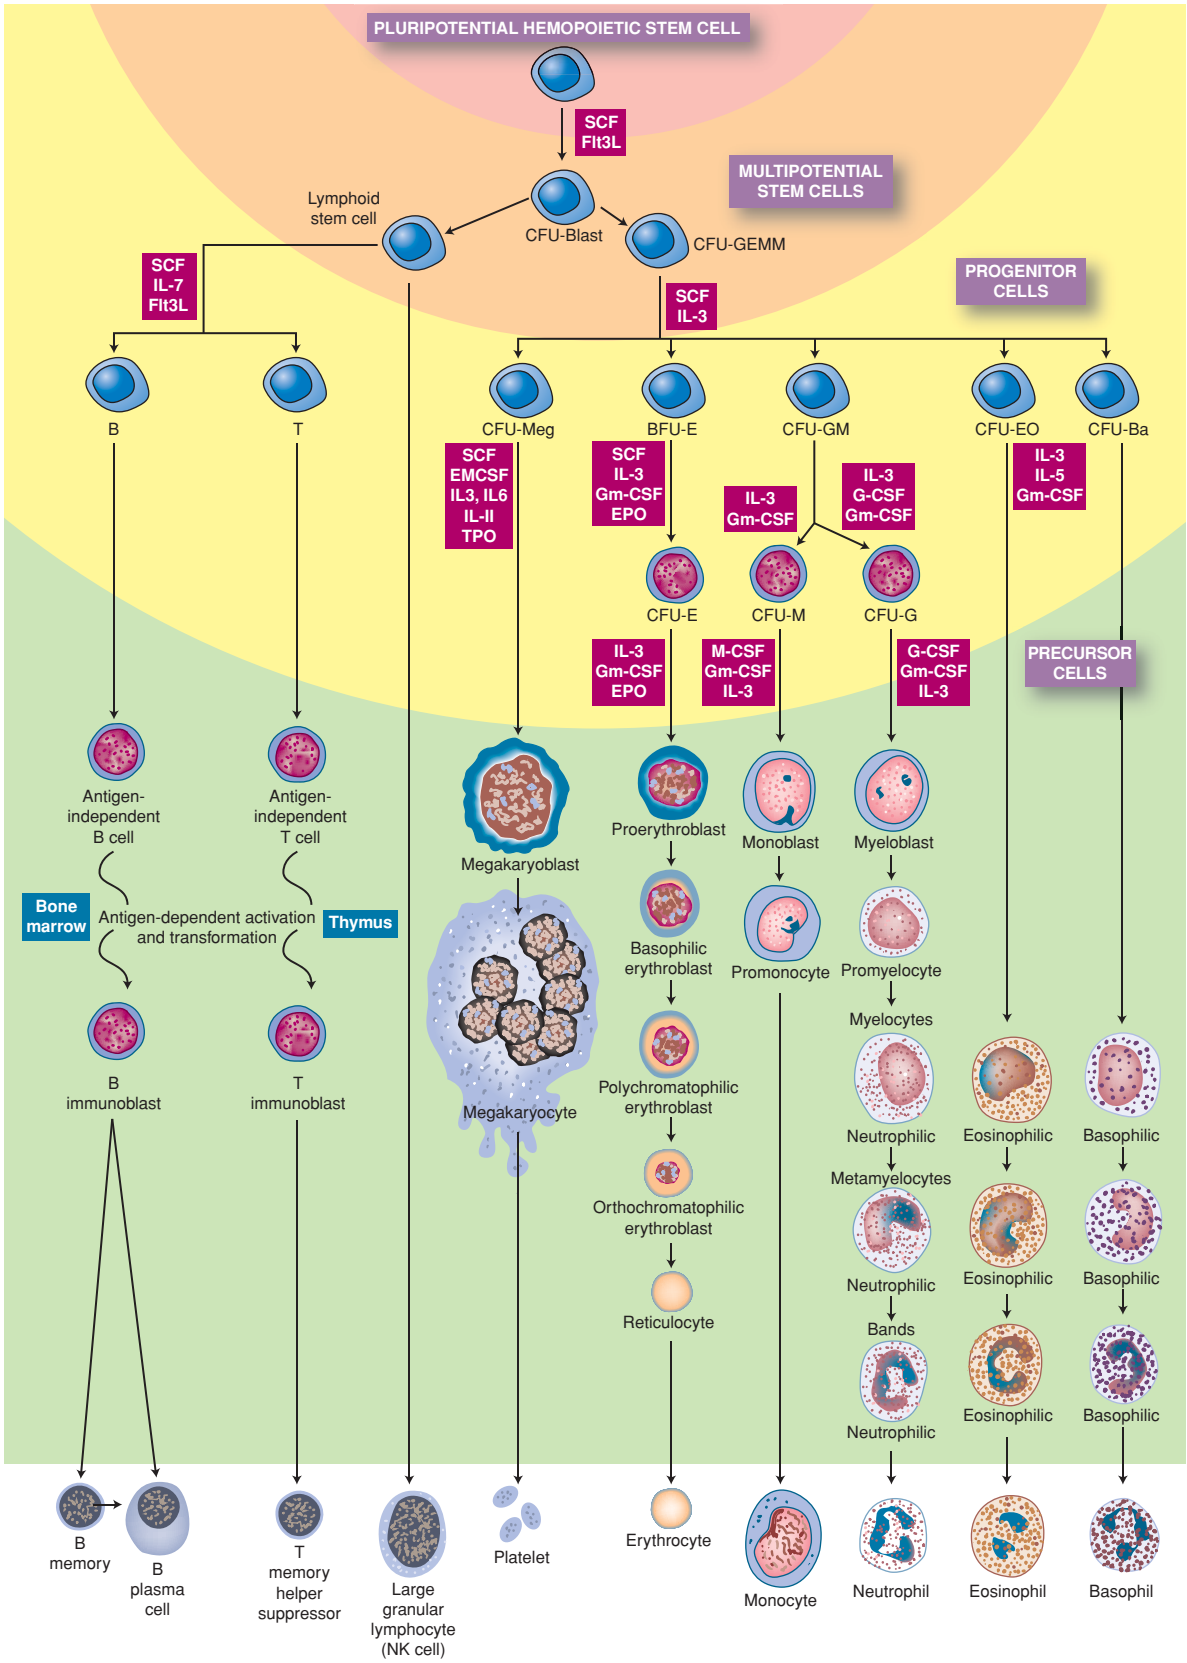

FIGURE 26-2. Cellular differentiation and maturation of the lymphoid and myeloid components of the hematopoietic system. Only the precursor cells (blasts and maturing cells) are identifiable by light microscopic evaluation of the bone marrow. *BFU* = burst-forming unit; *CFU* = colony-forming unit (*Ba* = basophils; *E* = erythroid; *Eo* = eosinophils; *G* = polymorphonuclear leukocytes; *GM* = granulocyte-monocyte; *M* = monocyte/macrophages; *Meg* = megakaryocytic); *EPO* = erythropoietin; *GM-CSF* = granulocyte-macrophage colony-stimulating factor; *IL* = interleukin; *NK* = natural killer; *SCF* = stem cell factor; *TPO* = thrombopoietin.

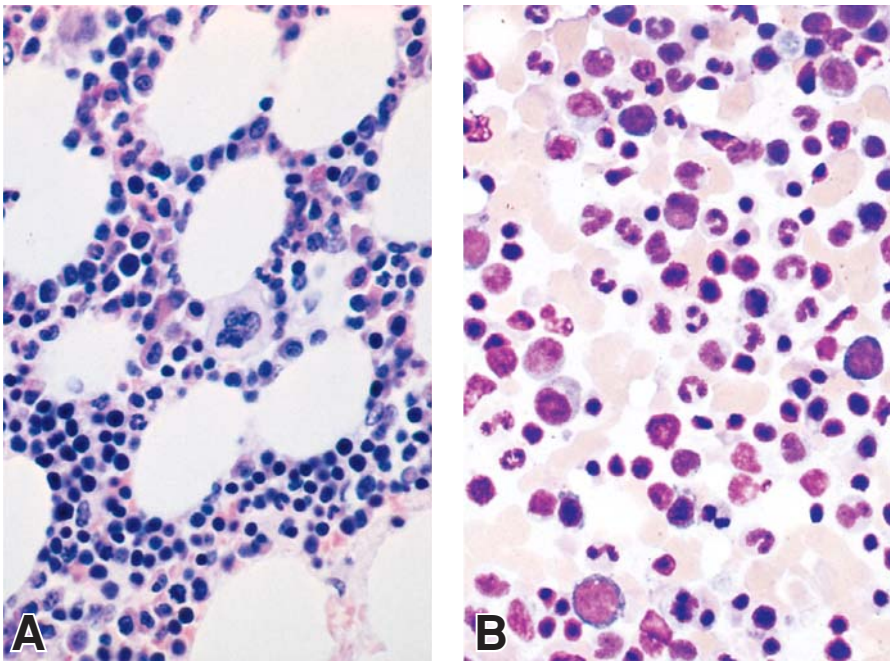

FIGURE 26-3. Normal bone marrow. A. Tissue section showing the normal relationship of cellular hematopoietic elements to fat cells, a normal myeloid-to-erythroid ratio (2:1) and a megakaryocyte in the center of the field (hematoxylin and eosin stain). **B.** Bone marrow aspirate smear from the same patient demonstrating normal hematopoietic elements in varying stages of differentiation (Wright-Giemsa stain).

stippled and azurophilic, eventually to be released into the sinusoids as long, platelet-containing ribbons. Some intact megakaryocytes are also released, and platelet production occurs after they localize in the pulmonary microcirculation.

RELEASE FROM THE MARROW: After they mature, hematopoietic cells leave the bone marrow through the sinusoids and enter the blood (Figs. 26-1 and 26-2). ***Hematopoietic homeostasis is highly regulated by cell-cell interactions in the bone marrow and/or by both stimulatory and inhibitory cytokines.*** The cellular release mechanism in the bone marrow responds to the needs of the peripheral circulation and can quickly provide a boost of mature cells in an emergency (e.g., red blood cells and/or reticulocytes during acute hemorrhage or neutrophils in acute infection).

Biopsy and Aspirate Smear Allow Complementary Analyses of Bone Marrow

The posterior iliac crest (or, rarely, the sternum) is the most common source of bone marrow for analysis in adults. In infants, the anterior tibia may also be used. Bone marrow core biopsy sections allow evaluation of the amount of hematopoietic elements and marrow architecture (Fig. 26-3A), while the several bone marrow cell lineages are identified and evaluated in stained smears made from aspirated liquid bone marrow (Fig. 26-3B). The ratio of hematopoietic cells to fat is the **cellularity,** which varies with age. In a normal middle-aged adult, about half of bone marrow core biopsy volume is adipocytes; the other half is actively dividing and differentiating hematopoietic cells. Marrow cellularity is higher in children and lower in the elderly.

Bone marrow cellularity mostly consists of maturing granulocyte precursors, erythroid precursors and megakaryocytes, called **trilineage hematopoiesis**. The ratio of myeloid to erythroid cells (i.e., the **M:E ratio**) is normally 2:1 to 5:1 (Table 26-1). There are usually 2–5 megakaryocytes per high-power field. Monocytic cells, lymphocytes and plasma cells are normally present in low numbers. Normal bone marrow has less than 3% plasma cells, up to 20% lymphocytes and only rare mast cells and macrophages. Blasts are usually less than 3% of marrow cells in normal adults.

Changes in the normal number and distribution of mature cells compared to immature cells are **left shifts**. These can occur in reactive and neoplastic processes. ***The number of blasts in the bone marrow helps to distinguish these two broad categories, as reactive states do not significantly increase the numbers of blasts in the marrow.*** In addition to evaluating cellularity and the proportions of the various cell types, bone marrow examination also enables assessment for evidence of normal maturation of hematopoietic precursors. ***Dyssynchronization or aberration in the highly regulated process of nuclear and cytoplasmic maturation is evidence of bone marrow disease.***

TABLE 26-1
NORMAL ADULT BONE MARROW (AGE 18–70 YEARS)

Fat-to-cell ratio: 50:50 ± 15%
Myeloid-to-erythroid ratio: 2:1 to 5:1
Cell distribution (% surface area) Fat cells: 35%–65% Erythroid series: 10%–20% Granulocytic (myeloid) series: 40%–65%
Megakaryocytes: 2–5/high-power field
Plasma cells: <3% of nucleated cells
Lymphocytes: <20% of nucleated cells
No fibrosis

Iron metabolism and storage also can be tested by staining the bone marrow aspirate with Prussian blue. Using this stain, storage and sideroblastic iron granules can be found within the cytoplasm of macrophages and nucleated red blood cell precursors, respectively. Finally, marrow infiltration by abnormal cells, such as metastatic tumor cells, malignant hematopoietic cells or infectious granulomas, can be identified.

Red Blood Cells

NORMAL STRUCTURE AND FUNCTION

Red blood cells (RBCs), or erythrocytes, transport oxygen to tissues. Mature RBCs are nonnucleated 7- to 8-μm biconcave disks, similar in size to small lymphocyte nuclei (Fig. 26-4). They are round with reddish, eosinophilic cytoplasm. Their main cytoplasmic component is hemoglobin, which imparts the red color. Because they are biconcave disks, their centers tend to be paler than their outer rims. Erythrocytes are released from the marrow as reticulocytes, which are larger and have more diffusely basophilic gray cytoplasm than mature RBCs. These cells still synthesize hemoglobin, and the ribosomes needed for this process impart the **polychromatophilia**.

RBC membranes are attached to an underlying cytoskeletal network (Fig. 26-5). Transmembrane receptors, channels and anchors for other membrane components insert into the lipid bilayer, as does the underlying cytoskeleton. ***Carbohydrate groups added to some membrane proteins lead to formation of different red cell antigen groups.*** The erythrocyte cytoskeleton contains interconnected spectrin dimers and other stabilizing proteins (ankyrin, actin, band 4.1), which allow the cells to deform their shape, which may be necessary from time to time. ***Changes in this membrane–cytoskeletal unit that lead to increased cell rigidity cause premature destruction of circulating RBCs.***

Hemoglobin accounts for the oxygen-carrying capacity of RBCs. Each hemoglobin molecule has 4 heme groups and 4 globin chains and, when fully saturated, transports 4 molecules of oxygen. The heme part of the molecule consists of a porphyrin ring (protoporphyrin IX), with one ferrous ion (Fe^{2+}). The globin portion of the molecule has pairs of two different protein chains. The most abundant normal form, hemoglobin A, has two alpha (α)- and two beta (β)-globin chains. Hemoglobins F and A_2 are normally present in minor amounts in healthy adults. Both have two α-chains each. In addition, hemoglobin F has two gamma (γ)- and hemoglobin A_2 has two delta (δ)-globin chains, instead of β-globin chains. Synthesis and assembly of each hemoglobin molecule requires multiple biochemical steps that require distinct enzymes.

Each heme group interacts with a hydrophobic pocket of one globin chain, and the entire molecule has a globular tertiary structure. Deoxygenated hemoglobin has low oxygen affinity and requires increased oxygen tension for heme–oxygen binding to occur. After this initial interaction, hemoglobin molecules undergo conformational change, which facilitates subsequent oxygen binding to the remaining heme groups. Progressive increase in oxygen affinity is reflected in the sigmoid shape of the oxygen dissociation curve (Fig. 26-6).

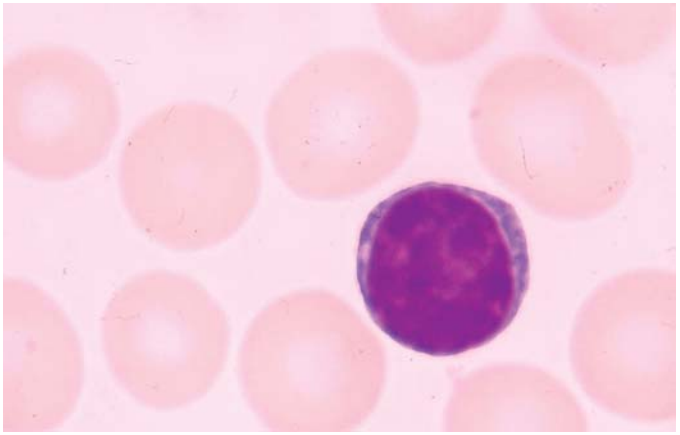

FIGURE 26-4. Normal red blood cells are approximately the same size as the nucleus of a small lymphocyte (approximately 7 μm).

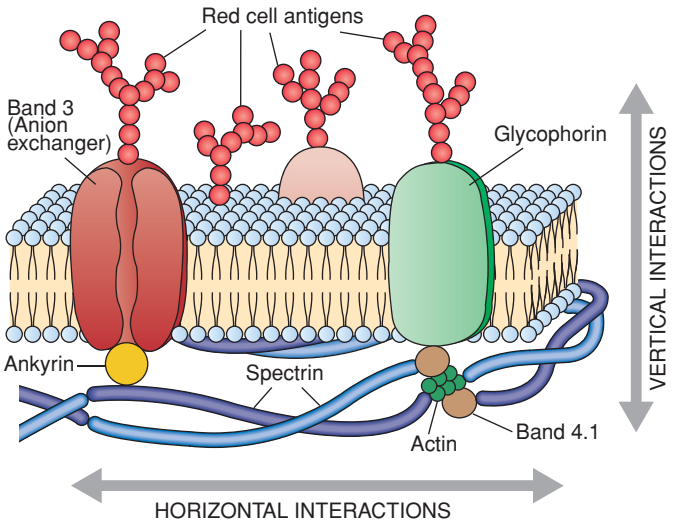

FIGURE 26-5. Structure of the erythrocyte plasma membrane. The membrane is stabilized by a number of interactions. The two vertical interactions are spectrin-ankyrin–band 3 and spectrin-protein 4.1–glycophorin. The two horizontal connections are spectrin heterodimers and spectrin-actin–protein 4.1.

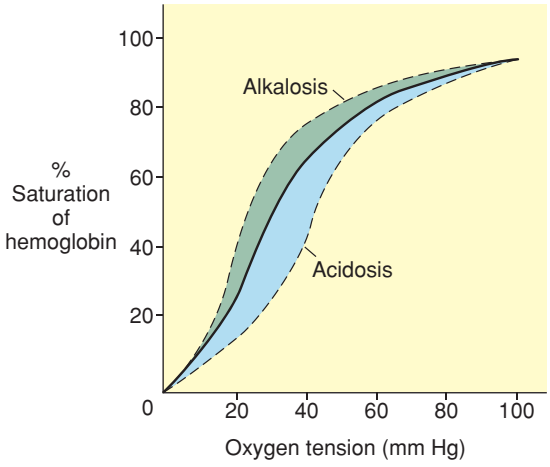

FIGURE 26-6. Oxygen dissociation curve of hemoglobin. With decreasing pH (acidosis), the oxygen affinity declines (shifts right); with increasing pH (alkalosis), the affinity increases (shifts left).

TABLE 26-2
COMPLETE BLOOD COUNT (CBC): NORMAL ADULT VALUES

Erythrocytes		
Hemoglobin	Male, 14–18 g/dL Female, 12–16 g/dL	
Hematocrit	Male, 40%–54% Female, 35%–47%	
Red blood cell (RBC) count	Male, 4.5–6 × 10^6/μL Female, 4–5.5 × 10^6/μL	
Reticulocytes	0.5%–2.5%	
Indices		
Mean corpuscular volume	82–100 μm^3	
Mean corpuscular hemoglobin	27–34 pg	
Mean corpuscular hemoglobin concentration	32%–36%	
	Absolute Count/μL	**Differential Count (%)**
Leukocytes		
White blood cells (WBCs)	4000–11,000	
Neutrophil granulocytes	1800–7000	50–60
Neutrophil bands	0–700	2–4
Lymphocytes	1500–4000	30–40
Monocytes	0–800	1–9
Basophils	0–200	0–1
Eosinophils	0–450	0–3
Platelets		
Quantitative normal value: 150,000–400,000/μL		
Qualitative estimation on smear: Number of platelets/oil immersion field × 10,000 = estimated platelet count		
Normal ratio of RBC to platelets = 15:1 to 20:1		

Acidosis shifts the slope of the oxygen dissociation curve to the right, which increases tissue oxygen delivery. Increased 2,3-diphosphoglycerate (2,3-DPG) (a product of an alternate pathway of glycolysis) has the same effect. Alkalosis shifts the curve to the left, increasing oxygen binding.

The average life span of blood erythrocytes is 120 days. Changes in membrane proteins and phospholipids appear in aged red cells and are likely signals for erythrocyte removal by mononuclear phagocytes.

The erythroid component of the blood is best analyzed by a complete blood count (CBC) plus microscopic examination of a blood smear (Table 26-2). The CBC measures hemoglobin (Hgb), RBC count and mean corpuscular volume (MCV). Additional calculated parameters include **hematocrit** (Hct = MCV × RBC), **mean corpuscular hemoglobin** (MCH = Hgb/RBC) and **mean corpuscular hemoglobin concentration** (MCHC = Hgb/Hct). Variability in RBC size, or red cell distribution width (RDW), is also derived. Reticulocytes can be accurately quantitated using supravital dyes that stain their cytoplasmic ribosome aggregates.

ANEMIA

Anemia is reduced circulating erythrocyte mass and is diagnosed as low hemoglobin, hematocrit (Hct) or RBC count. Anemia leads to decreased oxygen transport by the blood and ultimately tissue hypoxia.

Anemias Are Classified by Morphology or Pathophysiology

Morphologic classification of anemia is based on RBC appearance, as defined by automated blood counters and microscopy. RBC size (generally measured by analyzers) is reflected in the MCV, which divides anemias into three groups: (1) **microcytic** (decreased MCV), (2) **normocytic** and (3) **macrocytic** (increased MCV) (Table 26-3). Abnormally shaped RBCs **(poikilocytes)** are seen on blood smears in many anemias, and poikilocyte characteristics can aid in diagnosis (Fig. 26-7).

Pathophysiologic classification of anemia includes 4 groups (Table 26-4):

1. **Acute blood loss**
2. **Decreased production** of red cells by the bone marrow, either by **stem cell or progenitor cell defects**
3. **Ineffective hematopoiesis** with reduced release of erythrocytes from marrow
4. **Increased RBC destruction** outside the marrow, either **intracorpuscular** or **extracorpuscular**

In anemias with increased RBC destruction, circulating reticulocytes are elevated **(reticulocytosis)** as a response to hypoxia. This is different from the other groups.

TABLE 26-3
MORPHOLOGIC CLASSIFICATION OF ANEMIA

Macrocytic	
Nutritional deficiency	Hypothyroidism
Alcohol use	Reticulocytosis
Liver disease	Primary bone marrow disease
Microcytic	
Iron deficiency	
Thalassemias	
Sideroblastic	
Normocytic	
Anemia of chronic disease/inflammation	
Anemia of renal disease	
Acute blood loss	

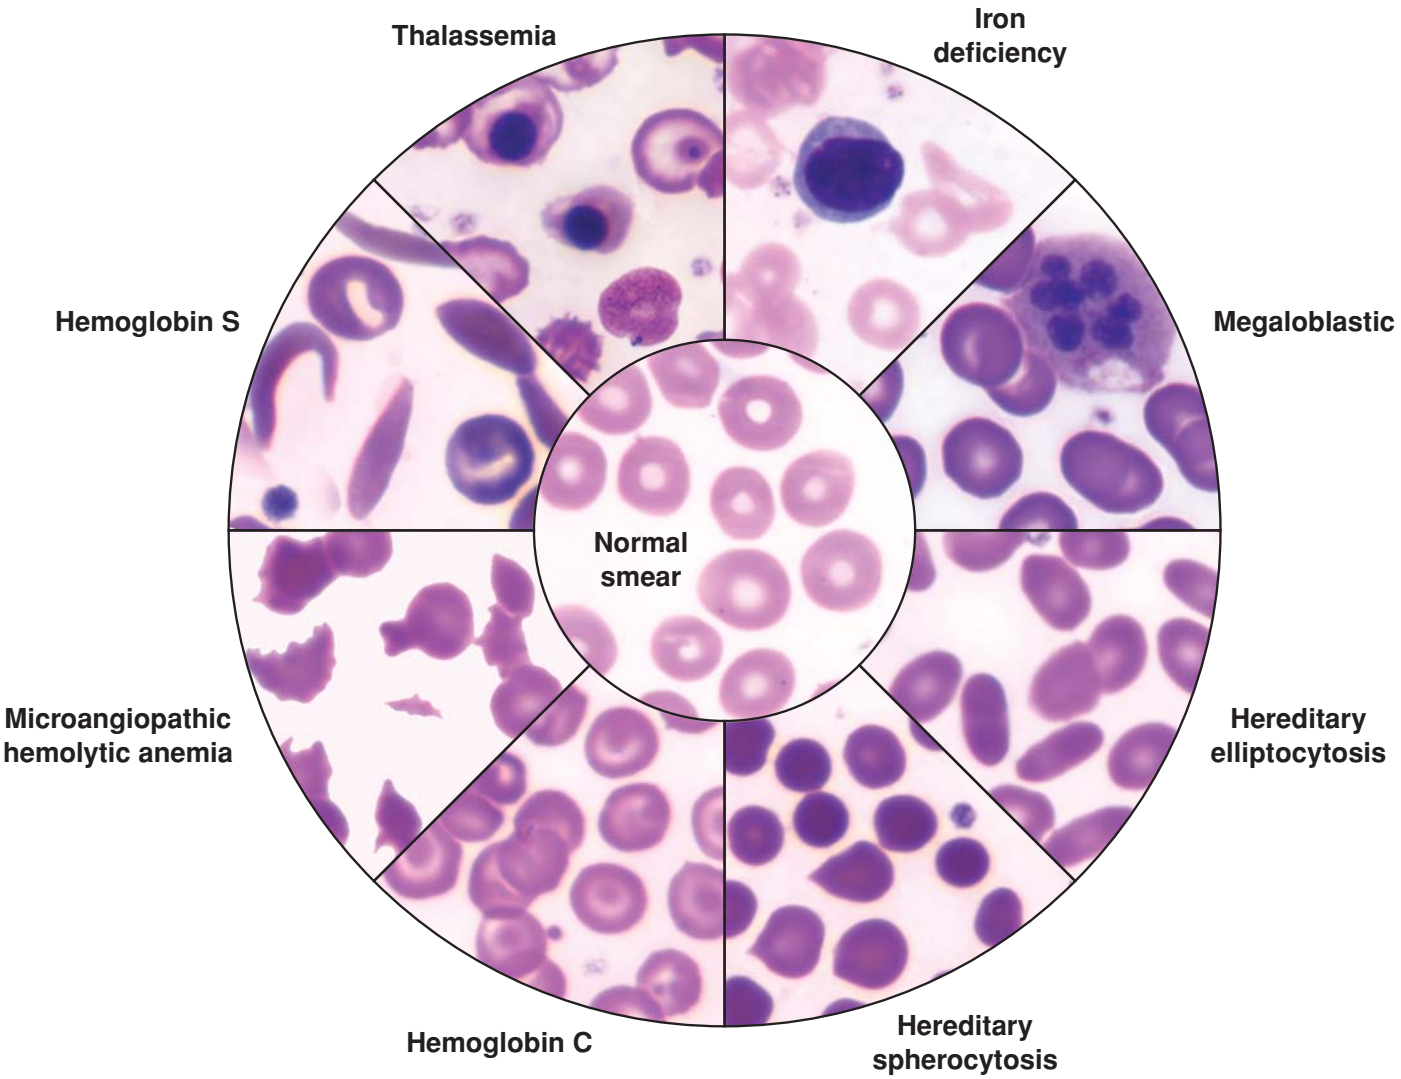

FIGURE 26-7. Abnormal red blood cell morphologies associated with various types of anemia. The morphology of normal erythrocytes is shown in the center. **Clockwise from 12:00:A. Iron deficiency (disturbance in hemoglobin synthesis; lack of iron):** Hypochromic, microcytic erythrocytes. A small lymphocyte is present for comparison. **B. Megaloblastic anemia (disturbance in DNA synthesis, most often caused by deficiency of vitamin B_{12} or folic acid):** Oval macrocytes, some irregularly shaped cells and hypersegmented neutrophils. **C. Hereditary elliptocytosis (membrane defect):** Elliptocytes. **D. Hereditary spherocytosis (membrane defect):** Spherocytes lacking central pallor. **E. Hemoglobin C disease (abnormal globin chain):** Target cells. **F. Microangiopathic hemolysis** (**mechanical damage to erythrocytes;** disseminated intravascular coagulation [DIC], thrombocytic thrombocytopenic purpura [TTP], heart valve prosthesis sequela): Schistocytes/fragments. **G. Sickle cell (hemoglobin S) disease (abnormal globin chain):** Sickle cells. **H. Thalassemia (disturbance in hemoglobin synthesis):** Hypochromic, microcytic erythrocytes; poikilocytosis; basophilic stippling; target cells, nucleated red blood cells (RBCs).

TABLE 26-4
PATHOPHYSIOLOGIC CLASSIFICATION OF ANEMIA

Acute Blood Loss	
Decreased Production	
Stem Cell and Progenitor Cell Defects	
Iron deficiency	Leukemia
Anemia of chronic disease	Myelodysplastic syndromes
Aplastic anemia	Marrow infiltration
Pure red cell aplasia	Lead poisoning
Paroxysmal nocturnal hemoglobinuria	Anemia of renal disease
Ineffective Hematopoiesis	
Megaloblastic anemia Myelodysplastic syndromes	Thalassemia
Increased Destruction	
Intracorpuscular	
Membrane defect	Hemoglobinopathies
Enzyme defect	
Extracorpuscular	
Immunologic	
Autoimmune	Alloimmune
Nonimmunologic	
Mechanical	Infectious
Hypersplenism	Chemical

CLINICAL FEATURES: In the face of anemia, there are several compensatory mechanisms to enhance oxygen delivery to tissues:

- Increased cardiac output
- Increased respiratory rate
- Shunting of blood flow to provide increased tissue perfusion of vital organs
- Decreased hemoglobin–oxygen affinity
- Increased marrow erythrocyte production due to EPO stimulation

Clinical signs and symptoms (tachycardia, shortness of breath, systolic murmurs) may reflect these compensatory processes. If anemia is severe (i.e., hemoglobin <7 g/dL), tissue hypoxia is uncompensated and additional clinical findings may include easy fatigability, faintness, angina and dyspnea on exertion.

Acute Blood Loss Leads to Normocytic Normochromic Anemia

Acute anemia reflects blood loss from the intravascular compartment.

PATHOLOGY AND CLINICAL FEATURES: Initial signs of acute blood loss reflect volume depletion and decreased tissue perfusion. Since whole blood is lost, the severity of the anemia may not be appreciated at first. Within 24–48 hours after significant hemorrhage, however, fluid is mobilized from extravascular locations into the intravascular space to restore overall blood volume. This is when the extent of the anemia becomes apparent, since red cell replacement is not as rapid. If the underlying bleeding is stopped, EPO-driven bone marrow erythroid hyperplasia will gradually correct the anemia. The blood smear shows no specific abnormalities, but polychromasia occurs during the recovery phase.

Decreased Red Blood Cell Production Often Reflects Impaired Erythrocyte Precursor Development

Some disorders in which RBC production is decreased are inherited or acquired diseases of hematopoietic stem cells or of their committed derivatives. These are discussed below under HSC diseases.

Iron-Deficiency Anemia

Iron deficiency interferes with normal heme (hemoglobin) synthesis and leads to impaired erythropoiesis and anemia. Iron deficiency is the most common cause of anemia worldwide.

ETIOLOGIC FACTORS: The normal Western adult diet contains about 20 mg of iron, 1–2 mg of which is absorbed by the duodenum and proximal jejunum (see Chapter 20). The rate of iron absorption is regulated by normal losses, but anemia (especially with ineffective erythropoiesis) triggers increased intestinal absorption and may ultimately lead to iron overload. About 85% of absorbed iron is transported by a carrier protein, transferrin, to be incorporated into developing red cells via transferrin receptors on their surface. As senescent red cells are removed from circulation, hemoglobin is broken down into its components, and iron is recycled. Excess iron is stored as **hemosiderin** and **ferritin**. Hemosiderin is large aggregates of iron with a disorganized structure; ferritin is complexed with protein (apoferritin) and appears highly organized.

Many underlying conditions cause iron deficiency. In infants and children, dietary iron may be insufficient for growth and development. Iron need also increases during **pregnancy** and **lactation**. In adults, iron deficiency typically results from **chronic blood loss** or, less often, **intravascular hemolysis.** Two milliliters of whole blood contains 1 mg of iron, which is lost with bleeding. In women of reproductive age, **gynecologic blood loss** (menstruation, parturition, vaginal bleeding) is most common. In postmenopausal women and men, unexplained iron deficiency should prompt a search for gastrointestinal **tumors** or **vascular lesions,** as this is the most common site of chronic blood loss.

PATHOLOGY: Iron deficiency causes a microcytic, hypochromic anemia (Fig. 26-8). Variation in RBC size **(anisocytosis)** and shape **(poikilocytosis)** is reflected in increased RDW. **Ovalocytes** may be found; some of these are very thin and are called **pencil cells**. Iron

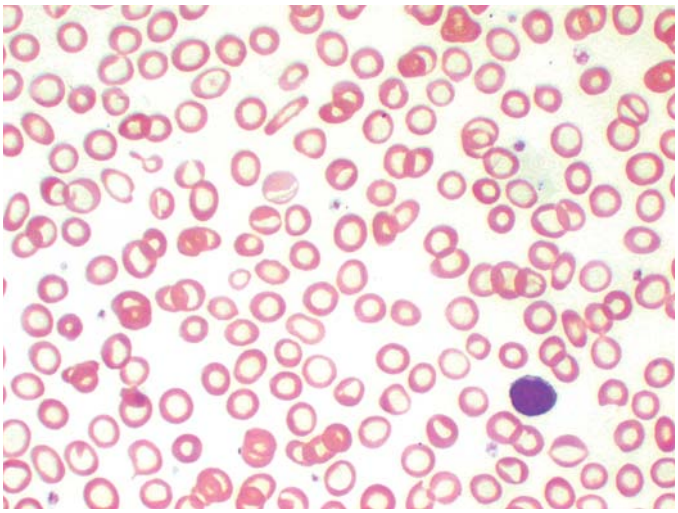

FIGURE 26-8. Microcytic hypochromic anemia caused by iron deficiency. Red blood cells (RBCs) are significantly smaller than the nucleus of a small lymphocyte, and they have increased central pallor (normal central pallor is about one third of the RBC diameter).

deficiency causes an RBC production defect, so marrow erythroid hyperplasia occurs but blood reticulocytosis does not. Prussian blue staining shows that iron storage and erythroid iron are absent.

Serum iron and ferritin levels are low in iron deficiency, while total iron-binding capacity (TIBC) is increased (because of increased serum transferrin levels). As a result, transferrin saturation is conspicuously lowered (often <5%).

CLINICAL FEATURES: The symptoms of iron deficiency are those of anemia in general. With advanced disease, a smooth and glistening tongue **(atrophic glossitis)** and inflammation at the corners of the mouth **(angular stomatitis)** may occur, as may a spoon-shaped deformity of the fingernails **(koilonychia)**. Treatment requires correcting the source of chronic blood loss and oral or parenteral iron supplementation.

Anemia of Chronic Disease

Anemia of chronic disease occurs in chronic inflammatory and malignant conditions.

PATHOPHYSIOLOGY: Chronic disease causes ineffective use of iron from macrophage stores in bone marrow. This results in a functional iron deficiency, even though iron stores may be normal or even increased. Other factors that may contribute to anemia are shorter RBC life span, blunted renal EPO response to tissue hypoxia and poor bone marrow response to erythropoietin. Inflammatory cytokines (lactoferrin, IL-1, tumor necrosis factor-α [TNF-α] and interferon) may inhibit iron mobilization.

PATHOLOGY: Anemia of chronic disease is mild to moderate; red cells are often normocytic and normochromic, but can be microcytic. In marrow aspirates, Prussian blue shows normal or increased iron in macrophages, but reduced erythroid iron. Serum iron levels tend to be low. However, unlike iron-deficiency anemia, TIBC also tends to be decreased (as is serum albumin). Reticulocyte counts are not appropriately increased for the degree of anemia. Successful treatment of the underlying disease restores normal hemoglobin levels.

Anemia of Renal Disease

PATHOPHYSIOLOGY: In some patients with chronic renal diseases, **decreased renal production of EPO** leads to anemia. The severity of anemia is proportional to the extent of renal insufficiency. Administration of recombinant EPO is the treatment of choice. A "uremic toxin," which suppresses erythroid precursors, and a minor hemolytic component may contribute to the anemia of chronic renal disease.

PATHOLOGY: Anemia of chronic renal disease is normocytic and normochromic. Erythrocytes with scalloped cell membranes may sometimes be seen **(Burr cells)**. If the renal insufficiency is due to malignant hypertension, red cells may be fragmented and form schistocytes.

Anemia Associated with Marrow Infiltration (Myelophthisic Anemia)

Myelophthisic anemia is a hypoproliferative anemia associated with marrow infiltration.

ETIOLOGIC FACTORS: Any infiltrative process (e.g., myelofibrosis, hematologic malignancies, metastatic carcinoma or granulomatous disease) may replace normal hematopoietic elements and cause anemia (and often leukopenia and thrombocytopenia). In an attempt to maintain blood cell production, extramedullary hematopoiesis may develop, mostly in the spleen and liver.

PATHOLOGY: Bone marrow infiltration causes moderate to severe normocytic anemia, with anisopoikilocytosis and teardrop cells. Circulating immature granulocytes and nucleated erythrocytes **(leukoerythroblastosis)** are common.

Anemia of Lead Poisoning

Lead poisoning results in anemia by interfering with several enzymes involved in heme synthesis (see Chapter 8).

In Ineffective Red Cell Production, There Are Fewer Circulating Erythrocytes

Various anemias reflect abnormal erythrocyte production caused by ineffective hematopoiesis. In these cases, the bone marrow erythrocyte precursor pool is expanded. Thus, sufficient erythroid precursors are formed in the bone marrow, but erythrocytes do not enter the circulation.

Megaloblastic Anemias

Megaloblastic anemias are caused by impaired DNA synthesis, usually because of vitamin B_{12} or folic acid deficiency.

PATHOPHYSIOLOGY AND ETIOLOGIC FACTORS: Megaloblastic anemia defines a group of diseases characterized by hallmark megaloblasts. Impaired DNA synthesis leads to abnormal nuclear maturation. This in turn leads to ineffective erythrocyte maturation and anemia. All proliferating cell types, including myeloid precursors, and cervical and gastrointestinal mucosal cells are affected.

Megaloblastic anemia is most commonly due to B_{12} or folate deficiency. Some chemotherapeutic agents (methotrexate, hydroxyurea) or antiretroviral drugs (5-azacytidine) may also be responsible. Inherited defects in purine or pyrimidine metabolism may rarely be involved.

Folate and B_{12} are critical for normal DNA synthesis. Tetrahydrofolate is converted from methyl tetrahydrofolate by methyltransferase, with vitamin B_{12} as a cofactor. Vitamin B_{12} is also required for converting homocysteine to methionine. Using tetrahydrofolate as a cofactor, thymidylate synthetase converts uridylate to thymidylate (Fig. 26-9). Dihydrofolate reductase restores tetrahydrofolate.

With impaired DNA synthesis, nuclear development is delayed, but the cytoplasm matures normally. This leads to **nuclear-to-cytoplasmic asynchrony** and results in formation of large nucleated erythrocyte precursors **(megaloblasts)**. Since these megaloblasts do not mature enough to be released into the blood, they undergo intramedullary destruction. Released erythrocytes are macrocytic.

Vitamin B_{12} (cyanocobalamin) cannot be synthesized by humans and must come from diet. It occurs in a variety of animal food sources and is produced by intestinal microorganisms. Proper vitamin B_{12} absorption requires intrinsic factor, which is in the stomach (see Chapter 19) and protects vitamin B_{12} from degradation by intestinal enzymes (Fig. 26-10). The intrinsic factor–vitamin B_{12} complex is absorbed in the distal ileum via specific receptors. In the blood, the vitamin is transported by a group of proteins called **transcobalamins,** of which transcobalamin II is the most important. The daily usage of vitamin B_{12} is 1 µg. Therefore, normal body stores of 1000–5000 µg provide several years of reserve.

Inadequate dietary intake of vitamin B_{12} is rare and usually occurs only in strict vegetarians (vegans). ***Most often, lack of intrinsic factor impairs its absorption.*** Surgery that resects the gastric fundus removes the source of intrinsic factor.

Pernicious anemia, an autoimmune disorder in which patients develop antibodies against parietal cells and intrinsic factor (see Chapter 19), leads to intrinsic factor deficiency. Antiparietal cell antibodies also cause atrophic gastritis with achlorhydria. Primary intestinal disorders (inflammatory bowel disease) or previous intestinal surgery (ileal bypass) can impair vitamin B_{12} absorption. Microbiologic competition (e.g., from bacterial overgrowth of a blind loop or infestation by a fish tapeworm, *Diphyllobothrium latum*) may lead to vitamin B_{12} deficiency.

Folic acid is present in leafy vegetables, meat and eggs. Dietary folic acid exists in a polyglutamate form but

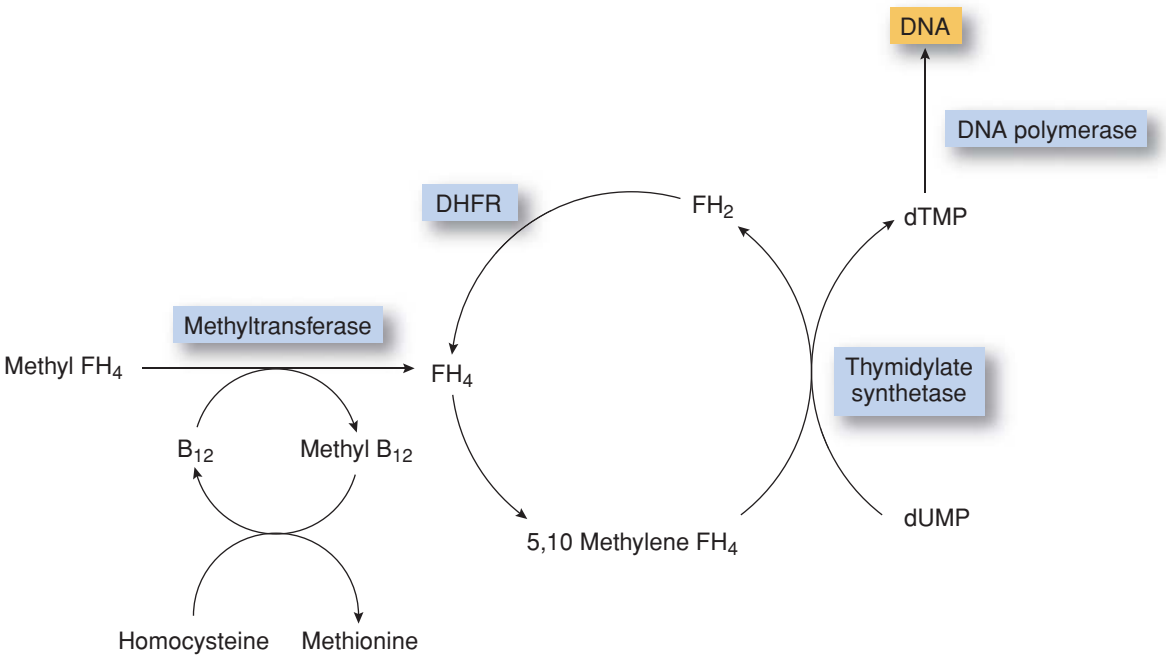

FIGURE 26-9. Relationship of folic acid to vitamin B_{12}. A 1-carbon transfer mediated by folic acid methylates dUMP to dTMP, which is then used for the synthesis of DNA. To enter this cycle, folate (methyl FH_4) is demethylated to FH_4, vitamin B_{12} acting as the cofactor. Thus, both vitamin B_{12} and folic acid deficiencies lead to impaired DNA synthesis and megaloblastic anemia. *DHFR* = dihydrofolate reductase; *dTMP* = deoxythymidine monophosphate; *dUMP* = deoxyuridine monophosphate; *FH_2* = dihydrofolate; *FH_4* = tetrahydrofolate.

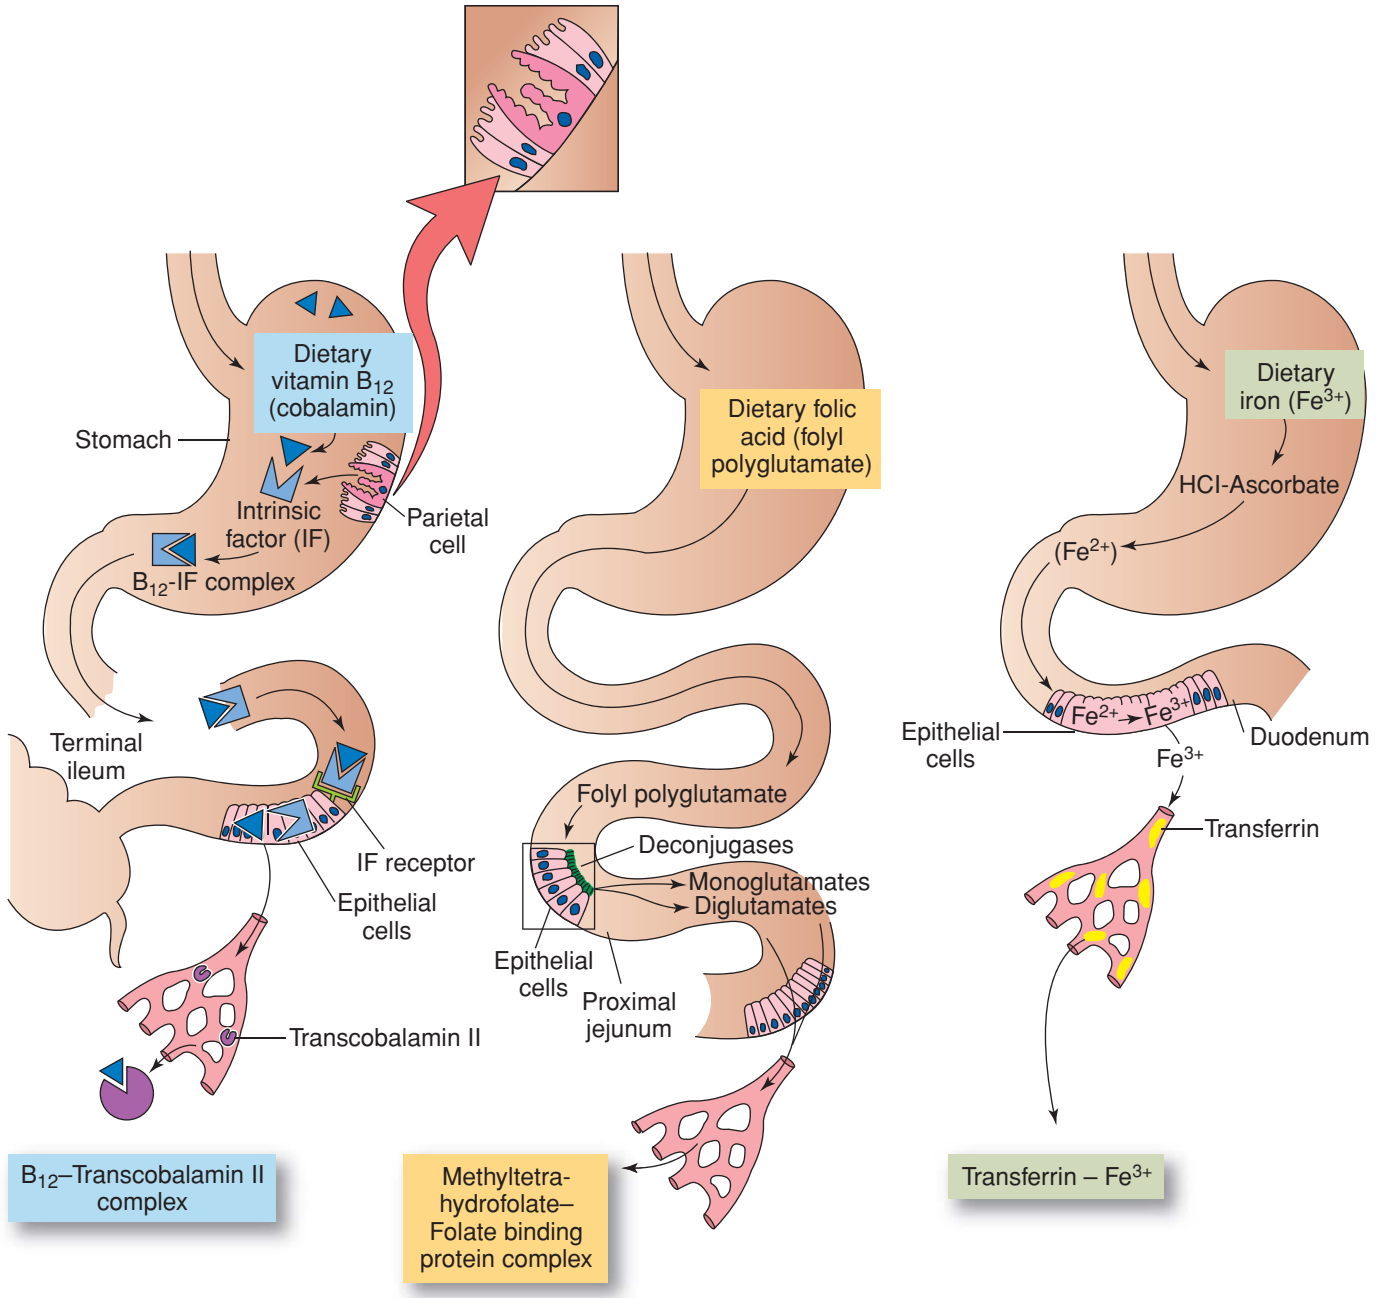

FIGURE 26-10. Absorption of vitamin B_{12}, folic acid and iron. Absorption of vitamin B_{12} requires initial complexing with intrinsic factor (IF), which is produced by the parietal cells of the gastric mucosa. Absorption then occurs in the terminal ileum, where there are receptors for the IF–B_{12} complex. Dietary folic acid is conjugated by conjugase enzymes to polyglutamate. Absorption occurs in the jejunum following deconjugation in the intestinal lumen. Reduction and methylation result in the generation of methyl tetrahydrofolate, which is then transported by folate-binding protein. Dietary ferric iron (Fe^{3+}) is reduced to ferrous iron (Fe^{2+}) in the stomach and absorbed principally in the duodenum. Iron is transported by transferrin in the circulation.

is deconjugated to monoglutamates in the intestines and absorbed primarily in the jejunum. Folate is then reduced and methylated to 5-methyl tetrahydrofolate, which is transported in the blood by folate-binding protein. The daily requirement for folate is about 50 µg. Body stores of folate average 2000–5000 µg, providing a few months' reserve before signs of deficiency develop.

The most common cause of folic acid deficiency is inadequate dietary intake. This occurs mostly in patients with poorly balanced diets (alcoholics, recluses). Demand for folic acid is increased in pregnancy, lactation, periods of rapid growth and chronic hemolytic disease. During these times, folate deficiency may occur unless folate supplementation is provided. Primary intestinal diseases (inflammatory bowel disease, sprue) may interfere with folic acid absorption. Various medications can also impair folic acid absorption (phenytoin) or metabolism (methotrexate).

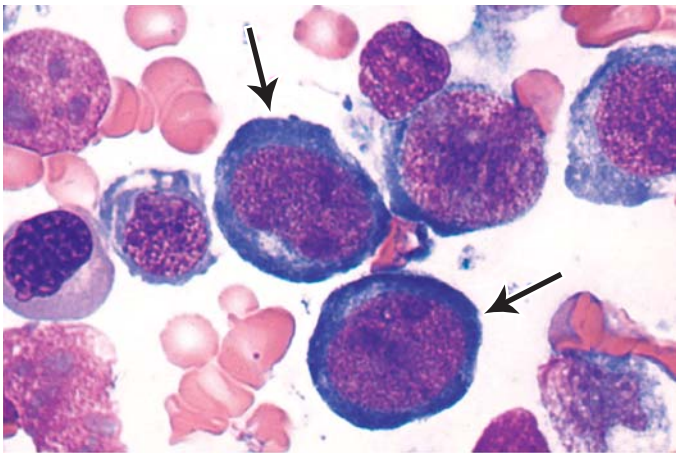

FIGURE 26-11. Megaloblastic anemia. A bone marrow aspirate from a patient with vitamin B_{12} deficiency (pernicious anemia) shows prominent megaloblastic erythroid precursors (*arrows*).

PATHOLOGY: The hematologic manifestations of both folic acid and vitamin B_{12} deficiency are identical. Hematopoiesis in the bone marrow tends to be increased, but the marrow releases insufficient mature, functional cells because of increased intramedullary cell death. This is called **ineffective hematopoiesis**. RBC precursors show megaloblastic maturation, in which cells enlarge but the cytoplasm matures while the nucleus lags (Fig. 26-11). The myeloid series shows similar dyssynchrony, with giant bands and metamyelocytes, and hypersegmented nuclei in mature granulocytes. The megakaryocytes may also be large.

The magnitude of the anemia varies but may be severe. Erythrocytes are macrocytic and may be oval (oval macrocytes). Anisopoikilocytosis is usually prominent, sometimes with teardrop cells. Circulating neutrophils often show nuclear hypersegmentation (>5 lobes) (Fig. 26-12). Reticulocytes are not increased.

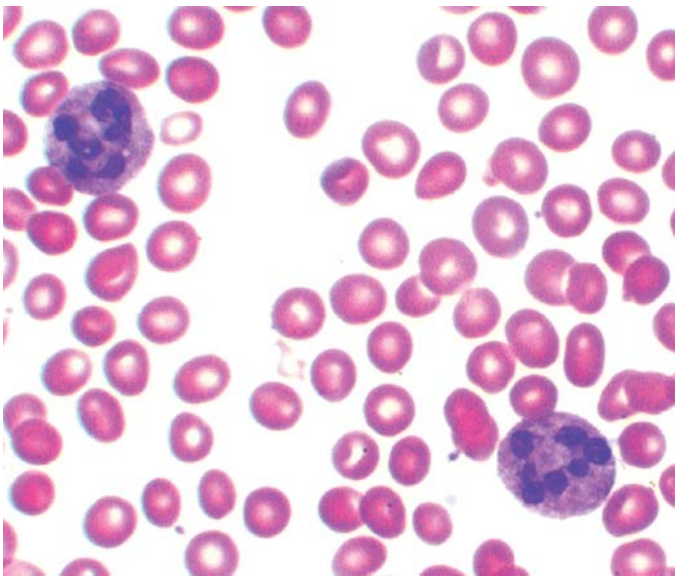

FIGURE 26-12. Hypersegmented granulocytes in a patient with vitamin B_{12} deficiency.

Folate and vitamin B_{12} deficiencies are usually distinguished by measuring serum levels of these vitamins. Occasionally, specific measurement of red cell folate provides more useful information than serum analyses. Because of massive intramedullary destruction of red cell precursors, serum levels of lactate dehydrogenase (LDH), especially isoenzyme 1, are conspicuously elevated.

The **Schilling test** can suggest the cause of B_{12} deficiency. It measures radiolabeled vitamin B_{12} absorption, with or without intrinsic factor. Urinary B_{12} is measured. However, this test is not commonly used. Elevated levels of homocysteine and methyl malonic acid may help diagnose vitamin B_{12} deficiency. Circulating antibodies against gastric parietal cells or intrinsic factor are present in cases of pernicious anemia. The former antibody is more often detected; the latter is more specific for pernicious anemia.

CLINICAL FEATURES: The clinical presentation of megaloblastic anemia is similar, whether due to B_{12} or folate deficiency. In general, the latter develops more rapidly (months) than the former (years). The most important difference clinically is that B_{12} deficiency is complicated by neurologic symptoms, owing to posterior and lateral column demyelination in the spinal cord. This may cause sensory and motor deficiencies (see Chapters 8 and 32). Unless treated quickly, those neurologic symptoms may be irreversible. Folate deficiency involves no such complications.

Thalassemia

Thalassemias are congenital anemias caused by deficient globin chain synthesis. Depending on the affected globin chain, β-thalassemia (defective β-chain production), α-thalassemia (defective α-chain production) and δ/β-thalassemia result.

The basic defect is reduced or absent production of β-globin (in β-thalassemia) or α-globin (in α-thalassemia) chains. A minority of thalassemia cases have structural hemoglobin variants yielding unstable globins. Since α- and β-chains normally pair to form hemoglobin tetramers, the lack of one type of chain leads to unpaired normal globin chains in thalassemic erythrocytes. In β-thalassemia, the excess normal α-chains form an unstable structure that precipitates at the cell membrane. This makes the RBCs very fragile, so they are destroyed within the bone marrow. In α-thalassemia, β-chains are in excess (in extrauterine life). Resulting hemoglobin contains only β-chains. In intrauterine life, the excess of γ-chains yields a hemoglobin with only γ-chains. In both cases, there is excessive red blood cell destruction.

EPIDEMIOLOGY: Thalassemia is most common in the Mediterranean area, especially Italy and Greece. However, it has a wide distribution, particularly in areas where malaria has been endemic (Middle East, India, Southeast Asia, China). Heterozygosity for thalassemia may help protect against malaria and increase the reproductive potential of heterozygotes, which may explain how these diseases persist. In many geographic areas where thalassemia is common, other structural hemoglobin defects (e.g., hemoglobin S [HgbS]) are also frequent. This can lead to double heterozygosity (e.g., sickle thalassemia), which demonstrates features of both disorders.

TABLE 26-5
MAJOR FORMS OF HEMOGLOBIN AND THEIR CHAIN COMPOSITION

Type of Hemoglobin	Contribution of Globin Chains					Explanation
	α	β	γ	δ	ζ	
A	2	2				Principal normal hemoglobin (>95% of total) in postnatal life.
A_2	2			2		Usually <3% of total hemoglobin, but may be slightly increased in β-thalassemia.
F	2		2			Normal hemoglobin for most of intrauterine life. Production usually ends by early infancy; hemoglobin F is largely undetectable after 6 months of age. Persists in β-thalassemia.
H		4				Mainly seen in α-thalassemia, where deficiency of α-chains leads to hemoglobins composed of β-chain tetramers. Responsible for formation of Heinz bodies.
Bart's			4			Seen in babies with α-thalassemia. Heinz bodies seen.
Portland			2		2	Hemoglobin present very early in fetal life. May persist in very severe α-thalassemia.

There are 4 α genes, paired on each chromosome 16. Non-α genes are on chromosome 11, two γ, one δ and one β gene per chromosome. Embryonic globin genes zeta (ζ) (α equivalent) and epsilon (ε) (non-α equivalent) are on chromosomes 16 and 11. The most important different types of hemoglobin and the globin chains that contribute to each are presented in Table 26-5.

MOLECULAR PATHOGENESIS: Normal hemoglobin contains four globin chains: 2 α- and 2 non–α-chains. There are 3 normal hemoglobin variants, based on the nature of the non–α-chains (Fig. 26-13). ***Adult hemoglobin is 95%–98% HgbA ($\alpha_2\beta_2$), plus small amounts of HgbF ($\alpha_2\gamma_2$) and A_2 ($\alpha_2\delta_2$).***

Thalassemias are generally classified by the affected globin chain. The two most clinically significant forms involve deficits of α- and β-chains. Thalassemias involving γ- and δ-globin chain synthesis occur but are not common.

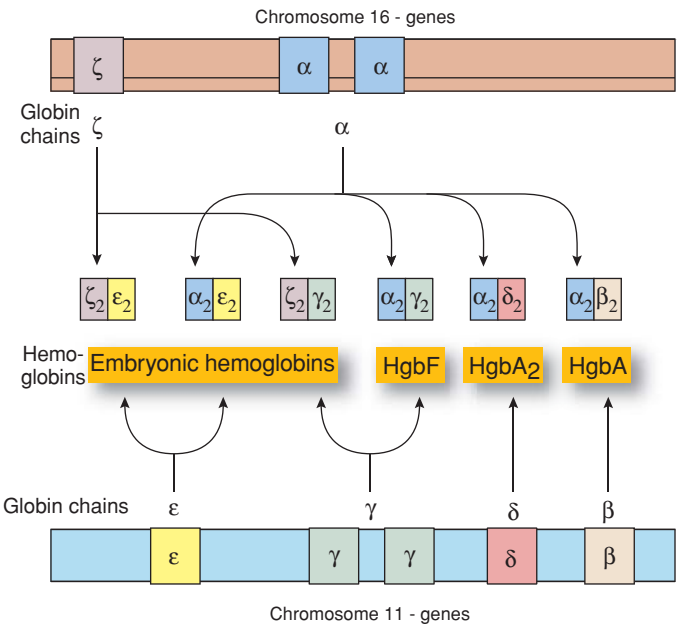

FIGURE 26-13. Hemoglobin assembly scheme using globin chains coded on chromosomes 11 and 16.

β-Thalassemia

MOLECULAR PATHOGENESIS: β-Thalassemias are a heterogeneous group of disorders that are mostly caused by point mutations in the β-globin gene. Mutations may be in the gene's promoter region, a splice site or other coding regions, or may lead to creation of an inappropriate stop codon. The result is that transcription of the gene is entirely (β^0) or partly (β^+) suppressed. Occasionally, a mutation may also affect the adjacent δ-globin gene, leading to a β–δ-thalassemia.

PATHOLOGY AND CLINICAL FEATURES: **Homozygous β-thalassemia (Cooley anemia)** is characterized by moderate to severe, microcytic and hypochromic anemia (Figs. 26-14 and 26-15). There is a marked excess of α-chains, which form unstable tetramers (α_4) that precipitate in the

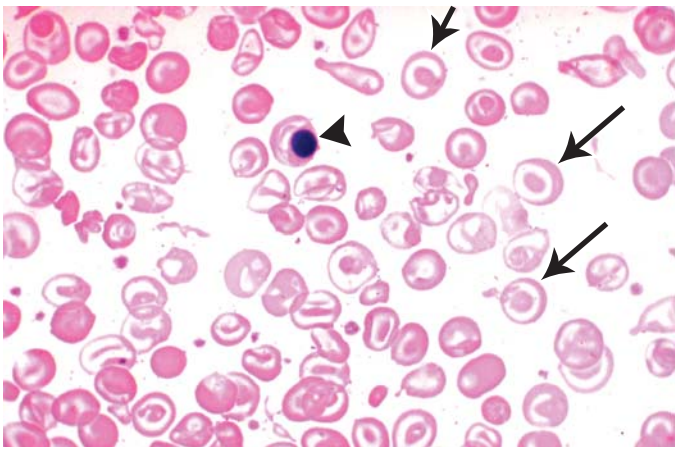

FIGURE 26-14. Thalassemia. The peripheral blood erythrocytes are hypochromic and microcytic and show anisopoikilocytosis with frequent target cells (*arrows*) and circulating nucleated red blood cells (*arrowhead*).

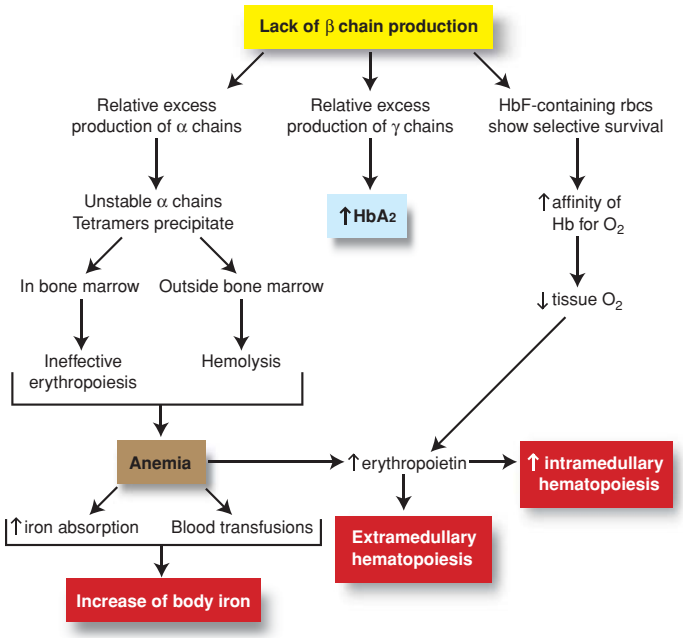

FIGURE 26-15. Pathogenesis of disease manifestations in β-thalassemia.

cytoplasm of developing erythroid precursors. In the β^o type, most hemoglobin is fetal hemoglobin, although increased (5%–8%) $HgbA_2$ is also present. In the β_1 type, some HgbA may be present (depending on the nature of the underlying defect) and $HgbA_2$ is mildly increased. A modest increase in $HgbA_2$ is characteristic of all forms of β-thalassemia, as δ-globin genes are upregulated.

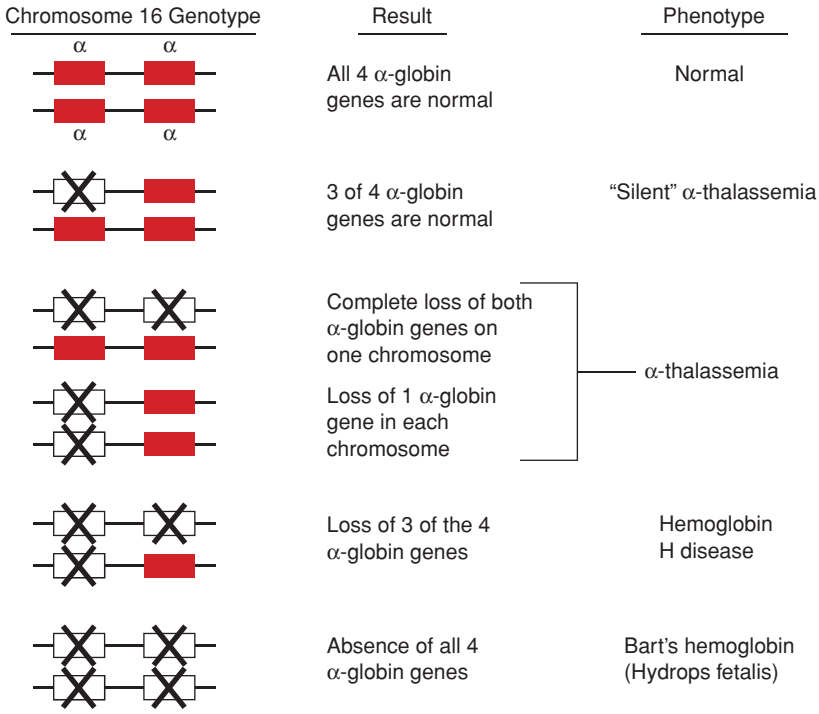
Blood smears show microcytosis, hypochromia and striking anisopoikilocytosis (uneven size and shape) with target cells, basophilic stippling and circulating normoblasts (especially after splenectomy). The increased oxygen affinity of HgbF, plus the underlying anemia, impairs oxygen delivery and elicits increased EPO. The latter causes marked bone marrow erythroid hyperplasia. The marrow space is expanded, causing facial and cranial bone deformities. Extramedullary hematopoiesis contributes to hepatosplenomegaly and may cause soft tissue masses.

Excess erythropoiesis stimulates iron absorption. This, together with repeated transfusions, causes iron overload. Excess iron deposition in tissues leads to morbidity and mortality in thalassemic patients and often requires aggressive chelation therapy.

Heterozygous β-thalassemia (heterozygous carrier of β-thalassemia) is associated with microcytosis and hypochromia. The degree of microcytosis is disproportionate to the severity of the anemia, which is generally mild or absent. Erythrocytosis (increased RBC count) with minimal anisocytosis (normal RDW) is common. Target cells, basophilic stippling, increased reticulocytes and a mild increase in $HgbA_2$ are present. Most patients are asymptomatic. Iron absorption is increased.

α-Thalassemia

MOLECULAR PATHOGENESIS: α-Thalassemias are most often due to gene deletions. More syndromes are clinically observed because of the potential number (up to four) of α-globin genes that may be affected. The genetics of the several α-thalassemias are illustrated in Fig. 26-16. α-Thalassemia is associated with excess β- or γ-chains, which can form the tetrameric HgbH (β_4) and Hgb Bart (γ_4). Hemoglobins H and Bart are both unstable and precipitate in the cytoplasm, forming Heinz bodies, but to a lesser degree than α_4 tetramers. Further, they have high oxygen affinities and cause decreased tissue oxygen delivery. The relative amount of these tetrameric hemoglobins depends on the number of α-genes involved and the patient's



Chromosome 16 Genotype
Result
Phenotype
α α α α
All 4 α-globin genes are normal
Normal
3 of 4 α-globin genes are normal
"Silent" α-thalassemia
Complete loss of both α-globin genes on one chromosome
Loss of 1 α-globin gene in each chromosome
α-thalassemia
Loss of 3 of the 4 α-globin genes
Hemoglobin H disease
Absence of all 4 α-globin genes
Bart's hemoglobin (Hydrops fetalis)

FIGURE 26-16. Genetics of α-globin deficiencies and their manifestations.

age. Because of the underlying impairment in hemoglobin synthesis, circulating red cells usually are microcytic and hypochromic.

PATHOLOGY AND CLINICAL FEATURES:

- **Silent carrier α-thalassemia** (one gene affected) is difficult to diagnose, because patients' only hematologic abnormality is small amounts of Hgb Bart, detectable only in infancy. There is no anemia; patients are asymptomatic.
- **α-Thalassemia trait** (two genes affected) is associated with a mild microcytic anemia. Like heterozygous β-thalassemia, the degree of microcytosis is disproportionately low compared to the degree of anemia. $HgbA_2$ is not increased, allowing distinction between α- and β-thalassemia traits. Up to 5% Hgb Bart can be seen during infancy.

  Two different genotypes are possible in heterozygous α-thalassemia. There may be a single gene deleted from each chromosome 16 or, alternatively, both genes may be deleted from the same chromosome 16. The former is more common in people of Mediterranean and African descent, while the latter occurs more often in Southeast Asia. Clinically, both genotypes present similarly, but homozygous α-thalassemia (see below) can only develop if both genes are deleted from the same chromosome.
- **Hemoglobin H disease** (3 genes affected) is associated with moderate microcytic anemia. Increased Hgb Bart (up to 25% in infancy) and variable levels of HgbH are seen. Both HgbH and Hgb Bart give characteristic patterns on hemoglobin electrophoresis, since they migrate faster than HgbA. Precipitated HgbH (Heinz bodies) also appears on supravital staining of blood smears.
- **Homozygous** (all 4 genes affected) **α-thalassemia,** also called α hydrops fetalis, is incompatible with life. Affected infants die in utero or shortly after birth with severe anemia, marked anisopoikilocytosis and large amounts of Hgb Bart. Severe impairment in tissue oxygen delivery is associated with heart failure and generalized edema. Massive hepatosplenomegaly is due to extramedullary hematopoiesis. A woman carrying a fetus with Hgb Bart has increased risk for obstetric complications, including eclampsia and postpartum bleeding.

Hemolytic Anemias Result from Increased Red Cell Destruction

Hemolysis (i.e., premature elimination of circulating RBCs) causes **hemolytic anemia**. These anemias are classified by the site of red cell destruction. In **extravascular hemolysis,** the monocyte/macrophage system in the spleen and, to a lesser extent, the liver is involved. In **intravascular hemolysis,** RBCs are destroyed while circulating.

Hemolytic anemias are characterized by a compensatory increase in red cell production and release. In the blood, this manifests as red cell polychromasia because of increased reticulocytes. Other laboratory findings commonly associated with hemolysis include increased LDH (particularly isoenzyme 1) and unconjugated (indirect) bilirubin, decreased haptoglobin, free (extracellular) hemoglobin in the blood and urine, increased urobilinogen and urine hemosiderin.

Erythrocyte Membrane Defects

Erythrocyte membranes are normally remarkably deformable, which allows red cells to pass unimpaired through the microcirculation and splenic vasculature. The red cell membrane consists of a phospholipid bilayer linked to an underlying cytoskeleton, composed primarily of spectrin, a dimer of α- and β-subunits and other erythrocyte specific cytoskeletal components (Fig. 26-5). Ankyrin (band 2.1) anchors spectrin to transmembrane proteins (band 3, anion exchanger proteins), while spectrin is bound to actin and glycophorin by protein 4.1. ***Alterations in any part of the red cell membrane can impair RBC plasticity, impacting the "vertical linkages" and rendering erythrocytes susceptible to hemolysis.***

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is a diverse group of inherited disorders of RBC cytoskeletons, in which spectrin or another cytoskeletal component (ankyrin, protein 4.2, band 3) is deficient. HS is the most common congenital hemolytic anemia in Caucasians.

MOLECULAR PATHOGENESIS: Deficiency of any cytoskeletal protein leads to a **"vertical"** defect in red cell membranes, with the lipid bilayer uncoupled from the underlying cytoskeleton. The result is progressive loss of membrane surface area and **spherocyte** formation. These abnormal red cells are more rigid and fragile, and so cannot easily traverse splenic sinusoids. While circulating through the spleen, spherocytes lose additional surface membrane, are trapped and ultimately succumb to extravascular hemolysis. About 75% of HS cases are inherited as autosomal dominant traits. The rare recessive cases all involve a spectrin α-subunit.

PATHOLOGY: Most patients with HS have a moderate normocytic anemia. Conspicuous spherocytes that appear hyperchromic (no central pallor) are typical, along with polychromasia and reticulocytosis (Fig. 26-17). The bone marrow shows erythroid hyperplasia. Although typical spherocytes have

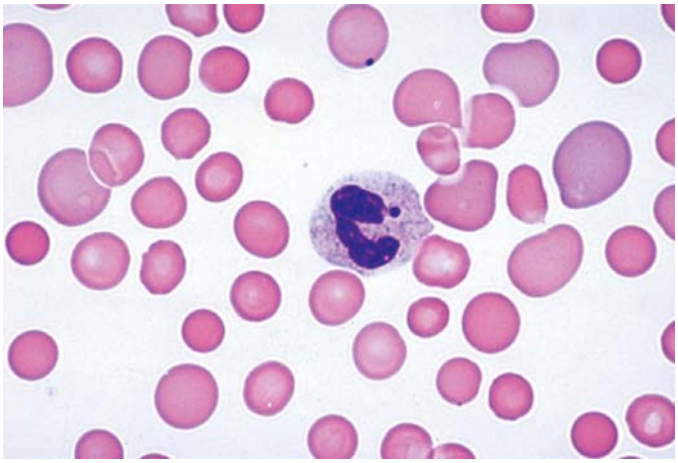


FIGURE 26-17. Hereditary spherocytosis. The peripheral blood smear shows frequent spherocytes with decreased diameter, intense staining and lack of central pallor (*arrows*).

low MCV because of membrane loss and cell dehydration, these patients may have normal mean MCV because of increased reticulocytes (which are larger than average red blood cells).

Spherocytes show greater **osmotic fragility** than normal erythrocytes. Laboratory findings are typical of hemolysis: decreased haptoglobin, increased indirect bilirubin, increased LDH.

CLINICAL FEATURES: Most patients have splenomegaly caused by chronic extravascular hemolysis. They may appear jaundiced, and up to 50% develop cholelithiasis, with pigmented (bilirubin) gallstones. Despite chronic hemolysis, transfusion is not usually needed. An exception is a sudden decline in hemoglobin and reticulocytes, which heralds **aplastic crisis** (usually caused by infection by parvovirus B19). Anemia may also become more severe in so-called **hemolytic crisis,** when hemolysis accelerates transiently. Patients with HS can be managed effectively by splenectomy, although spherocytes still persist in the circulation. Splenectomy, however, renders patients more susceptible to certain infections, particularly with *Streptococcus* spp.

Hereditary Elliptocytosis

Hereditary elliptocytosis (HE) is a diverse group of inherited disorders affecting the erythrocyte cytoskeleton.

MOLECULAR PATHOGENESIS: HE is characterized by elliptical or oval red blood cells. The most commonly described HE variants include defects in self-assembly of spectrin, spectrin–ankyrin binding, protein 4.1 and glycophorin C. RBCs have an area of central pallor, since there is no loss of the lipid bilayer (as seen in HS). Most forms of HE are autosomal dominant.

PATHOLOGY AND CLINICAL FEATURES: HE is more common in malaria endemic regions of West Africa. Patients with HE usually have only mild normocytic anemia. Many are asymptomatic. Blood smears show many elliptocytes with only minimal reticulocytosis (Fig. 26-18). Generally, less hemolysis and subsequent anemia are seen than are seen with HS. Occasional patients with more severe hemolysis may require splenectomy.

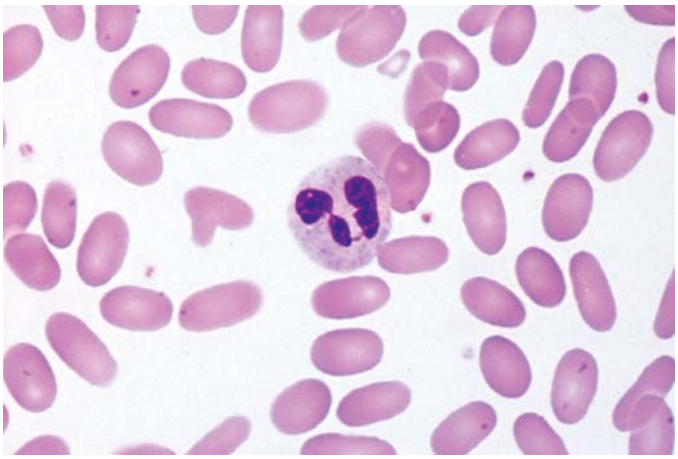

FIGURE 26-18. Hereditary elliptocytosis. A peripheral blood smear reveals that virtually all of the erythrocytes are elliptical with parallel sides.

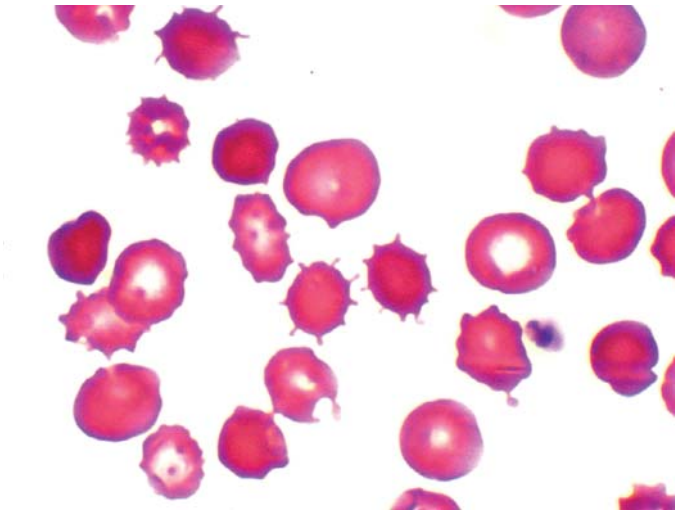

FIGURE 26-19. Acanthocytes. The red cells lack central pallor and display irregular spikes on the surface.

Acanthocytosis

Acanthocytosis results from a defect within the red cell membrane lipid bilayer and features irregularly spaced spiny projections of the surface, which may be associated with hemolysis.

PATHOPHYSIOLOGY: The most common cause is chronic liver disease, in which increased free cholesterol deposits in cell membranes. Acanthocytes also occur in abetalipoproteinemia, an autosomal recessive disorder with lipid membrane abnormalities (see Chapter 19).

PATHOLOGY AND CLINICAL FEATURES: Abnormalities in their lipid membranes cause erythrocytes to deform and develop irregular spiny surface projections and centrally dense cytoplasm (no central pallor) (Fig. 26-19). These **acanthocytes** (spur cells) should be distinguished from burr cells (crenated cells, **echinocytes**), which show more uniform membrane scalloping and keep their central pallor. Hemolysis and anemia in acanthocytosis are mild.

Enzyme Defects

Erythrocytes generate energy mainly by glycolysis. Inherited defects of enzymes in the glycolytic pathway can predispose circulating red cells to hemolysis. The most common enzyme defect involves glucose-6-phosphate dehydrogenase (G6PD), which catalyzes conversion of glucose-6-phosphate to 6-phosphogluconate. Deficiencies of other glycolytic enzymes are rare and autosomal recessive. Among these, pyruvate kinase deficiency is the most common. Clinically, these defects cause variable degrees of anemia and are classified as **hereditary nonspherocytic anemias**.

G6PD deficiency is an X-linked disease in which RBCs are abnormally sensitive to oxidative stress, which triggers hemolytic anemia. G6PD deficiency is most common in areas where malaria is historically endemic, notably Africa and the Mediterranean. The various G6PD mutations appear to protect somewhat against malaria.

PATHOPHYSIOLOGY: Since G6PD helps to recycle reduced glutathione, red cells deficient in this enzyme are susceptible to oxidative stress (e.g., infections, drugs or fava bean ingestion [favism]). Hemoglobin oxidation generates methemoglobin, in which Fe^{2+} ions are converted to ferric (Fe^{3+}). Methemoglobin cannot transport oxygen, is unstable and precipitates in the cytoplasm as Heinz bodies. These precipitates increase cell rigidity and lead to hemolysis.

PATHOLOGY: In quiescent periods, erythrocytes in G6PD deficiency appear normal. But, in a hemolytic episode precipitated by oxidative stress, Heinz bodies appear with supravital staining. Passage through the spleen may remove part of red blood cell membranes, to form so-called **bite cells**.

CLINICAL FEATURES: Full expression of G6PD deficiency is seen only in males; females are asymptomatic carriers. The A variant of G6PD is seen in 10%–15% of American blacks. It is associated with 10% of normal enzyme activity because of instability of the molecule. In affected patients, exposure to oxidant drugs, such as the antimalarial primaquine, may trigger hemolysis. In the Mediterranean type of G6PD mutation, enzyme activity is absent. Thus, exposure to oxidant stress sets off more sustained and severe hemolysis. Potentially lethal hemolysis may follow ingestion of fava beans **(favism)** in susceptible patients.

Hemoglobinopathies

Most clinically relevant hemoglobinopathies are caused by point mutations in the β-globin chain gene.

Sickle Cell Disease

In sickle cell disease, an abnormal hemoglobin, HgbS, causes RBCs to sickle upon deoxygenation.

EPIDEMIOLOGY: HgbS is most common in people of African ancestry, although the gene is also present in Mediterranean, Middle Eastern and Indian people. In some regions of Africa, up to 40% of the population is heterozygous for HgbS. Ten percent of American blacks are heterozygous and 1 in 650 is homozygous. Heterozygosity for HgbS may partially protect against falciparum malaria. Infected erythrocytes selectively sickle and are removed from the circulation by splenic and hepatic macrophages, effectively destroying the parasite.

MOLECULAR PATHOGENESIS: A point mutation in the gene for the β-globin chain gene substitutes valine for glutamic acid at the 6th amino acid. This single change makes an unstable molecule that polymerizes upon deoxygenation. Polymerization of HgbS transforms the cytoplasm into a rigid filamentous gel and produces less deformable sickled erythrocytes.

The rigidity of sickled erythrocytes obstructs the microcirculation, leading to tissue hypoxia and ischemic injury in many organs. The inflexibility of sickle cells also renders them susceptible to destruction (hemolysis) during passage through the spleen. Thus, the two primary manifestations of sickle cell disease are recurrent ischemic events and chronic extravascular hemolytic anemia.

At first, reoxygenation can reverse the sickling, but after several cycles of sickling and unsickling, the process becomes irreversible. Sickled erythrocytes also have changes in their membrane phospholipids, and so adhere more strongly to endothelial cells. This further impairs capillary blood flow.

People homozygous for HgbS show the full clinical picture of sickle cell disease. A sickling disorder also occurs in patients who are doubly heterozygous for two β-chain mutations (e.g., HgbSC disease, sickle/β-thalassemia). Heterozygotes for HgbS (sickle trait), however, do not develop red cell sickling, because their HgbA prevents HgbS polymerization. HgbF also interferes with HgbS polymerization, and patients who are homozygous for HgbS and have increased HgbF have a milder form of disease.

PATHOLOGY: Homozygous patients (HgbSS) have severe normocytic or macrocytic anemia. The macrocytosis reflects increased numbers of reticulocytes, owing to chronic hemolysis. Blood smears show marked anisopoikilocytosis and polychromasia. There are classic sickle cells and target cells, as well as other abnormally shaped erythrocytes (Fig. 26-20). Howell-Jolly bodies, which represent nuclear remnants, are evident in most patients beyond childhood and reflect hyposplenism because of ischemic loss of splenic tissue.

Electrophoretic analysis shows that HgbS accounts for 80%–95% of the total hemoglobin and HgbA is absent. HgbF and $HgbA_2$ make up the remaining hemoglobin.

CLINICAL FEATURES: Infants with SS hemoglobin are asymptomatic for their first 8–10 weeks of life, because they have high levels of HgbF.

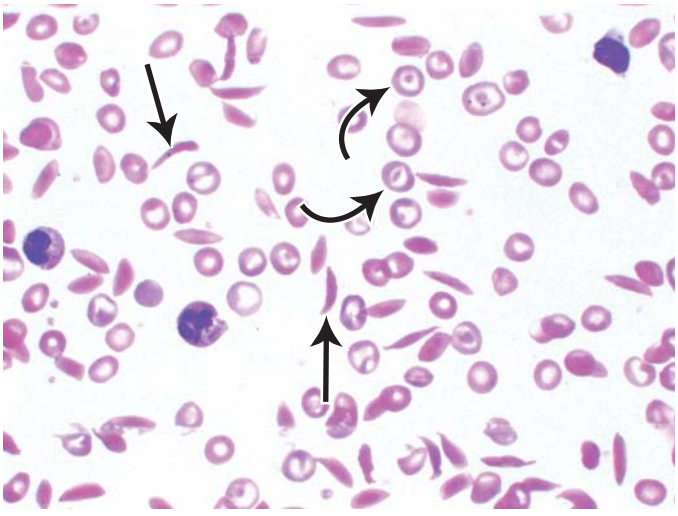

FIGURE 26-20. Sickle cell anemia. Sickled cells (*straight arrows*) and target cells (*curved arrows*) are evident in the blood smear.

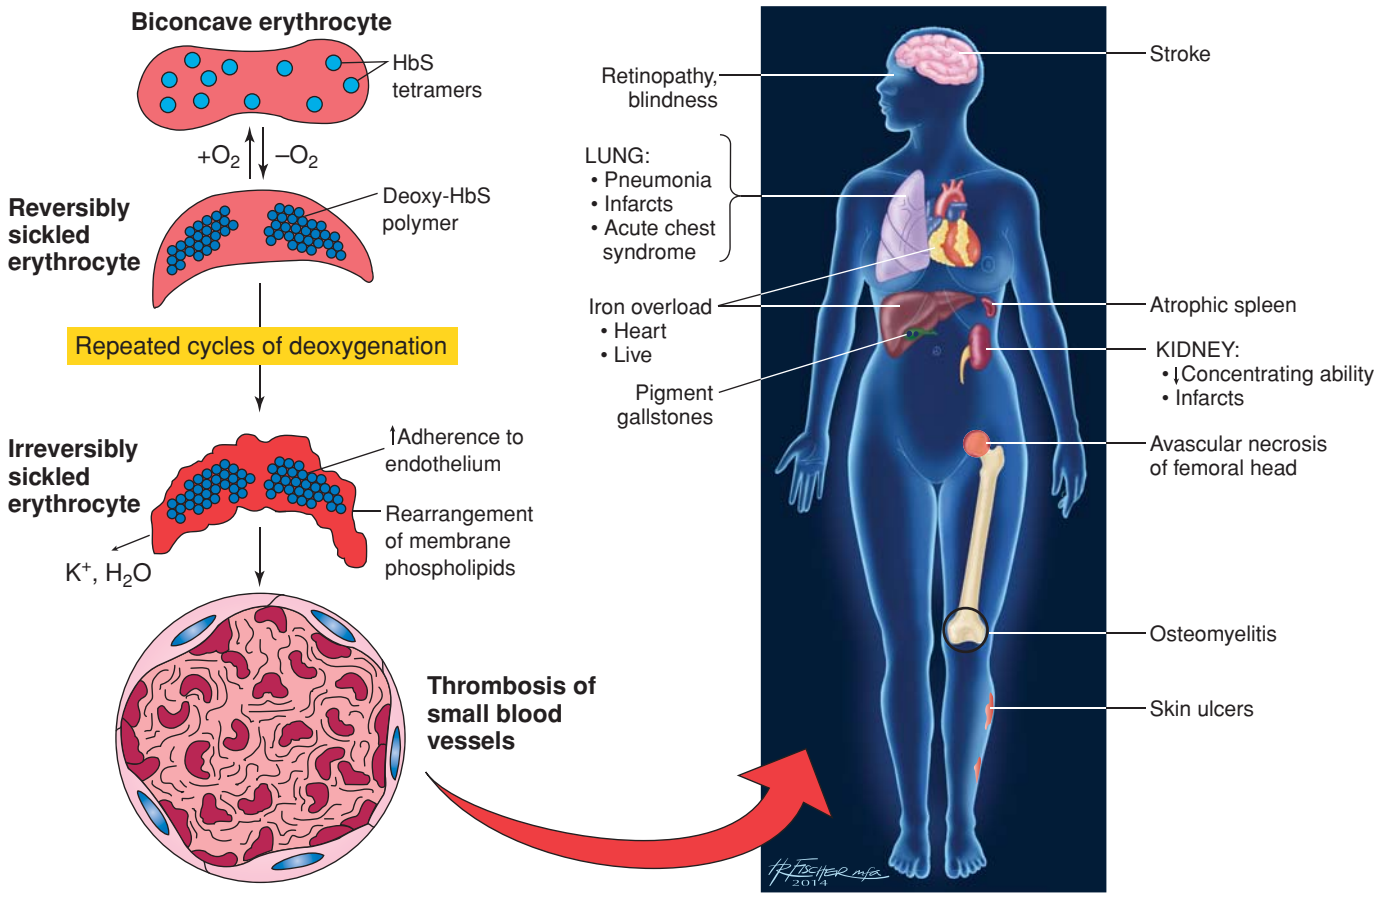

FIGURE 26-21. Pathogenesis of the vascular complications of sickle cell anemia. Substitution of valine for glutamic acid leads to an alteration in the surface charge of the hemoglobin molecule. Upon deoxygenation ($-O_2$), sickle hemoglobin (HbS) tetramers aggregate to form poorly soluble polymers. The erythrocytes change shape from a biconcave disk to a sickle form with the polymerization of HbS. This process is initially reversible upon reoxygenation ($+O_2$), but with repeated cycles of deoxygenation and reoxygenation, the erythrocytes become irreversibly sickled. Irreversibly sickled cells display a rearrangement of phospholipids between the outer and inner monolayers of the cell membrane, in particular an increase in aminophospholipids in the outer leaflet. Potassium (K^+) and water (H_2O) are lost from the cells. The erythrocytes are no longer deformable and are more adherent to endothelial cells, properties that predispose to thrombosis in small blood vessels. The resulting vascular occlusions lead to widespread ischemic complications.

Clinical symptoms first appear in children when synthesis of γ-globin chains declines. This decline is somewhat delayed in homozygous S patients. Although patients suffer from lifelong hemolysis, adaptation occurs over time and most may not require regular transfusions. Instead, the clinical picture is dominated by sequelae of repeated **vaso-occlusive disease**. In an attempt to minimize these complications by decreasing the amount of HgbS in circulation, a chronic exchange transfusion may be necessary. Sickle cell anemia is a systemic disorder and eventually impairs the functions of most organ systems and tissues (Fig. 26-21).

Patients with sickle cell disease develop episodic painful crises, which vary in number. Capillary occlusion leads to ischemia and hypoxic cell injury, which cause severe pain, especially in the chest, abdomen and bones. Painful crises can be triggered by various stimuli (e.g., underlying infection, acidosis or dehydration).

APLASTIC CRISIS: In aplastic crisis, the bone marrow fails to compensate for the high level of red cell loss. Hemoglobin levels drop rapidly, with no reticulocyte response. Parvovirus B19 is the most frequent cause of an aplastic crisis, although other viral and bacterial infections may also cause transient bone marrow suppression.

SEQUESTRATION CRISIS: In this case, sudden pooling of erythrocytes, especially in the spleen, decreases circulating blood volume and lowers hemoglobin levels. The etiology is unclear, but it occurs most often in young children who still have functioning spleens. This complication is followed by hypovolemic shock and is the most common cause of death early in life.

- **Heart:** Chronic demand for increased cardiac output may lead to cardiomegaly and congestive heart failure. In addition, obstruction of coronary microcirculation may cause myocardial ischemia. Myocyte function may also be impaired by excess iron deposition, owing to chronic hemolysis and repeated transfusions.
- **Lungs:** Up to 1/3 of patients with sickle cell anemia may rapidly lose respiratory function, with pulmonary infiltrates on chest radiography. This **acute chest syndrome** may be fatal. Pulmonary infarction may occur, and sickle cell patients are more susceptible to a variety of pulmonary infections.
- **Spleen:** Splenomegaly often occurs in childhood, but repeated splenic infarction leads to functional autosplenectomy. In most adults, only a small fibrous remnant of

the spleen remains. The asplenic state renders the patient susceptible to infections with encapsulated bacteria, especially pneumococcus.

- **Brain:** Patients with sickle cell anemia develop neurologic complications related to vascular obstruction, including transient ischemic attacks, strokes and cerebral hemorrhages. Occlusion of retinal microvasculature may lead to retinal hemorrhage and detachment, proliferative retinopathy and blindness.
- **Kidney:** The hypoxic, acidotic and hypertonic environment in the renal medulla often leads to sickling there. This impairs the inability to form concentrated urine and causes renal infarcts and papillary necrosis. Men may develop priapism, which, if not treated promptly, may lead to permanent erectile dysfunction.
- **Liver:** As in any form of chronic hemolytic anemia, patients with sickle cell anemia have increased levels of unconjugated (indirect) bilirubin, which can predispose to pigmented bilirubin gallstones. Cholelithiasis may lead to cholecystitis and require cholecystectomy. Hepatomegaly and increased hepatic iron deposition are also seen.
- **Extremities:** Cutaneous ulcers over the lower extremities, especially near the ankles, are common and reflect obstruction of dermal capillaries. Children may develop "hand–foot syndrome," with self-limited swelling of the hands and feet because of underlying bone infarcts. Avascular necrosis of the femoral head requires corrective hip surgery. Sickle cell disease is also associated with increased incidence of osteomyelitis, particularly with *Salmonella typhimurium*, possibly because of the underlying impairment in splenic function.

Sickle Cell Trait

Heterozygosity for the HgbS mutation is called sickle cell trait.

PATHOPHYSIOLOGY: In patients with sickle cell trait, the HgbA in their red cells prevents HgbS polymerization, so their erythrocytes do not normally sickle. However, under extreme conditions (e.g., high altitudes, deep-sea diving), their RBCs may sickle. Heterozygotes are clinically asymptomatic, do not develop hemolytic anemia and live normal life spans.

Double Heterozygosity for HgbS and Other Hemoglobinopathies

Some patients with a sickling disorder are actually heterozygous for both HgbS and other abnormal hemoglobins (e.g., HgbC or HgbD), or for thalassemia.

PATHOPHYSIOLOGY: The presence of an additional abnormal hemoglobin or thalassemic gene does not prevent HgbS polymerization, and the clinical expression and severity of disease may be affected. People who are doubly heterozygous may have less frequent crises, higher baseline hemoglobin values, microcytic red cell indices or persistent splenomegaly into adult life.

CLINICAL FEATURES: Double heterozygosity for HgbS and HgbC causes a milder sickle phenotype than does homozygosity for HgbS. These patients have episodic skeletal or abdominal pain. However, they develop a retinopathy that is relatively common and severe. They are also prone to undergo necrosis of their femoral heads. These features probably reflect the high blood viscosity conferred by HgbSC.

Blood smears from hemoglobin SC patients reveal mild reticulocytosis, target cells and relatively few sickled erythrocytes. However, red blood cells with hemoglobin crystals caused by hemoglobin C are seen.

Double heterozygosity for HgbS and β-thalassemia is either Hgb $S\beta^0$ thalassemia, in which β-globin is absent, or Hgb $S\beta^+$ thalassemia, in which β-globin is present but reduced. Hgb $S\beta^0$ thalassemia is clinically similar to sickle cell disease in severity. $S\beta^+$ thalassemia is milder than HgbSC disease.

Hemoglobin C Disease

HgbC disease results from homozygous inheritance of a structurally abnormal hemoglobin, which increases erythrocyte rigidity and causes mild chronic hemolysis.

PATHOPHYSIOLOGY: In HgbC, lysine replaces glutamic acid at the sixth amino acid of β-globin. HgbC precipitates in erythrocyte cytoplasm, leading to cellular dehydration and decreased deformability. When passing through the spleen, the abnormal red cells are removed from the circulation, causing mild anemia and splenomegaly. HgbC has reduced oxygen affinity, so tissue oxygen delivery is increased. This mitigates the severity of disease. HgbC is mostly found in the same populations as HgbS, although it occurs less commonly.

PATHOLOGY: Homozygosity for HgbC disease (CC) causes a mild normocytic anemia. Hemoglobin may be unevenly distributed within red cells, and dense, rhomboidal crystals (precipitated HgbC) occur in some erythrocytes. Hemoglobin electrophoresis reveals no HgbA and greater than 90% HgbC.

Two to 3% of American blacks are heterozygous for HgbC and are asymptomatic (HgbC trait). In such people, about 40% of hemoglobin is HgbC. Red cell morphology is normal, except for some target cells.

Hemoglobin E Disease

HgbE disease is a result of homozygosity for a structurally abnormal hemoglobin, leading to a thalassemia-like defect that is associated with mild chronic hemolysis.

MOLECULAR PATHOGENESIS: In hemoglobin E, lysine substitutes for glutamic acid at position 26 of the β-globin chain. This is at a splice site in the gene, so the mutation results in a structurally abnormal molecule, decreased gene transcription and unstable β-globin messenger RNA (mRNA). The latter defects diminish synthesis of HgbE, creating a situation like that seen in thalassemia. HgbE is relatively unstable and may precipitate in the cell, leading to hemolysis. HgbE is most prevalent in Southeast Asia and globally is second in incidence only to HgbS. HgbE may help protect against malaria.

PATHOLOGY: Patients homozygous for HgbE (EE) have a mild microcytic anemia. MCV is decreased, and there is often erythrocytosis because of the thalassemia-like component. Their RBCs are microcytic and hypochromic and include target cells. More than 90% of hemoglobin is HgbE.

Other Hemoglobinopathies

Several hundred additional known hemoglobin variants result from mutations in α- or β-globin genes. These mutations may lead to structural abnormalities or to a functional derangement of the hemoglobin molecule.

PATHOPHYSIOLOGY: Some mutations alter hemoglobin tertiary structure, destabilizing it and causing it to precipitate in the cytoplasm. As a group, these are **unstable hemoglobins** and are often named after the place where they were first discovered (e.g., hemoglobin Köln). Unstable hemoglobins precipitate and form Heinz bodies within erythrocytes that can be visualized with supravital staining. Heinz bodies bind to cell membranes, increasing their rigidity and leading to mild chronic hemolysis. Patients may suffer jaundice and splenomegaly.

Other hemoglobin mutations cause **abnormal oxygen affinity**. **Increased oxygen affinity** decreases tissue oxygen delivery. Resulting hypoxia elicits increased EPO production and bone marrow erythroid hyperplasia. This, in turn, causes erythrocytosis. Patients are mostly asymptomatic, but some may have symptoms related to hyperviscosity. Abnormal hemoglobins with **decreased oxygen affinity** readily release oxygen in tissues. EPO levels are low, and most patients have mild anemia. Because of increased deoxyhemoglobin, patients may appear cyanotic.

Immune and Autoimmune Hemolytic Anemias

In immune hemolytic anemias, red cell destruction (hemolysis) is caused by antibodies against erythrocyte surface antigens. The red cells themselves are intrinsically normal but are targets for immune-mediated attack. Immune hemolytic anemia can reflect auto- or alloantibodies, and the site of hemolysis may be **extravascular** or **intravascular.** The most common cause of anemia in the elderly is autoimmune hemolytic anemia associated with chronic lymphocytic leukemia and small lymphocytic lymphoma.

In autoimmune hemolytic anemia (AIHA), there are autoantibodies against red cells. Autoantibodies can be classified as either **warm** or **cold antibodies**.

Warm Antibody Autoimmune Hemolytic Anemia

PATHOPHYSIOLOGY: Warm autoantibodies optimally bind their antigens at 37°C and account for 80% of cases of AIHA. They are usually immunoglobulin G (IgG) directed against erythrocyte membrane antigens, such as **Rh group proteins**. They do not bind complement, but "coat" red blood cells, and cause these RBCs to be removed by macrophages of the reticuloendothelial system (extravascular hemolysis), mainly in the spleen. Splenic macrophages have Fc receptors that recognize erythrocyte-bound warm antibodies and remove pieces of the membrane with attached antibody. Progressive membrane loss leads to formation of spherocytes, which ultimately undergo hemolysis.

Warm antibody AIHA affects women more than men. Half of cases are idiopathic. In the remaining cases, the antibody reflects an underlying condition (e.g., infection, collagen vascular disease, lymphoproliferative disorders and drug reactions).

Drug-induced warm antibodies arise by several different mechanisms (see Chapter 4). In the **hapten** mechanism, a drug such as penicillin attaches to RBC surfaces. With this modification, the red cell–drug complex elicits antibodies, some of which react with the erythrocyte itself. In the **immune complex** mechanism, a drug (like quinidine) reacts with specific circulating antibody to form immune complexes, which then bind to red cell membranes. In the **autoantibody** mechanism, a drug (e.g., α-methyldopa) elicits antibodies that cross-react with red cell membrane components. In hapten and immune-complex models, the drug is required for hemolysis, while in the autoantibody model, hemolysis occurs in the absence of the initiating drug.

PATHOLOGY AND CLINICAL FEATURES: Warm antibody AIHA is associated with normocytic or occasionally macrocytic anemia, with spherocytes and polychromasia. Extravascular hemolysis leads to increased serum bilirubin, mostly unconjugated bilirubin; hemoglobinemia (free hemoglobin in the blood) and hemoglobinuria (hemoglobin in the urine) are uncommon. The direct antiglobulin (Coombs) test is usually positive and helps to distinguish immune from nonimmune spherocytosis. In the direct Coombs test, a patient's red cells are incubated with antihuman Ig. Agglutination indicates antibody is present on the cell surface. Warm antibody AIHA is treated with immunosuppression. Refractory cases may require splenectomy or transfusions.

Cold Antibody Autoimmune Hemolytic Anemia

Cold antibodies have maximal reactivity at 4°C. Some 20% of cases of AIHA are caused by cold IgM or IgG antibodies, which occur as cold agglutinins or hemolysins.

PATHOPHYSIOLOGY: Cold agglutinins may be idiopathic or may be due to an underlying condition, mostly infections (Epstein-Barr virus [EBV], *Mycoplasma*) or lymphoproliferative disorders. Cold agglutinins are mostly IgMs directed against I/i antigens on red cells. At cooler temperatures in the peripheral circulation, these antibodies may bind and agglutinate red cells (Fig. 26-22). They may fix, then activate, complement to a variable extent.

The entire complement cascade may be activated (through the membrane attack complex). This process leads to intravascular hemolysis, resulting in hemoglobinemia, hemoglobinuria and decreased haptoglobin levels (free hemoglobin released into the circulation binds haptoglobin, which causes a decline in haptoglobin).

Alternatively, complement may only be activated through C3. In that case, complement-coated red cells are removed in the liver, because Kupffer cells have more complement receptors than do splenic macrophages.

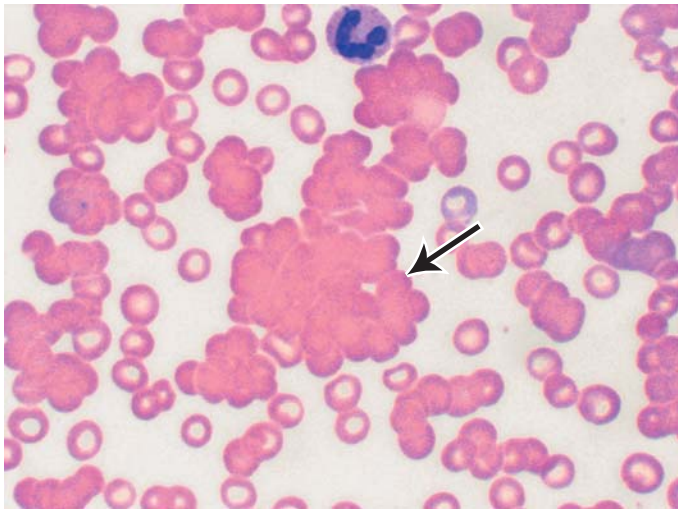

FIGURE 26-22. Red blood cell clumping (agglutination) caused by cold agglutinins (*arrow*). Note that this is not the same phenomenon as rouleaux formation.

PATHOLOGY AND CLINICAL FEATURES: Cold agglutinins often are activated when blood cools to room temperature, and erythrocytes agglutinate in blood smears (Fig. 26-22). Agglutination leads to falsely low RBC counts and hematocrit (Hct), and falsely elevated MCV and MCHC. Warming a blood sample to 37°C before analysis corrects the spurious results. The direct Coombs test is positive but usually only for the presence of complement on red cells. Significant hemolysis is uncommon with cold agglutinins and patients are more likely to develop peripheral vascular symptoms (Raynaud phenomenon; see Chapter 11), owing to red cell agglutination with cold exposure.

Cold Hemolysin Disease (Paroxysmal Cold Hemoglobinuria)

PATHOPHYSIOLOGY: Cold hemolysins (Donath-Landsteiner antibodies) are usually biphasic IgGs directed against P antigens on red cells. Cold hemolysins have biphasic activity and rarely cause AIHA. The antibody binds to erythrocytes at low temperatures and fixes complement, but intravascular hemolysis does not occur at these temperatures. Because the antibody is IgG, red cells do not agglutinate. Upon warming to 37°C, the cold hemolysin remains attached, complement is activated and intravascular hemolysis occurs.

The clinical syndrome caused by cold hemolysins is **paroxysmal cold hemoglobinuria (PCH)**. PCH most often follows viral illness. Immunosuppressive therapy and splenectomy are usually ineffective. Cold avoidance and supportive therapy such as RBC transfusions are required.

PATHOLOGY: Patients with PCH may develop severe anemia, decreased haptoglobin levels and hemoglobinuria due to intravascular hemolysis. The direct Coombs test is positive for complement but may be negative for IgG, since cold hemolysins may readily dissociate from red cells in vitro.

Hemolytic Transfusion Reactions

An **immediate hemolytic transfusion** reaction occurs when a patient with preformed alloantibodies receives grossly incompatible blood, usually because of a clerical error. Massive hemolysis of the transfused blood may cause severe complications, including hypotension, renal failure and death. Hemolytic transfusion reaction and hemolytic disease in the newborn (see below, Chapter 6) are examples of **alloimmune hemolytic anemia,** in which alloantibodies cause destruction of red cells.

Delayed hemolytic transfusion reactions usually involve antibodies to minor red cell antigens. After a first exposure to such antigens, antibody levels rise, but then may fall to become undetectable by routine pretransfusion screening. Subsequent reexposure to the offending antigen elicits an anamnestic antibody response; hemolysis occurs several days later. Delayed hemolytic transfusion reactions are usually less severe than immediate reactions and may be clinically undetectable. In both types of hemolytic transfusion reactions, the direct antiglobulin test is positive.

Hemolytic Disease of the Newborn

Hemolytic disease of the newborn (HDN) reflects incompatibility of blood types between a mother and her developing fetus; the mother lacks an antigen present on fetal RBCs. Maternal IgG alloantibodies can cross the placenta and cause hemolysis of fetal erythrocytes. Erythroblastosis is visible in peripheral blood smears (Fig. 26-23). Erythroblasts (immature red blood cells) are released from the fetal bone marrow in an effort to compensate for the RBC loss. HDN antibodies are mostly directed against ABO or Rh antigens.

With ABO-type HDN, the mother is type O and the fetus is usually type A. Naturally occurring maternal anti-A antibodies cause hemolysis in the fetus. No prior exposure through pregnancy or transfusion is required for hemolysis to develop. The anemia associated with ABO incompatibility is usually mild. Affected babies develop hyperbilirubinemia, spherocytosis and a positive direct antiglobulin test.

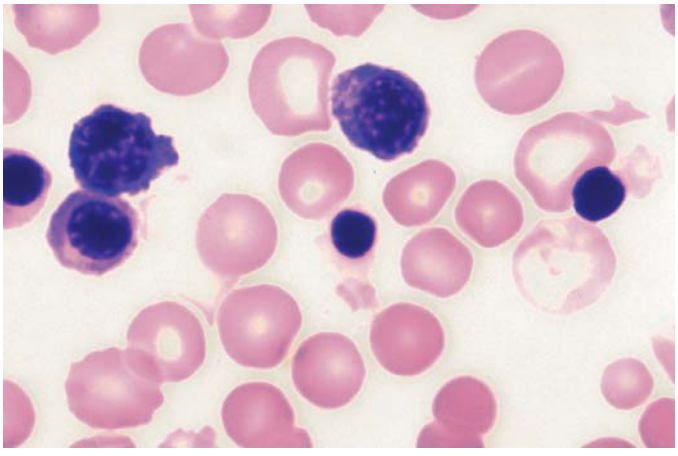

FIGURE 26-23. Hemolytic disease of the newborn (HDN). The presence of nucleated red blood cells in the peripheral blood is abnormal. They are often present in various types of hemolytic disorders, but are particularly numerous in HDN.

With Rh-type HDN, the mother is Rh negative and the fetus is Rh positive. The D antigen is most frequently involved, although minor Rh antigens can also cause disease. Prior maternal exposure occurs via previous pregnancy or transfusion. Disease severity varies, but hemolysis in Rh incompatibility is generally more significant than in ABO-type HDN. Severely affected fetuses may develop **hydrops fetalis,** with heart failure, generalized edema, ascites and intrauterine death (see Chapter 6). Fortunately, today most cases of D-related HDN are prevented by passive immunization of Rh-negative mothers during pregnancy with injections of Rh immune globulin. Laboratory findings are similar to those described above for ABO HDN.

Nonimmune Hemolytic Anemias

In nonimmune hemolytic anemias, factors other than antibodies to red cell antigens destroy RBCs (e.g., red cell fragmentation syndromes and "march" hemoglobinuria).

Mechanical Red Cell Fragmentation Syndromes (Microangiopathic Hemolytic Anemias)

In red cell fragmentation syndromes, intrinsically normal erythrocytes are damaged mechanically as they circulate in the blood (intravascular hemolysis).

ETIOLOGIC FACTORS: In **thrombotic microangiopathic** hemolytic anemia, red cells are fragmented mechanically either by contact with an abnormal surface (e.g., prosthetic heart valve, synthetic vascular graft) or by altered small blood vessel endothelial surfaces associated with microthrombosis, fibrin deposition and platelet aggregation. As RBCs travel through such damaged vessels, these fibrin meshworks cause them to fragment (Fig. 26-7). Classic examples of microangiopathic hemolysis include **disseminated intravascular coagulation** (DIC), **thrombotic thrombocytopenic purpura** (TTP) and hemolytic–uremic syndrome (HUS). Altered blood flow, as occurs in malignant hypertension or vasculitis, may also lead to mechanical fragmentation of erythrocytes.

Long-distance running or walking ("march hemoglobinuria") or prolonged vigorous exercise can cause repetitive trauma to red cells and lead to hemolysis.

PATHOLOGY: Laboratory findings in microangiopathic hemolytic anemia include a mild to moderate microcytic or normochromic anemia with appropriate reticulocyte response. Blood smears show fragmented erythrocytes (schistocytes) and polychromasia (Fig. 26-24). Abnormalities in coagulation and thrombocytopenia characterize DIC, while thrombocytopenia alone is seen in cases of TTP (see below).

Hypersplenism

A mild hemolytic anemia may develop in patients with hypersplenism and congestive splenomegaly. Splenomegaly causes pooling of blood and delayed transit of blood cells through the splenic circulation. Prolonged exposure of red cells to splenic macrophages may lead to their premature destruction.

PATHOLOGY AND CLINICAL FEATURES: The anemia of hypersplenism shows no specific morphologic features. Leukopenia and thrombocytopenia are common and are caused by sequestration of these elements in the enlarged spleen, not destruction. Bone marrow shows compensatory hyperplasia of all cell lines.

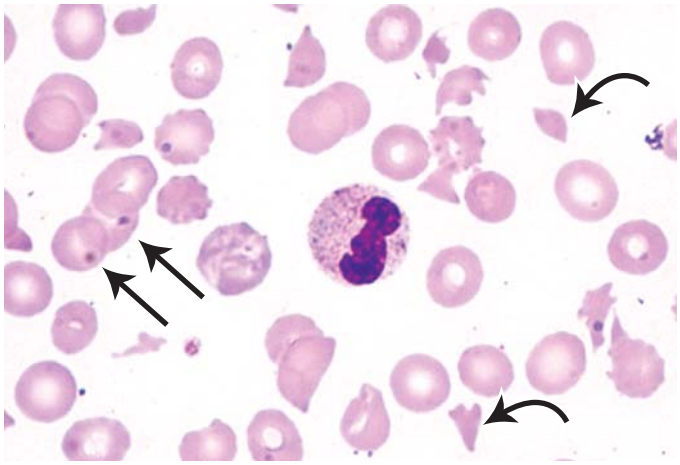

FIGURE 26-24. Microangiopathic hemolytic anemia (MAHA). Irregular, fragmented erythrocytes (schistocytes, *curved arrows*) are seen in the blood smear of a patient with disseminated intravascular coagulation. Howell-Jolly bodies are also present (*straight arrows*).

Other Hemolytic Anemias

Thermal burns lead to intravascular RBC hemolysis. Normal red cell membranes are disrupted and fragmented at temperatures over 49°C. Blood smears show schistocytes, microspherocytes and polychromasia. Direct Coombs tests are negative.

Infection can cause both pancytopenia and isolated anemia. Several **infectious microorganisms** specifically parasitize erythrocytes and can cause hemolysis. All species of *Plasmodium* have an intraerythrocytic life cycle, which causes RBC lysis when it is done (see Chapter 9). Infected red cells are also removed from circulation by splenic macrophages. *Babesiosis,* found in more temperate climates (northeastern United States), is also associated with hemolysis after the intraerythrocytic life cycle is over. In both cases, blood smears reveal the parasites within red cells.

POLYCYTHEMIA

Polycythemia (erythrocytosis) is an increase in RBC mass.

ETIOLOGIC FACTORS: Polycythemia is defined arbitrarily as an Hct greater than 54% in men and greater than 47% in women. Blood viscosity increases exponentially at Hcts over 50%, and cardiac function and peripheral blood flow may be impaired. If the Hct exceeds 60%, blood flow may be so compromised as to cause tissue hypoxia.

Polycythemia can be further divided on the basis of overall red cell mass into relative and absolute categories.

- **Relative polycythemia** occurs in dehydration. Plasma volume is decreased, but red cell mass is normal. This is sometimes called Gaisböck syndrome, or spurious polycythemia: it is not a true increase in red cell mass, but rather a reflection of altered total blood volume.

- **Absolute polycythemia** is a true increase in red cell mass. It can be primary or secondary.
  - **Primary polycythemia,** or **polycythemia vera (PV),** is autonomous, EPO-independent proliferation of erythroid cells caused by an acquired, clonal, HSC disorder. PV is a chronic myeloproliferative disorder (see below).
  - **Secondary polycythemia** arises from EPO stimulation of erythropoiesis, usually to compensate for general tissue hypoxia. Tissue hypoxia may arise from chronic lung disease, cigarette smoking, residence at high altitudes, a right-to-left cardiac shunt or an abnormal hemoglobin with high oxygen affinity.

    Secondary polycythemia can also occur under certain circumstances unrelated to tissue hypoxia. Some tumors secrete ectopic EPO as a paraneoplastic syndrome (see below), particularly renal cell carcinoma, hepatocellular carcinoma, cerebellar hemangioblastoma and uterine leiomyoma. Some nonneoplastic conditions of the kidney may cause secondary polycythemia. Renal cysts or hydronephrosis may exert direct pressure on the kidney, leading to localized hypoxia and increasing EPO production. Some athletes use EPO to enhance their maximal exercise capacity.

Platelets and Hemostasis

NORMAL HEMOSTASIS

Normal hemostasis requires that platelets, endothelial cells, coagulation factors and endogenous anticoagulants and thrombolytics maintain a resting nonthrombotic state but that they can respond instantly to vascular damage and form a clot. After blood vessel injury, platelets adhere to the vascular endothelium to form a hemostatic plug. Activated platelets recruit and activate additional platelets to form a **platelet aggregate** and a **fibrin clot**. Fibrin stabilizes platelet aggregates after coagulation is activated.

Platelets Develop from Hematopoietic Stem Cells by Thrombopoiesis

A platelet count is 150–350 × 10^3/μL. To maintain this level requires continued proliferation, differentiation and release into the blood. Platelets are derived from megakaryocytes via the process of proplatelet formation and fragmentation. Thrombopoiesis requires the marrow microenvironment, plus stimulation by TPO. TPO is produced by the liver and binds the TPO receptor, c-Mpl, to stimulate megakaryocyte proliferation and differentiation. Mature megakaryocytes undergo proplatelet formation and fragmentation to release 1000–4000 anucleate platelets.

Morphology and Function

Platelets are small discoid cells, 2–3 μm in diameter (Fig. 26-25), with a life span of about 10 days. On Wright-stained smears they are pale blue with faint pink granules. They contain mitochondria, glycogen particles, dense granules and α granules. Dense granules contain adenosine diphosphate (ADP), a potent aggregating molecule; adenosine triphosphate (ATP); calcium; histamine; serotonin; and epinephrine. α Granules express the adhesive proteins P-selectin on their membranes and contain fibrinogen, von Willebrand factor (vWF), fibronectin and thrombospondin, as well as the chemokines platelet factor 4, neutrophil-activating peptide 2, platelet-derived growth factor (PDGF) and transforming growth factor-α (TGF-α).

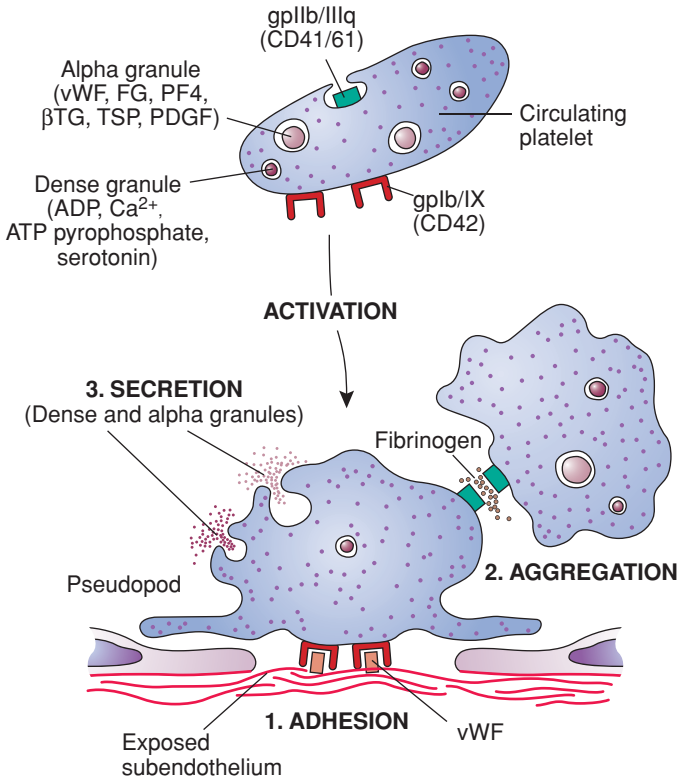

FIGURE 26-25. Platelet activation involves three overlapping mechanisms. 1. Adhesion to the exposed subendothelium is mediated by the binding of von Willebrand factor (vWF) to glycoprotein (Gp) Ib/IX (CD42) and is the initiation signal for activation. **2.** Exposure of Gp IIb/IIIa (CD41/61) to the fibrinogen (FG) receptor on the platelet surface allows for platelet aggregation. **3.** At the same time, platelets secrete their granule contents, which facilitates further activation. α-Granules contain vWF, fibrinogen, platelet factor 4 (PF4), thromboglobulin (TG), thrombospondin (TSP) and platelet-derived growth factor (PDGF).

Platelet Activation

When vascular endothelium is disrupted, platelets respond by creating a platelet plug to minimize bleeding. After contact with the extracellular matrix, particularly type I collagen, platelets undergo a sequence of steps of platelet activation (Fig. 26-25):

1. **Platelets adhere** to subendothelial matrix proteins with specific platelet surface glycoproteins (Gps). Major adhesive ligands include collagen (via the Gp Ia/IIa [$\alpha_2\beta_1$ integrin] and Gp VI receptors) and vWF (via Gp Ib/IX).
2. **Shape change,** from discoid to spherical to stellate, follows initial adhesion.
3. **Secretion of platelet granule contents from both the dense granules and α granules** results in the release of ADP, epinephrine, calcium, vWF and PDGF.

4. **Thromboxane A_2** is generated by cyclooxygenase 1.
5. **Membrane changes** expose P-selectin and procoagulant anionic phospholipids such as phosphatidylserine.
6. **Aggregation of platelets** occurs by fibrinogen receptor Gp IIb/IIIa cross-linking.

Each of these functional steps has specific consequences. Initial adhesion signals platelet activation. Secreted granule contents and thromboxane A_2 provide positive feedback to activate additional platelets via their surface receptors. The stellate shape projects the procoagulant membrane surface and activated Gp IIb/IIIa/fibrinogen to the site of interaction with coagulation factors and other platelets, respectively. ***Thus, the surface of activated platelets is an optimal environment for propagating assembly of the coagulation–factor complex, including the prothrombinase complex. The resulting thrombin has many consequences, particularly further platelet activation.*** Finally, P-selectin participates in binding leukocytes and localizing them to participate in healing, together with substances secreted by platelets such as PDGF. ***As a result of these concerted steps, activated platelets form a strong primary plug and then an aggregate within a platelet–fibrin meshwork, which stops bleeding and begins healing.***

Activation of the Coagulation Cascade Completes Blood Clot Formation

Platelets and leukocytes circulate in an inactive state. Similarly, coagulation factors are present as inactive zymogen forms. Activation of platelets and coagulation factors is concerted and highly constrained in space and time, to prevent clots from spreading through the circulation. The localization of coagulation–factor complexes to activated surfaces of blood cells, especially platelets, accelerates activation of coagulation factors and avoids the many anticoagulant factors in plasma.

Activation of the coagulation cascade by damaged tissue exposes tissue factor and culminates in conversion of prothrombin (factor II) to thrombin (factor IIa), and generation of fibrin from fibrinogen (Fig. 26-26). Thrombin has additional roles. It activates both platelets and factors that sustain coagulation (see Chapter 16).

There are three essential procoagulant complexes and one anticoagulant complex (Figs. 26-26 and 26-27). ***Generally, each active enzyme in the cascade is assisted by a cofactor and localized to a phospholipid surface (PL).***

PROCOAGULANT PATHWAYS: Factor Xa, together with its cofactor Va (Xa/Va complex), cleaves factor II (prothrombin) to IIa (thrombin). There are two complexes that activate factor X, the so-called Xase complexes.

1. The complex of **tissue factor (TF) and factor VIIa** initiates coagulation. Its activation is controlled by exposure to subendothelial cells or activated monocytes and endothelial cells. Microparticles derived from activated leukocytes and endothelial cells contribute to a pool of circulating TFs that participates in hemostasis and thrombosis. TF/VIIa/PL initiates factor X activation but is then rapidly shut off by **TF pathway inhibitor (TFPI)** (Fig. 26-27). The

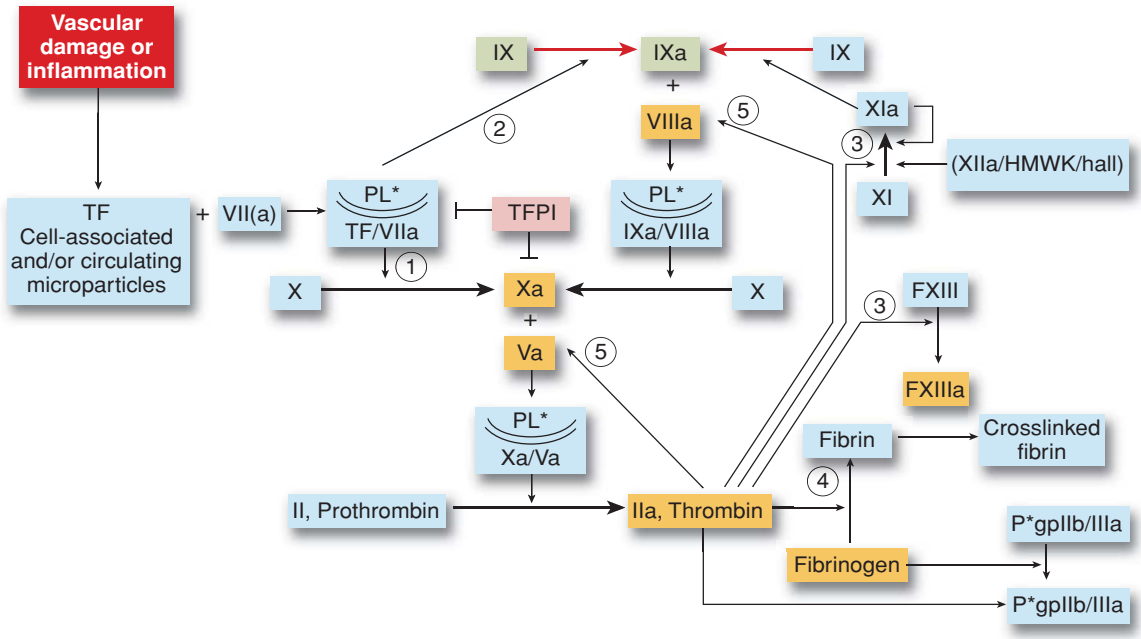

FIGURE 26-26. Hemostasis and thrombosis. Following injury to a vessel, rupture of an atherosclerotic plaque or the presence of major inflammation, coagulation is initiated when tissue factor (TF) binds to circulating factor VII, a small proportion of which is activated (VIIa). TF is located on cells (subendothelial or activated endothelial cells or leukocytes) or circulating microparticles. The TF/VIIa complex is activated by localizing to an activated phospholipid surface (PL*) such as that provided by activated platelets. TF/VIIa activates factor X to form Xa (*1*) and IX to form IXa (*2*). However, TF pathway inhibitor (TFPI) inhibits both (*1*) and (*2*). Sustained amplification is achieved through the actions of factors XI, IX and VIII. Factor XI is activated through the small amount of initial thrombin formed and, to a limited extent, by autoactivation or factor XIIa. Cofactors V and VIII, when activated by thrombin, form complexes with X (Xa/Va) and IX (IXa/VIIIa), respectively, on activated PL surfaces. Note the central and multiple roles for thrombin (*4*), which converts fibrinogen to fibrin, activates cofactors V and VIII (*5*), activates factors XI and XIII (*3*) and activates platelets. Fibrinogen binds to the Gp IIb/IIIa integrin receptor on activated platelets (P*). Note the extensive control in time and space of these concerted surface reactions. The combined result is the platelet–fibrin thrombus.

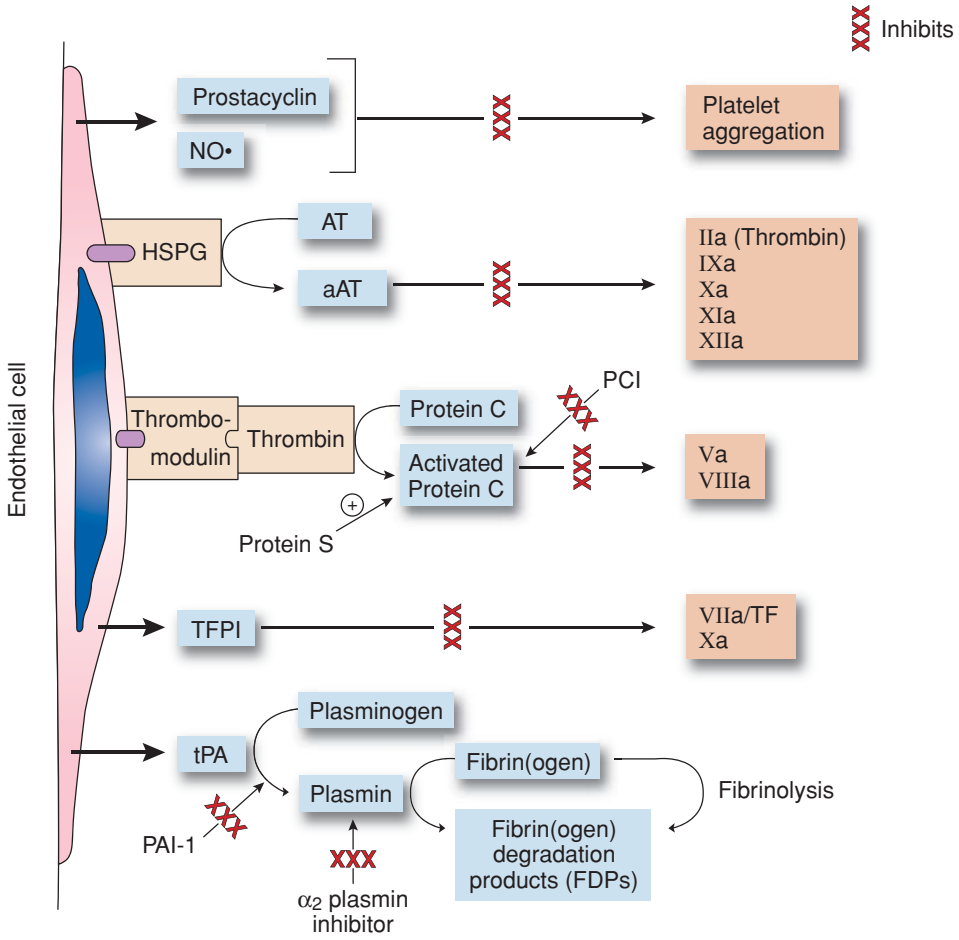

FIGURE 26-27. The role of endothelium in anticoagulation, platelet inhibition and thrombolysis. The endothelial cell plays a central role in the inhibition of various components of the clotting mechanism. Heparan sulfate proteoglycan potentiates the activation of antithrombin (AT) 15-fold. Thrombomodulin stimulates the activation of protein C by thrombin 30-fold. *HSPG* = heparan sulfate proteoglycan; *NO•* = nitric oxide; *PAI-I* = plasminogen activator inhibitor-I; *PCI* = protein C inhibitor; *tPA* = tissue plasminogen activator.

TF/VIIa/PL complex also cleaves and thus activates a small amount of factor IX.

2. The **IXa/VIIIa/PL complex** also initiates factor X activation, with ongoing activation of factor IX by XIa.

The coagulation pathways are presented in detail in Chapter 16.

Note that thrombin activates the Xase complexes by activating factors XI, VIII and V. ***In summary, the three procoagulant complexes are the prothrombinase complex, Xa/Va/PL, and the two Xase complexes, TF/VIIa/PL and IXa/VIIIa/PL.***

ANTICOAGULANT PATHWAYS: An anticoagulant complex (α-thrombin–thrombomodulin) activates protein C (Fig. 26-27). The **protein C_{ase} complex** contains thrombin and thrombomodulin in endothelial cell plasma membranes. Endothelial protein C receptor also participates in forming this cell surface complex. Activated protein C, with its cofactor protein S, inactivates the key cofactors VIIIa and Va, thus limiting further generation of Xa and IIa (see Chapter 16).

Antithrombin III inhibits thrombin activity. Antithrombin III also cleaves activated factors IXa, Xa, XIa and XIIa. In vivo this effect is accentuated by heparan sulfate proteoglycans and, most dramatically, by therapeutic administration of heparin.

Thrombolysis Is Mediated by Plasminogen Activation

After a thrombus is firmly established, its growth is curtailed further by removal of platelet-activating factors and coagulation proteins. Endothelial cells near the thrombus produce plasminogen activators, which activate circulating plasminogen to plasmin and initiate thrombolysis (i.e., **fibrinolysis**). There are two major plasminogen activators, **tissue plasminogen activator** (t-PA) and **urokinase-type plasminogen activator** (u-PA). Together, the protease plasmin and the activity of macrophages dissolve the thrombus. Plasmin targets specific sites in the fibrin meshwork for degradation, helping to localize its activity to sites where it is needed (see Chapter 16).

The factors that limit clot formation are themselves limited in turn. Several naturally occurring inhibitors do the honors. Plasminogen activator inhibitor-I (PAI-I), antiplasmin and thrombin-activatable fibrinolysis inhibitor (TAFI) block plasminogen cleavage to plasmin and plasmin action.

Thrombolysis coincides with the start of wound repair (see Chapter 7). The latter involves fibroblasts and endothelial cells migrating and proliferating, secretion of new extracellular matrix and restoration of blood vessel patency. Angiogenesis (i.e., new blood vessels budding from existing ones) occurs in the setting of tissue ischemia or damage. Many products of coagulation and fibrinolysis are potent angiogenic agents.

Blood Vessels and Endothelial Cells Interact with Platelets

The above discussion highlights the many roles of endothelial cells in regulating platelets and coagulation (Fig. 26-27).

Endothelial cells rest on a basement membrane containing collagens, elastin, laminin, fibronectin, vWF and other structural and adhesive proteins. Subendothelial cells are a potent source of TF. When exposed, the intimal matrix is intensely thrombogenic. Its adhesive proteins bind corresponding platelet membrane glycoprotein receptors, which then adhere to the exposed matrix. TF binds circulating activated factor VIIa to activate factors X and IX (Fig. 26-26).

The endothelium provides a smooth, nonthrombogenic surface. It synthesizes anticoagulant molecules and prevents unstimulated platelets from adhering to, or penetrating, the endothelial barrier. Endothelial cells also synthesize prostacyclin, a potent vasodilator that also inhibits platelet activation. Nitric oxide (NO) exerts similar effects. These actions prevent clots from forming until injury to the endothelium exposes subendothelial tissue (see Chapters 2 and 16).

HEMOSTATIC DISORDERS

Defects in hemostasis occur when the balance of procoagulant and anticoagulant activities tilts toward one or the other. Such defects are either **hemostatic** disorders or **thrombotic** disorders. If hemostasis fails to restore an injured vessel's integrity, the result is **bleeding**. Inability to maintain the fluidity of blood causes **thrombosis**.

Clinical manifestations of hemorrhage associated with disorders of each component of the hemostatic system tend to be distinctive (Table 26-6). Platelet abnormalities result in both **petechiae** and purpuric hemorrhages in the skin and mucous membranes. Deficiencies of coagulation factors lead to hemorrhage into muscles, viscera and joint spaces. Disorders of the blood vessels usually cause **purpura**.

TABLE 26-6
PRINCIPAL CAUSES OF BLEEDING

Vascular Disorders
Senile purpura
Purpura simplex
Glucocorticoid excess
Dysproteinemias
Allergic (Henoch-Schönlein) purpura
Hereditary hemorrhagic telangiectasia
Platelet Abnormalities
Thrombocytopenia (see Table 26-7)
Qualitative disorders
Inherited
Glycoprotein IIb/IIIa deficiency (Glanzmann thrombasthenia)
Glycoprotein Ib/IX/V deficiency (Bernard-Soulier syndrome)
Storage pool diseases (α and δ)
Abnormal arachidonic acid metabolism
Acquired
Uremia
Drugs
Cardiopulmonary bypass
Myeloproliferative disorders
Liver disease
Coagulation Factor Deficiencies
Inherited
von Willebrand disease
Hemophilia A
Hemophilia B
Acquired
Vitamin K deficiency/antagonism
Liver disease
Disseminated intravascular coagulation

Hemostatic Disorders of Blood Vessels Reflect Dysfunction of Vascular or Extravascular Tissues

Dysfunction of the extravascular or vascular tissues may cause hemorrhages ranging from cosmetic blemishes to life-threatening blood loss.

Extravascular Dysfunction

SENILE PURPURA: The most common disorder in extravascular dysfunction, senile purpura, is age-related atrophy of supporting connective tissues. Senile purpura is associated with superficial, sharply demarcated, persistent purpuric spots on the forearms and other sun-exposed areas.

PURPURA SIMPLEX: A similar type of purpura occurs principally in women during menses. Purpura simplex occurs in the deep dermis and resolves quickly.

SCURVY: Vitamin C deficiency (scurvy) impairs collagen synthesis and leads to purpura (see Chapter 8). Perifollicular hemorrhages are characteristic.

Vascular Dysfunction

Deposition of immunoglobulin fragments in vessel walls occurs in **amyloidosis** (see Chapter 15), **cryoglobulinemia** and **other paraproteinemias** and can weaken vessel walls and cause purpura. Certain **arteritides** also injure vessel walls and may lead to hemorrhage (see Chapter 16).

Hereditary Hemorrhagic Telangiectasia (Rendu-Osler-Weber Syndrome)

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disorder of blood vessel walls (venules and capillaries) in which arteriovenous malformations (AVMs) and telangiectases (dilated, tortuous small blood vessels) form in solid organs, mucous membranes and dermis. The incidence is 1–2 individuals per 10,000.

MOLECULAR PATHOGENESIS: The underlying defect is dilation and thinning of vessel walls due to inadequate elastic tissue and smooth muscle. The disorder is caused by mutations in TGF-β family members, endoglin (*ENG*) or an activin receptor–like kinase 1 (*ALK1*).

CLINICAL FEATURES: At first, telangiectasias are punctate reddish spots on the lips and nose, up to 0.5 cm in diameter. They can remain as such or progress to arteriovenous malformations or aneurysmal dilations throughout the body. Patients with HHT have recurrent hemorrhages. These may occur spontaneously or after trivial trauma. As a consequence, patients also often are anemic. Bleeding may occur at the site of any lesion, but over 80% of patients have recurrent epistaxis, beginning at an early age. Later in life, gastrointestinal hemorrhage may be the dominant symptom. Arteriovenous fistulas in the lungs, brain and retina may lead to hemorrhage or clinically significant shunting of blood. Recurrent bleeding may limit patients' activities, but death from exsanguination is rare.

Allergic Purpura (Henoch-Schönlein Purpura)

Allergic purpura is a vascular disease that results from immunologic damage to blood vessel walls (see Chapter 22). In children, it often follows viral infections and is self-limited. In adults, it often reflects exposure to a variety of drugs and may be chronic.

PATHOLOGY: Henoch-Schönlein purpura is characterized by **leukocytoclastic vasculitis,** with perivascular infiltration of neutrophils and eosinophils, fibrinoid necrosis of vessel walls and platelet plugs in vascular lumens. IgA and complement complexes circulate in the blood and often deposit in vessel walls. Purpuric spots often accompany raised urticarial lesions. Cramps and bleeding indicate gastrointestinal involvement. If kidneys are affected, renal failure may ensue.

Platelet Disorders May Result from Insufficient Production, Excessive Destruction or Impaired Platelet Function

Patients may have histories of easy bruising; mucocutaneous bleeding, including gingival bleeding, epistaxis and menorrhagia; or life-threatening bleeds into the gastrointestinal (GI) tract, genitourinary tract and brain. Petechiae are characteristic of platelet disorders but may also accompany vascular diseases. They are nonblanching, red lesions less than 2 mm in diameter. They usually occur in the legs and dependent parts of the body, on the buccal mucosal and soft palate and at pressure points (waistband, wristwatch band). Platelet disorders reflect:

1. Decreased production
2. Increased destruction
3. Impaired function

Thrombocytopenia

Thrombocytopenia, defined as platelet counts under 150,000/μL, results from either decreased production or increased destruction. Manifestations of thrombocytopenia include spontaneous bleeding, prolonged bleeding time and normal prothrombin time (PT) and partial thromboplastin time (PTT). The lower the platelet count, the greater the risk of bleeding. Patients with less than 10,000 platelets/μL are at greatest risk of spontaneous hemorrhage (Table 26-7).

TABLE 26-7
PRINCIPAL CAUSES OF THROMBOCYTOPENIA

Decreased Production
Aplastic anemia
Bone marrow infiltration (neoplastic, fibrosis)
Bone marrow suppression by drugs or radiation
Ineffective Production
Megaloblastic anemia
Myelodysplasias
Increased Destruction
Immunologic (idiopathic, HIV, drugs, alloimmune, posttransfusion purpura, neonatal)
Nonimmunologic (DIC, TTP, HUS, vascular malformations, drugs)
Increased Sequestration
Splenomegaly
Dilutional
Blood and plasma transfusions

DIC = disseminated intravascular coagulation; HUS = hemolytic–uremic syndrome; TTP = thrombocytic thrombocytopenic purpura.

ETIOLOGIC FACTORS AND MOLECULAR PATHOGENESIS: **Decreased platelet production** can result from multiple congenital or acquired defects in megakaryocytopoiesis, including diseases that affect the marrow generally, abnormalities that selectively impair platelet production and defects that lead to ineffective megakaryocytopoiesis. Marrow infiltration with malignant cells or bone marrow failure (e.g., in patients with aplastic anemia or who received radiotherapy or chemotherapy) may cause pancytopenia, including thrombocytopenia. Certain viral infections, such as cytomegalovirus (CMV) and HIV, and certain drugs impair platelet production. (HIV may also increase platelet destruction; see below.) Megaloblastic anemia and myelodysplasia may cause thrombocytopenia due to ineffective megakaryopoiesis.

May-Hegglin anomaly is a congenital form of thrombocytopenia that entails decreased platelet production. It is the most common of a family of inherited thrombocytopenias called myosin heavy chain 9 (MYH9)-related platelet disorders. These disorders all result from mutations in the *MYH9* gene, which encodes a cytoskeletal contractile protein, nonmuscle myosin heavy chain IIA (NMMHC-IIA). There are 3 other overlapping disorders: Epstein syndrome, Fechtner syndrome and Sebastian platelet syndrome. These all lead to abnormal megakaryocyte maturation and abnormally large platelets (macrothrombocytopenia). Neutrophils are also slightly abnormal morphologically, with blue cytoplasmic inclusions (**Döhle-like bodies;** true Döhle bodies occur in acute infections).

Increased platelet destruction can result from immune-mediated damage with consequent removal of circulating platelets, as in idiopathic thrombocytopenic purpura and drug-induced thrombocytopenia. Or, excessive platelet destruction

occurs by nonimmunologic conditions such as intravascular platelet aggregation (e.g., in TTP).

Abnormal platelet distribution, or pooling, is seen in disorders of the spleen and hypothermia.

Idiopathic (Autoimmune) Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is a syndrome in which antibodies against platelet or megakaryocytic antigens cause thrombocytopenia. It is, thus, more fittingly called **immune thrombocytopenic purpura**. ITP occurs in two forms: an acute, self-limited, hemorrhagic syndrome in children and a chronic bleeding disorder in adolescents and adults. The autoantibodies often recognize the platelet membrane glycoproteins, Gp IIb/IIIa or Ib/IX, which are involved in platelet adhesion and clot formation.

PATHOPHYSIOLOGY: Like autoimmune hemolytic anemia, ITP reflects antibody-mediated destruction of platelets or their precursors. In most cases, these are IgGs, but IgM antiplatelet antibodies also occur.

Acute ITP typically appears in children of either sex after a viral illness and is likely caused by virus-induced changes in platelet antigens that elicit autoantibodies. Complement bound at the surface lyses platelets in the blood or mediates their phagocytosis and destruction by splenic and hepatic macrophages.

Chronic ITP occurs mainly in adults (male-to-female ratio = 1:2.6) and may be associated with autoimmune (e.g., systemic lupus erythematosus) or malignant lymphoproliferative (e.g., chronic lymphocytic leukemia; see below) diseases. It is also common in people infected with HIV. The magnitude of thrombocytopenia in ITP reflects the balance between (1) levels of antiplatelet antibodies; (2) the extent to which platelet production in the marrow is impaired, as some antibodies may bind to megakaryocytes; and (3) expression of Fc and complement receptors at macrophage cell surfaces. This expression is upregulated in infection and pregnancy but is restored by certain drugs, for example, corticosteroids, danazol and intravenous γ-globulin, all of which are used to treat ITP.

PATHOLOGY: In acute ITP, the platelet count is typically less than 20,000/μL. In chronic adult ITP, platelet counts vary from a few thousand to 100,000/μL. Peripheral blood smears show many large platelets, owing to accelerated release of young platelets by bone marrow actively engaged in platelet production. Bone marrow thus shows compensatory increases in megakaryocytes (Fig. 26-28). Platelets carry detectable IgG in more than 80% of patients with chronic ITP; in half of these, platelet-associated C3 is also detectable.

CLINICAL FEATURES: Children with **acute ITP** experience sudden onset of petechiae and purpura but are otherwise asymptomatic. Spontaneous recovery occurs within 6 months in over 80% of cases. The major threat (<1% of cases) is intracranial hemorrhage. Treatment is rarely necessary, but with serious disease,

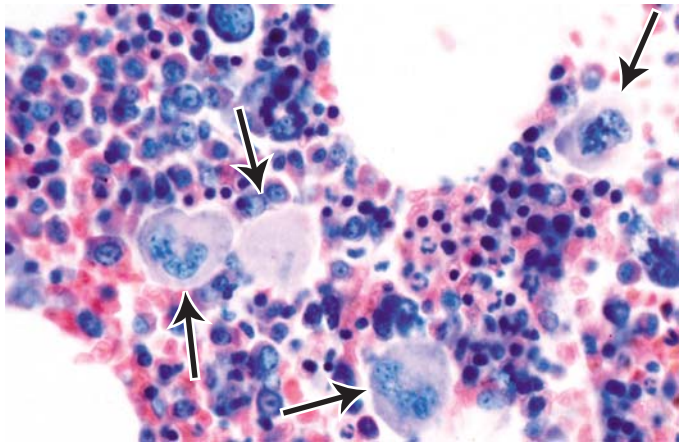

FIGURE 26-28. Idiopathic thrombocytopenic purpura. A section of the bone marrow reveals increased megakaryocytes (*arrows*).

corticosteroids and intravenous immunoglobulin may be needed. Glucocorticoids decrease antiplatelet antibody production and downregulate macrophage Fc receptors. γ-Globulin inhibits clearance of IgG-coated platelets from the circulation via multiple mechanisms.

Chronic ITP in adults manifests as bleeding episodes, such as epistaxis, menorrhagia or ecchymoses, and excessive bleeding after trauma and minor procedures (e.g., tooth extraction). Life-threatening hemorrhages are uncommon. Occasionally, asymptomatic people are discovered to have thrombocytopenia on a routine blood cell count. Most adults with chronic ITP improve with corticosteroids and intravenous γ-globulin. Danazol (a synthetic anabolic steroid) acts like glucocorticoids. In 70% of patients who do not respond adequately to drug therapy within 2–3 months, splenectomy produces complete or partial remission. For patients with severe ITP, ongoing studies are testing the efficacy of thrombopoietic agents that activate the TPO receptor.

Drug-Induced Autoimmune Thrombocytopenia

Many drugs cause immune-mediated platelet destruction: quinine, quinidine, heparin, sulfonamides, gold salts, antibiotics, sedatives, tranquilizers and anticonvulsants. The drugs often complex with a platelet-related protein to make a neoepitope that elicits antibody production. Chemotherapeutic agents, ethanol and thiazides cause thrombocytopenia by directly suppressing platelet production.

Heparin-induced thrombocytopenia (HIT) is a distinct type of drug-induced thrombocytopenia. There are two types of HIT. About 25% of patients experience mild, transient thrombocytopenia 2–5 days after heparin treatment starts. This mild form of HIT is self-limited, entails aggregation of platelets by nonimmune mechanisms and follows a relatively benign course.

Type II HIT is immunologically mediated, caused by acquired IgG antibodies against platelet factor 4–heparin complexes. It occurs in 1%–3% of patients treated with unfractionated heparin. After 4–10 days of therapy, these patients develop severe consumptive thrombocytopenia, platelet activation and thus a hypercoagulable state. Because this form of HIT entails hypercoagulability, platelet aggregation predisposes patients to arterial and venous thromboembolic events that may be lethal.

In both cases, the heparin functions seemingly paradoxically activate platelet aggregation. In type I HIT, it is the heparin itself that induces platelets to aggregate. In type II HIT, heparin acts as a hapten, binding platelet membranes and eliciting antibodies. These antibodies, in turn, trigger platelet aggregation. Thus, the principal complication of HIT is thrombosis.

Pregnancy-Associated Thrombocytopenia

Minimal thrombocytopenia occurs often during the third trimester of pregnancy, owing to dilution of platelets. Since platelet counts are usually above 100,000/μL, no special management is needed. Conversely, preeclampsia/eclampsia syndromes can result in maternal thrombocytopenia. A condition related to preeclampsia is called **HELLP** (hemolysis, elevated liver enzyme tests and low platelets; see Chapter 14). The latter two syndromes can be life-threatening.

Neonatal Thrombocytopenia

Neonatal thrombocytopenias are either **inherited** or **acquired**.

Inherited causes associated with increased platelet destruction include **Wiskott-Aldrich syndrome** (WAS), an X-linked recessive disorder caused by a defect in the Wiskott-Aldrich syndrome protein (*WASP*) gene. Affected boys have small platelets, eczema and immunodeficiency. A variant of WAS is **X-linked thrombocytopenia,** with mutations in the same gene, but which only involves thrombocytopenia. Other inherited defects associated with poor platelet production include amegakaryocytic thrombocytopenia, thrombocytopenia-absent radius syndrome and Fanconi anemia. Thrombocytopenia can also be seen in infants with trisomy 13, 18 or 21.

Fanconi anemia is an inherited, autosomal recessive, bone marrow failure disorder that often includes thrombocytopenia and RBC macrocytosis. The family of Fanconi genes mediate DNA double-strand break repair and genetic stability. There is a high incidence of malignancies as well as congenital anomalies, such as skin hypopigmentation and hyperpigmentation, short stature, microcephaly, microphthalmia and radial/thumb abnormalities (see Chapters 5 and 6).

Neonatal alloimmune thrombocytopenia (NAIT) is caused by increased destruction of platelets, because of alloimmunization to HPA-1a and other platelet-specific antigens that occurs during pregnancy. In NAIT, antibodies made by an HPA-1a–negative mother recognize a paternal HPA-1a–positive antigen on the fetus's platelets. The fetus or neonate, but not the mother, develops thrombocytopenia. NAIT predisposes to fetal and neonatal intracranial hemorrhage.

Nonimmune causes of thrombocytopenia in the neonate are like those in adults, with additional considerations such as birth asphyxia, hypoxic injury, sepsis and DIC, necrotizing enterocolitis, hemangiomas and thrombosis.

Posttransfusion Purpura

This complication of blood transfusion typically develops in women who are HPA-1 negative, and who were sensitized to HPA-1 as a result of previous pregnancies. It may also occur in men who have had previous blood transfusions. Thus, HPA-1–negative people may develop antibodies to HPA-1–positive platelets, after either pregnancy or transfusion with HPA-1–positive platelets. Any HPA-1–positive platelets infused thereafter are then destroyed by those antibodies. Curiously, the patient's own HPA-1–negative platelets are also destroyed. They may acquire the antigen passively or immune complexes may localize to the host platelet membranes. In any event, a self-limited thrombocytopenia occurs about a week after the transfusion.

Thrombotic Thrombocytopenic Purpura

Thrombotic microangiopathies (TMAs) are a heterogeneous group of syndromes that all cause thrombocytopenia, microangiopathic hemolytic anemia, neurologic symptoms, fever and renal impairment. TMAs include TTP and hemolytic–uremic syndrome. Their pathology reflects widespread platelet aggregation and deposition of hyaline thrombi in the microcirculation.

MOLECULAR PATHOGENESIS: In TTP, platelet cross-linking by inappropriate vWF multimers from injured endothelial cells reflects altered cleavage of multimeric vWF multimers. vWF monomers are normally assembled into multimeric molecules of varying size (up to millions of daltons) within endothelial cells and released locally in response to endothelial stimulation. ADAMTS13 is a metalloprotease that normally cleaves large vWF multimers. *In TTP, ADAMTS13 is deficient, causing ultra-large vWF multimers to accumulate. These multimers bind platelets, which form thrombi in the microvasculature, depleting platelets and causing thrombocytopenia.* ADAMTS13 is genetically absent or defective in familial TTP because of mutations of the *ADAMTS13* gene. The protein is inactivated by autoantibodies in idiopathic TTP. Prophylactic plasma infusion, which replaces the missing *ADAMTS13*, is most effective in familial forms of TTP, and plasma exchange is preferred in acquired types.

Although most cases arise in otherwise normal people, TTP may also complicate systemic diseases such as autoimmune collagen vascular disorders (systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome), drug-induced hypersensitivity reactions and malignant hypertension. It has also been triggered by infections, cancer chemotherapy, bone marrow transplantation and pregnancy in HELLP syndrome (see Chapter 12).

Other TMA disorders are much less well understood.

PATHOLOGY: In TTP, periodic acid–Schiff (PAS)-positive hyaline microthrombi deposit in arterioles and capillaries throughout the body, mainly in the heart, brain and kidneys (Fig. 26-29). These microthrombi contain platelet aggregates, fibrin and a few erythrocytes and leukocytes. Unlike immune-mediated vasculitis, there is no inflammation in TTP. Fragmented erythrocytes (schistocytes) always appear in peripheral blood smears (Fig. 26-30) and are caused by RBC shearing in vessels narrowed by thrombi. RBC polychromasia is also a feature and reflects an increase in reticulocytes in response to anemia. Hemolysis increases serum LDH and unconjugated bilirubin levels.

CLINICAL FEATURES: TTP may occur at any age but is most common in women in the 4th and 5th decades. It may be chronic and recurrent for years or, more frequently, occur as an acute, fulminant disease that is often fatal. Most patients present with neurologic

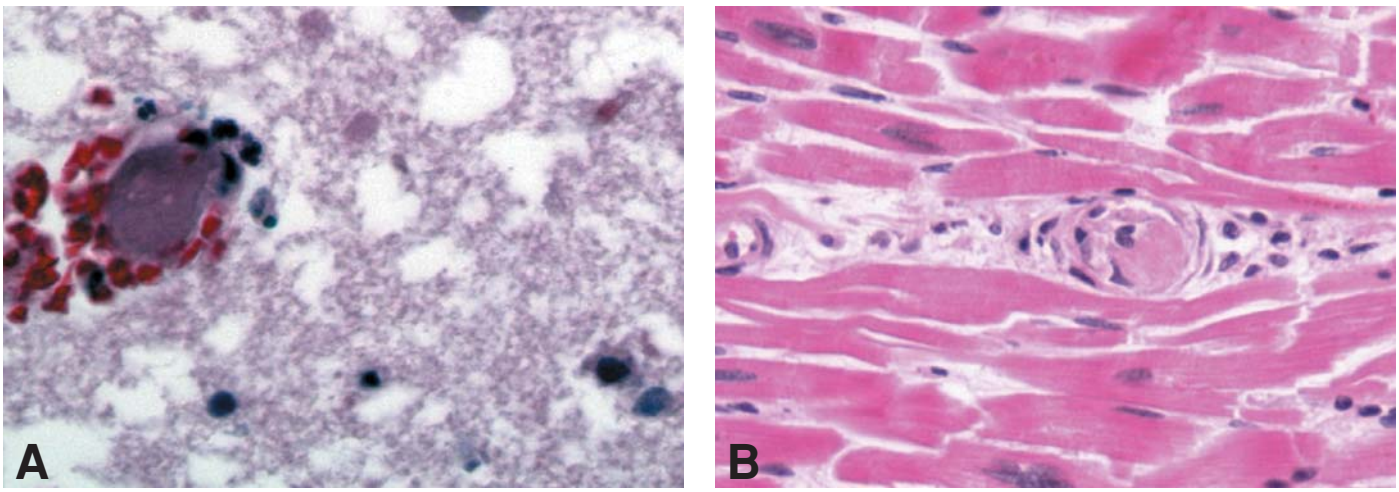

FIGURE 26-29. Thrombotic thrombocytopenic purpura. Microthrombi are present in the brain **(A)** and heart **(B)** of a patient who died of thrombotic thrombocytopenic purpura.

symptoms, including seizures, focal weakness, aphasia and alterations in consciousness. Widespread purpura is often present and vaginal bleeding may occur in women. Hemolytic anemia is a constant feature; hemoglobin levels are often below 6 g/dL. Jaundice caused by hemolysis may be severe. Renal dysfunction includes proteinuria, hematuria and mild renal insufficiency.

More than half of patients with TTP have platelet counts below 20,000/μL. Despite the presence of aggregated platelets, the coagulation cascade is not activated. Thus, PT, PTT and fibrinogen all remain normal. These parameters distinguish this syndrome from DIC (see below). With plasma infusion and plasmapheresis, about 89% of patients survive this once almost uniformly fatal disease.

Hemolytic–Uremic Syndrome

HUS is a thrombotic microangiopathy that resembles TTP, but its pathogenesis is entirely different. HUS is characterized by thrombocytopenia, microangiopathic hemolysis and acute renal failure.

Classic HUS occurs in children, usually after an acute infectious hemorrhagic gastroenteritis caused by *E. coli* strain O157:H7 or *Shigella dysenteriae* (see Chapter 22). Production of a Shiga-like toxin damages vascular endothelium and activates platelets. Fibrinogen then binds activated platelet Gp IIb/IIIa complex and platelets aggregate. In HUS, aggregated platelet thrombi are primarily in the renal microvasculature. Kidney failure, rather than neurologic abnormalities, is the main clinical feature.

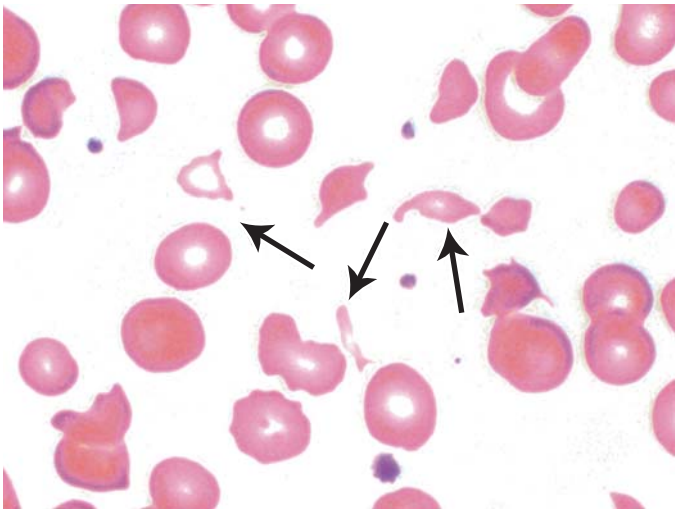

FIGURE 26-30. Microangiopathic hemolytic anemia. Numerous schistocytes (*arrows*) are present in a patient with thrombotic thrombocytopenic purpura.

Splenic Sequestration of Platelets

Many patients with splenomegaly, irrespective of the cause, show **hypersplenism**. This syndrome includes sequestration of platelets in the spleen. One third of platelets are normally stored temporarily in the spleen, but in massive splenomegaly, up to 90% of the total platelet pool may be sequestered in that organ. Interestingly, platelet life span is normal, or only slightly reduced. Thrombocytopenia associated with hypersplenism is rarely severe and by itself does not produce a hemorrhagic diathesis.

Other Causes of Thrombocytopenia

Vascular malformations, including hemangiomas and arteriovenous malformations, can cause thrombocytopenia. Platelet consumption due to hemangiomas has been called the **Kasabach-Merritt syndrome**. Platelet loss occurs in patients who have massive hemorrhage, such as in bleeding from a peptic ulcer or during surgery with heavy blood loss. Transfused blood does not contain viable platelets because it is stored at 4°C before administration. Thus, thrombocytopenia occurs in transfused patients because of platelet loss and dilution. Platelet transfusion may prevent this development.

Hereditary Disorders of Platelets

Bernard-Soulier Syndrome (Giant Platelet Syndrome)

Bernard-Soulier syndrome is an autosomal recessive disorder in which platelets have a quantitative or qualitative

defect in the membrane glycoprotein complex (Gp Ib/IX [CD42] and sometimes Gp V) that serves as a receptor for vWF. The complex helps mediate platelet adhesion to vWF in injured subendothelial tissues. In Bernard-Soulier syndrome, platelets vary widely in size and shape, and the diagnosis is suggested by the combination of *thrombocytopenia and giant platelets* on a blood smear.

The syndrome manifests in infancy or childhood with a bleeding pattern characteristic of *abnormal platelet function:* ecchymoses, epistaxis and gingival bleeding. At a later age, traumatic hemorrhage, gastrointestinal bleeding and menorrhagia occur. Many patients have only a mild bleeding disorder, but others suffer more severe hemorrhage that requires frequent platelet transfusions and that may even be fatal.

Glanzmann Thrombasthenia

Glanzmann thrombasthenia is an autosomal recessive defect in platelet aggregation caused by a quantitative or qualitative abnormality in the glycoprotein complex IIb/IIIa (CD41/61). In normal platelets, this complex is activated during platelet adhesion. It acts as a receptor for fibrinogen and vWF, to mediate platelet aggregation and generate a solid plug. The IIb/IIIa complex is also linked to platelet cytoskeleton and transmits the force of contraction to adherent fibrin, which promotes clot retraction. In Glanzmann thrombasthenia, the impaired aggregation and clot retraction hampers hemostasis and causes bleeding, despite a normal platelet count.

The disease becomes clinically apparent shortly after birth when an infant has mucocutaneous or gingival hemorrhage, epistaxis or bleeding after circumcision. Later, patients may suffer unexpected hemorrhage after trauma or surgery. Disease severity varies, and only a few patients experience life-threatening hemorrhage. Platelet transfusions correct the condition temporarily.

α Storage Pool Disease (Gray Platelet Syndrome)

α Storage pool disease is a rare inherited disease in which platelets lack morphologically recognizable α granules. The defect is in granule membranes, which are abnormal. Thrombocytopenia is common; platelets are large and pale. The bleeding diathesis tends to be mild.

δ Storage Pool Disease

This heterogeneous illness affects platelet-dense granules. It is sometimes associated with other multisystem hereditary disorders, including Chédiak-Higashi syndrome or Hermansky-Pudlak syndrome (both of which include oculocutaneous albinism). Bleeding manifestations are mild to moderate.

Acquired Qualitative Platelet Disorders

Several acquired disorders may impair platelet function (Table 26-7).

- **Drugs:** Various drugs can limit platelet activity. Aspirin irreversibly acetylates cyclooxygenase (COX), primarily COX-1. It thus blocks production of platelet thromboxane A_2, which is important for platelet aggregation. Platelets cannot synthesize cyclooxygenase, so the aspirin effect lasts for the life span of platelets (7–10 days). Nonsteroidal analgesics, such as indomethacin or ibuprofen, impair platelet function, but as their inhibition of cyclooxygenase is reversible, their effect on platelets is short. Antibiotics, particularly β-lactams (penicillin and cephalosporins), can cause platelet dysfunction. Ticlopidine markedly impairs platelet function and is used to treat thromboembolic disease. However, it may cause TTP.
- **Renal failure:** Qualitative platelet defects leading to prolonged bleeding times and a tendency toward hemorrhage may complicate kidney disease. These platelet abnormalities are heterogeneous and are aggravated by uremic anemia. Reestablishing a normal hematocrit using EPO may return bleeding time to normal without affecting the azotemia.
- **Cardiopulmonary bypass:** Use of extracorporeal circuit during bypass surgery may impair platelet function by activating and fragmenting platelets.
- **Hematologic malignancies:** Platelet dysfunction in chronic myeloproliferative neoplasms and myelodysplastic syndromes reflects intrinsic platelet defects. In dysproteinemias, platelets are coated with plasma paraprotein, impairing function.

Thrombocytosis

Reactive Thrombocytosis

Increases in platelet counts occur in association with (1) iron-deficiency anemia, especially in children; (2) splenectomy; (3) cancer; and (4) chronic inflammatory disorders. Reactive thrombocytosis is rarely symptomatic, but it may trigger thrombotic episodes, especially in patients bedridden after splenectomy.

Clonal Thrombocytosis

Myeloproliferative neoplasms (see below) such as polycythemia vera and essential thrombocythemia entail malignant proliferations of megakaryocytes. Resulting increases in circulating platelets may lead to episodic thrombosis or bleeding.

Coagulopathies Are Caused by Deficient or Abnormal Coagulation Factors

Quantitative and qualitative disorders of all of the coagulation factors are known, and may be **inherited** or **acquired**. Most result from deficiency of the protein factor, leading to inadequate hemostasis and concomitant bleeding. Occasionally the protein factor is present but dysfunctional. Only hereditary deficiencies of factor VIII (hemophilia A), factor IX (hemophilia B) and vWF are common.

Hemophilia is an X-linked recessive disorder of blood clotting that results in delayed bleeding along with joint and muscle bleeding. Classic hemophilia is actually two distinct diseases resulting from mutations in the genes for **factor VIII (hemophilia A)** and **factor IX (hemophilia B)**.

Hemophilia is one of the oldest genetic diseases recorded, having been described in the Talmud almost 2000 years ago: male infants of Jewish families that had a history of fatal bleeding after circumcision were excused from this ritual. Transmission of a bleeding tendency to boys from unaffected mothers has been known for 200 years. Dissemination of hemophilia throughout Europe's royal families by Queen Victoria's daughters highlighted this disease.

Hemophilia A (Factor VIII Deficiency)

MOLECULAR PATHOGENESIS: ***Hemophilia A is the most common X-linked inherited bleeding disorder (1 per 5000–10,000 males).*** The gene for factor VIII was cloned in 1984. Causative mutations in the very large factor VIII gene at the tip of the long arm of the X chromosome (Xq28) include deletions, inversions, point mutations and insertions. Each family with a history of hemophilia actually harbors a different mutation (private mutant allele). In half of cases, hemophilia A can be traced through many generations, but the other half represent de novo mutations arising within two generations of the index case. In most cases of de novo mutations, an origin in the mother, maternal grandfather or maternal grandmother has been identified.

CLINICAL FEATURES: Patients with hemophilia A have mild, moderate or severe bleeding tendencies. In most, the severity of the illness parallels factor VIII activity in the blood. Half of patients have virtually no factor VIII activity and often suffer spontaneous bleeding. A third of patients, with 1%–5% of normal factor VIII activity, will only occasionally bleed spontaneously, but often do so after minor trauma. One fifth have factor VIII activity levels from 5% to 40% of normal and bleed only after significant trauma or surgery.

The most frequent complication of hemophilia A is a degenerative joint disease caused by repeated bleeding into many joints. Although uncommon, bleeding into the brain was formerly the most common cause of death. Hematuria, intestinal obstruction and respiratory obstruction may all occur with bleeding into the respective organs.

Management consists of factor VIII replacement, either prophylactically to prevent bleeding or therapeutically in response to bleeding episodes. The aim is to correct factor VIII levels to control bleeding and prevent long-term sequelae. Unfortunately, in the 1980s, many of these patients developed AIDS and viral hepatitis from contamination of pooled factor VIII preparations (from plasma-derived concentrates). Screening blood donors for HIV, heat treating purified factor VIII to inactivate HIV and, now, the use of human recombinant factor VIII have eliminated these complications. Screening to detect female carriers and prenatal diagnosis using DNA markers are highly accurate.

Hemophilia B

MOLECULAR PATHOGENESIS: ***Hemophilia B is an X-linked inherited disorder of factor IX deficiency.*** It is 1/4 as common as hemophilia A, at 1 in 20,000 male births, and accounts for 15% of cases of hemophilia. Factor IX is a vitamin K–dependent protein made in the liver. Many different mutations, from single base substitutions to gross deletions, may cause hemophilia B.

CLINICAL FEATURES: Bleeding manifestations in hemophilia B are like those of hemophilia A. Treatment relies on infusion of purified or recombinant factor IX concentrates.

von Willebrand Disease

von Willebrand disease (vWD) is a heterogeneous complex of hereditary bleeding disorders related to deficiency or abnormality of vWF. Over 20 distinct subtypes are known. A simplified classification (see below) recognizes 3 major categories. Variable expression of vWF (especially type I) confounds estimates of prevalence, although some hold that vWD is the most common inherited coagulopathy (1%–2% of the population).

PATHOPHYSIOLOGY AND MOLECULAR PATHOGENESIS: vWF is an adhesive molecule made by endothelial cells and megakaryocytes as a 250-kd monomer. It polymerizes to form multimers with molecular weights in the millions. vWF is stored in cytoplasmic Weibel-Palade bodies of endothelial cells, from which it is released into subendothelial tissues and plasma. After endothelial insult, subendothelial vWF binds platelet glycoprotein receptors (Gp Ib/IX or CD42), triggering platelet adherence and sealing the injury (Fig. 26-31). vWF also binds Gp IIb/IIIa (CD41/61) to promote platelet aggregation. In plasma, it binds and protects factor VIII. In its absence, factor VIII activity is always impaired.

vWD is an autosomal disease, affecting men and women. The *vWF* gene on chromosome 12 is large and complex (180 kb with 52 exons). Three types of the disease are recognized, each of which is heterogeneous:

- **Type I vWD:** These variants constitute 75% of cases of vWD and are inherited as autosomal dominant traits with variable penetrance. Type I vWD is a **quantitative deficiency in vWF,** in which levels of **all** multimers are reduced, though their relative concentrations remain unchanged.
- **Type II vWD: Qualitative defects in vWF** characterize type II variants, which account for 20% of vWD. In type II disease, interactions of vWF and the blood vessel wall are defective. The plasma activities of both vWF and factor VIII are low. In type IIa, higher–molecular-weight multimers are **absent** from platelets and plasma. Type IIb, an **abnormal** vWF, has increased affinity for platelets and may cause thrombocytopenia.
- **Type III vWD:** This severe form of vWD is least common. It is inherited as an autosomal recessive trait, but some patients are compound heterozygotes with different mutations in the two vWF alleles. vWF activity is absent and plasma factor VIII levels are less than 10% of normal.

CLINICAL FEATURES: Except for type III, most cases of vWD entail only a mild bleeding diathesis.

In contrast to hemophilia-related bleeding, patients with vWD show immediate, mucocutaneous bleeding such as easy bruising, epistaxis, GI bleeding and (in women) menorrhagia. The presenting symptom is often excessive hemorrhage after trauma or surgery. Patients with type III vWD may have life-threatening hemorrhage from the gut; hemarthroses like those in hemophilia are not unusual.

All forms of vWD respond well to vWF concentrates or cryoprecipitate. The vasopressin analog desmopressin (DDAVP) is the treatment of choice in types I and IIa, because it increases release of preformed vWF from endothelial storage pools. DDAVP intranasal sprays are now available.

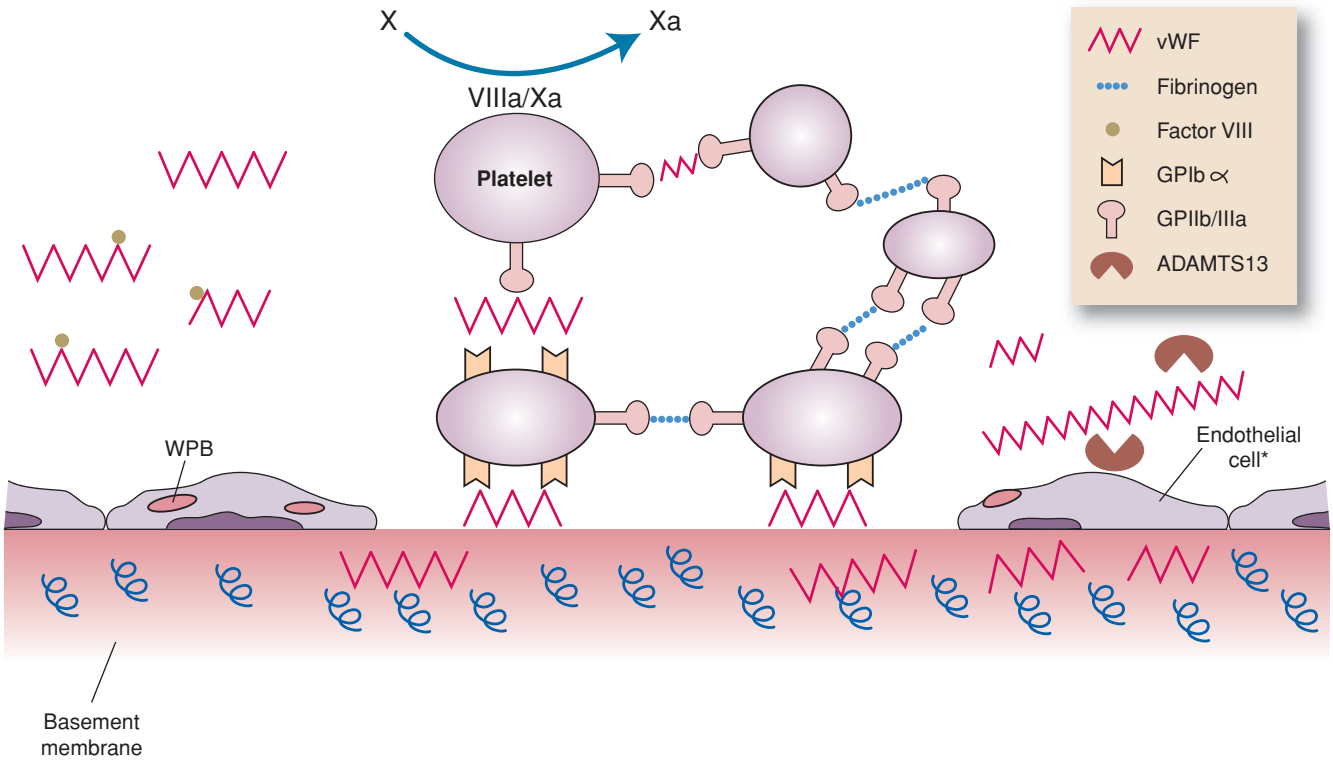

FIGURE 26-31. von Willebrand factor (vWF). vWF is stored in Weibel-Palade bodies (WPBs) of endothelial cells and is secreted from activated endothelial cells (*) into the subendothelial space. vWF is also secreted from platelet α granules. After endothelial injury, vWF binds to platelet glycoprotein (Gp) receptors Gp Ibα and promotes platelet adherence and protects factor VIII. Released vWF stabilizes platelet adhesion to the damaged vessel wall and promotes platelet–fibrin interactions. vWF also binds Gp IIB/IIA on the activated platelet surface to promote platelet aggregation. ADAMTS13 is the protease that cleaves ultralarge multimers of vWF.

Other Coagulation Factor Deficiencies

Deficiencies of all coagulation factor proteins, including factors VII, X, V, XI and II (prothrombin) and fibrinogen, have been reported in humans. As expected, the severity of bleeding usually correlates with the level of functional protein activity. Prolonged PT or PTT in patients who bleed excessively helps to identify a problem with coagulation factors. Factor-specific assays confirm the diagnosis. The thrombin time helps to screen for deficiency or dysfunction of fibrinogen. Deficiency of fibrinogen causes bleeding. By contrast, dysfibrinogenemia may cause bleeding but more often leads to thrombosis.

Liver Disease

Many coagulation factors are produced by the liver (e.g., II, V, VII, IX, X). In addition, the liver plays a key role in vitamin K absorption. Severe liver disease may impair secretion of coagulation factors, as a manifestation of the general protein synthetic defect. In this case, levels of all liver-synthesized coagulation factors are low, affecting the intrinsic and extrinsic pathways. PT and PTT are both prolonged.

Because vitamin K–dependent factors are disproportionately affected, in liver disease the PT is far more affected than the PTT. This is unlike DIC (see below).

Vitamin K Deficiency

Liver-derived coagulation factors depend on vitamin K as an essential cofactor in γ-carboxylation of glutamic acid residues to Gla residues. The secreted proteins are only functional if Gla residues are present. By contrast, factor V is made in the liver but does not require vitamin K. Thus, in vitamin K deficiency (see Chapter 8), activities of factors II, VII, IX and X are low but factor V activity is normal. Severe liver disease will, however, cause decreased activities of all of these factors.

CLINICAL FEATURES: Levels of vitamin K are physiologically low in neonates, and it is standard practice to administer vitamin K to newborns to prevent hemorrhagic disease. In adults, vitamin K deficiency may reflect poor dietary intake. Since colonic bacteria produce the form of vitamin K that is best absorbed, prolonged antibiotic intake or large colonic resections may lead to vitamin K deficiency.

Inhibitors of Coagulation Factors

Acquired inhibitors of coagulation factors, **circulating anticoagulants,** are usually IgG autoantibodies. Most are directed against factor VIII and vWF, but rarely antibodies to any of the other coagulation factors can be present. In hereditary coagulation disorders, especially hemophilia, circulating anticoagulants arise because of administration of plasma concentrates containing the deficient factor. Anticoagulants also develop in some patients with autoimmune disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis; see Chapter 11), presumably owing to abnormal immune regulation. Finally, acquired anticoagulants often appear in apparently normal people.

CLINICAL FEATURES: Acquired anticoagulants may be asymptomatic laboratory findings, or they may cause life-threatening hemorrhage. These autoantibodies are difficult to eliminate, but 1/3 of patients

remit spontaneously. Treatment includes plasma concentrates, corticosteroids and immunosuppression.

Disseminated Intravascular Coagulation

DIC is widespread intravascular activation of coagulation, generating thrombin and microvascular fibrin thrombi and triggering fibrinolysis. Platelets and clotting factors are consumed, so patients also tend to hemorrhage. DIC is serious and often fatal. It may complicate massive trauma, burns, sepsis (see Chapter 12) from diverse organisms and obstetric emergencies. It is also associated with metastatic cancer, hematopoietic malignancies, cardiovascular and liver disease and many other conditions.

PATHOPHYSIOLOGY: DIC begins with activation of clotting cascades within the vascular compartment by tissue injury, endothelial damage or both. **Subsequent generation of substantial amounts of thrombin** ***(Fig. 26-32), combined with the failure of natural inhibitory mechanisms to neutralize thrombin, triggers DIC.*** With consequent uncontrolled intravascular coagulation, the delicate balance between coagulation and fibrinolysis goes awry. This leads to consumption of clotting factors, platelets and fibrinogen and a consequent hemorrhagic diathesis.

Procoagulant TF is released into the circulation after many kinds of injury, including direct trauma, brain injury and obstetric accidents (e.g., premature separation of the placenta) (see Chapter 14). **Bacterial endotoxin** also stimulates macrophages to release TF (see Chapter 12). **Certain tumor cells** cause DIC by releasing TF. With activation of the clotting cascade, intravascular fibrin microthrombi deposit in the smallest blood vessels. Stimulation of the fibrinolytic system by fibrin generates fibrin split products, which possess anticoagulant properties and contribute to the bleeding diathesis.

Endothelial injury often plays an important role in the development of DIC. The anticoagulant properties of

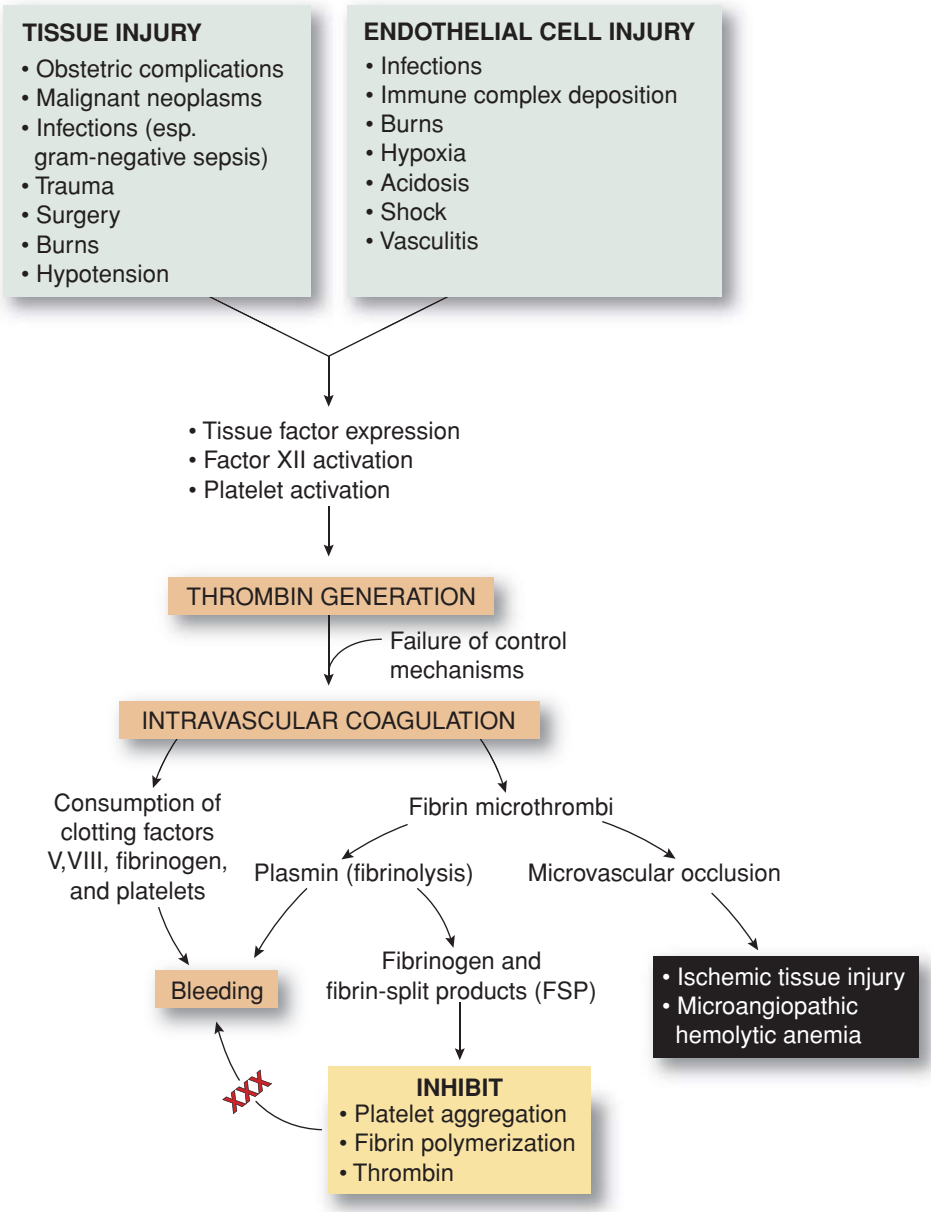

FIGURE 26-32. The pathophysiology of disseminated intravascular coagulation (DIC). The DIC syndrome is precipitated by tissue injury, endothelial cell injury or a combination of the two. These injuries trigger increased expression of tissue factor on cell surfaces and activation of clotting factors (including XII and V) and platelets. With the failure of normal control mechanisms, generation of thrombin leads to intravascular coagulation.

the endothelium (Fig. 26-27) are impaired by diverse injuries, including (1) TNF in Gram-negative sepsis; (2) other inflammatory mediators, such as activated complement, IL-1 or neutrophil proteases; (3) viral or rickettsial infections; and (4) trauma (e.g., burns). Thus, platelet aggregates form in the microvasculature.

PATHOLOGY: Arterioles, capillaries and venules throughout the body are occluded by **microthrombi** made of fibrin and platelets (Fig. 26-33). However, because fibrinolysis is activated, these thrombi may no longer be visible at the time of autopsy. Microvascular obstruction is associated with widespread **ischemic changes,** particularly in the brain, kidneys, skin, lungs and GI tract. These organs are also sites of bleeding, which, in the case of the brain and gut, may be fatal.

Erythrocytes fragment **(schistocytes)** in passing through webs of intravascular fibrin, resulting in **microangiopathic hemolytic anemia**. Consumption of activated platelets leads to **thrombocytopenia,** while **depletion of clotting factors** causes prolonged PT and PTT and decreased plasma fibrinogen. Plasma fibrin split products prolong the thrombin time. Fibrinopeptide A and D-dimers are elevated (as markers of coagulation and fibrinolytic activation, respectively).

CLINICAL FEATURES: DIC symptoms reflect both microvascular thrombosis and a bleeding tendency. Ischemic changes in the brain lead to seizures and coma. Depending on the severity of DIC, renal symptoms range from mild azotemia to fulminant acute renal failure. Acute respiratory distress syndrome (see Chapter 18) may supervene, and acute ulcers in the gut may bleed. The bleeding diathesis is evidenced by cerebral hemorrhage, ecchymoses and hematuria. Patients with DIC are treated with heparin anticoagulation to interrupt the cycle of intravascular coagulation, and replenishment of platelets and clotting factors to control the bleeding.

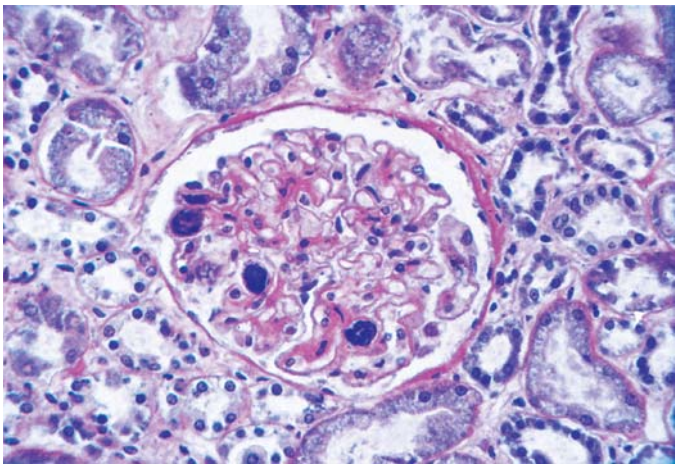

FIGURE 26-33. Disseminated intravascular coagulation. A section of a glomerulus stained with phosphotungstic acid hematoxylin (PTAH), which colors fibrin deep purple, demonstrates several microthrombi.

TABLE 26-8
PRINCIPAL CAUSES OF HYPERCOAGULABILITY

Heparin
Oral contraceptives
Hyperlipidemia
Thrombotic thrombocytopenic purpura

Hypercoagulability Causes Widespread Thrombosis

Hypercoagulability is increased tendency to form clots, compared to normal. A possible hypercoagulable state should be explored if a patient develops unexplained thrombotic episodes in one of the following contexts:

- Recurrence
- Development at a young age
- Family history of thrombotic episodes
- Thrombosis in unusual anatomic locations
- Difficulty in controlling with anticoagulants

Disorders that enhance thrombosis are covered in Chapters 7, 16 and 17.

Hypercoagulable states are either inherited and acquired (Table 26-8).

Inherited Hypercoagulability

Inherited hypercoagulability reflects alterations in the natural anticoagulant pathways. A hereditary tendency to clot excessively, regardless of its origin, is **thrombophilia**.

- **Activated protein C (APC) resistance—factor V Leiden:** A point mutation in the *factor V* gene (factor V Leiden) renders it resistant to inhibition by APC. ***Resistance APC action is the most common genetic hypercoagulability disorder. It accounts for up to 65% of patients with venous thrombosis.*** The factor V Leiden mutation occurs worldwide, but more so in whites (up to 5% of the general population) and much less so in Africans (near 0%). Compared with normal people, heterozygotes for factor V Leiden have 7 times the risk for deep venous thrombosis. In homozygotes, the increased risk is 80-fold.
- **Antithrombin (ATIII) deficiency:** This autosomal dominant disorder, which has incomplete penetrance, occurs in 0.2%–0.4% of the general population and can result in

either a quantitative or a qualitative effect on ATIII. The risk of a thrombotic event (usually venous) is 20%–80% in different families.

- **Protein C and protein S deficiencies:** Homozygous protein C deficiency causes life-threatening neonatal thrombosis with **purpura fulminans**. Up to 0.5% of the general population has heterozygous protein C deficiency, but many of them are symptom free. Clinically, deficiencies of proteins C and S resemble ATIII deficiency.
- **Other causes of hypercoagulability:** A genetic variant (G20210A) in the 3′-untranslated region of prothrombin mRNA is associated with thrombosis. The mechanism is unclear, but may involve excessively high prothrombin levels in people with this variant. Unusually high levels of fibrinogen and factors VII and VIII are associated with thrombosis. Again, how the elevated levels occur remains to be elucidated. Some dysfibrinogenemias are also associated with thrombosis.

Acquired Hypercoagulability

Venous stasis contributes to hypercoagulability associated with prolonged immobilization and congestive cardiac failure. Increased platelet activation probably accounts for excessive clotting in patients with myeloproliferative disorders, heparin-associated thrombocytopenia and TTP.

Antiphospholipid Antibody Syndrome

Antibodies against several negatively charged protein/phospholipid complexes are associated with antiphospholipid antibody syndrome. This is an autoimmune disorder that entails arterial and venous thrombosis, spontaneous abortions and immune-mediated thrombocytopenia or anemia.

In this syndrome, antibodies (mainly, but not exclusively, IgG) react with proteins that bind anionic phospholipids, such as phosphatidylserine (PS) or cardiolipin. These membrane lipids are only exposed when cells such as platelets are activated. Many plasma proteins and Gla domain–containing procoagulant proteins (e.g., prothrombin) bind to PS and related anionic phospholipids. Diagnosis entails detecting (1) lupus-type anticoagulant activity, (2) anticardiolipin antibodies and (3) antibodies to plasma protein β_2-glycosyl phosphatidylinositol (GPI). Anticardiolipin antibodies bind β_2-GPI in the presence of cardiolipin.

Lupus anticoagulants (a misnomer: these antibodies are not restricted to patients with systemic lupus erythematosus [see Chapter 11] and in fact cause increased coagulability) are antiphospholipid antibodies that occur in patients with systemic lupus erythematosus and other autoimmune conditions, or in otherwise asymptomatic people. Because they inhibit phospholipids, lupus anticoagulants prolong PTT in vitro, but these patients actually tend to be prone to hypercoagulability.

Antiphospholipid antibody syndrome is the leading acquired hematologic cause of thrombosis. Resulting thromboses may occur via several possible mechanisms, including platelet activation, endothelial cell activation and altered coagulation factor assembly on membranes. Thrombosis in the uteroplacental vasculature is the likely mechanism in recurrent fetal loss.

Nonmalignant Disorders of White Blood Cells

Chapters 2 through 4 discuss white blood cell structure and function.

DISORDERS OF NEUTROPHILS

Neutropenia Is an Absolute Neutrophil Count below 1500/μL

The clinical consequences of neutropenia depend entirely on the extent of neutropenia. In mild cases, absolute neutrophil counts (ANCs) are 1000–1500/μL; in moderate neutropenia, ANCs are 500–1000/μL. In severe cases, ANCs are less than 500/μL. In patients with mild neutropenia **(granulocytopenia)**, the number of neutrophils is adequate to defend against microorganisms. With moderate neutropenia, patients become vulnerable to microbial infections. In severe neutropenia, the risk of serious infection is high. **Agranulocytosis** is the virtual absence of neutrophils, caused by depletion of both the marginated pool and the bone marrow reserve.

Neutropenia reflects either decreased production or increased destruction of neutrophils (Table 26-9). Most cases are asymptomatic and unexplained, to which the term **chronic benign neutropenia** is applied. Sometimes, total granulocyte numbers are normal, but excessive neutrophils are stored in the marrow or marginated in blood vessels.

DECREASED NEUTROPHIL PRODUCTION: Radiation or chemotherapeutic drugs suppress normal hematopoiesis

TABLE 26-9
PRINCIPAL CAUSES OF NEUTROPENIA

Decreased Production
Irradiation
Drug induced (long and short term)

Felty syndrome
Systemic lupus erythematosus
Dialysis (induced by complement activation)
Splenic sequestration
Increased margination

and so interfere with generation of neutrophils. Certain drugs, such as phenothiazines, phenylbutazone, antithyroid drugs and indomethacin, can cause **idiosyncratic** marrow suppression. Viral infection and alcohol intake may also suppress myelopoiesis.

MOLECULAR PATHOGENESIS: Decreased granulocyte production can also result from constitutional genetic alterations in several rare hereditary disorders, including **Kostmann syndrome** and **infantile genetic agranulocytosis**. The genetic bases of several of these diseases are known. Mutations in the neutrophil elastase gene cause the most common form of congenital agranulocytosis. Mutations in *HAX*, a gene regulating apoptosis, are responsible for Kostmann syndrome. Ineffective myelopoiesis is involved in the neutropenia of megaloblastic anemias and myelodysplastic syndromes. In **cyclic neutropenia,** episodes recur regularly about every 21 days.

INCREASED PERIPHERAL DESTRUCTION OF GRANULOCYTES: Accelerated elimination of granulocytes is caused by:

- Increased consumption of neutrophils in overwhelming infections
- Increased sequestration in hypersplenism
- Increased destruction by antibodies

Many **drugs** can lead to immune-mediated neutrophil destruction, especially sulfonamides, phenylbutazone and indomethacin. The toxic effect results from attachment of circulating antigen–antibody complexes to granulocyte surfaces, with subsequent complement-mediated injury.

Neutropenia is common in AIDS patients and is multifactorial. Virus-induced depression of neutrophil production is aggravated by infectious consumption of neutrophils and often by antiretroviral drugs (e.g., zidovudine).

Gout
Thyroid storm
Tissue Necrosis
Infarction
Trauma
Burns

Neutrophilia Is an Absolute Neutrophil Count above 7000/μL

Neutrophilia has many causes (Table 26-10) and reflects (1) **increased mobilization** of neutrophils from bone marrow storage, (2) **enhanced release** from the peripheral blood marginal pool or (3) **stimulation of marrow granulopoiesis**. Increased mobilization of neutrophils from the marrow pool or from peripheral marginal pools occurs in settings of acute trauma or infections. Mild neutrophilia is seen in 20% of women in the third trimester of pregnancy, but the mechanism is poorly defined.

LEUKEMOID REACTION: In acute infections and occasionally in times of severe hemorrhage or acute hemolysis, white blood counts (and, implicitly, neutrophils) may be so high as to be mistaken for leukemia, especially chronic myeloid leukemia (CML). Such nonneoplastic increases in leukocyte counts are **leukemoid reactions**. Clues to the benign (or reactive) nature of a leukemoid reaction include the following: (1) the cells in the peripheral blood are usually segmented neutrophils and fewer neutrophilic myeloid precursors, (2) leukocyte alkaline phosphatase activity is high in a leukemoid reaction but low in CML, (3) white blood cell (WBC) counts are usually under 50,000/μL in reactive conditions and (4) reactive neutrophils often contain large blue cytoplasmic inclusions **(Döhle bodies)** or prominent blue-black granulation of the cytoplasm **(toxic granulation)**. If uncertain, the absence of the Philadelphia chromosome (see below) or other cytogenetic abnormality supports a reactive, nonneoplastic diagnosis.

Qualitative Disorders of Neutrophils Are Associated with Impaired Function

If granulocyte functionality is impaired, resistance to infection may decrease despite a normal granulocyte count. Such rare hereditary disorders of granulocyte activity include chronic granulomatous disease, myeloperoxidase deficiency and Chédiak-Higashi syndrome (see Chapter 2).

DISORDERS OF OTHER WHITE BLOOD CELL SERIES

Eosinophilia Occurs with Allergic Reactions and Malignancies

Eosinophils differentiate in the bone marrow under the influence of eosinophil growth factors (e.g., IL-5). They circulate briefly in the blood, then migrate preferentially to the gut, respiratory tract and skin. Eosinophils respond to

TABLE 26-11

Interleukin-2 therapy

chemotactic substances made by mast cells or are induced by persistent antigen–antibody complexes, such as occur in chronic parasitic, dermatologic and allergic conditions. The main causes of eosinophilia are listed in Table 26-11.

In **idiopathic hypereosinophilic syndrome,** circulating eosinophils exceed 1500/μL for more than 6 months without evident underlying disease. Eosinophil counts in this condition may reach 50,000–100,000/μL.

Hypereosinophilia may accompany mast cell disease (see below), tumors like Hodgkin or non-Hodgkin lymphoma or myeloproliferative disorders (see below). Some of these neoplasms are associated with platelet-derived growth factor receptor (PDGFR) or fibroblast growth factor receptor-1 (FGFR-1) gene rearrangements.

Regardless of the cause, accumulation of eosinophils in tissues often leads to necrosis, particularly in the myocardium, where it produces endomyocardial disease (see Chapter 17). Neurologic dysfunction may also develop. Eosinophil-mediated tissue injury is related to constituents of the eosinophil granules, particularly major basic protein and cationic protein (see Chapter 2).

The prognosis of untreated idiopathic hypereosinophilic syndrome is grave: only 10% of untreated patients survive 3 years. With aggressive corticosteroid therapy, 70% live over 5 years, even with cardiac involvement. If hypereosinophilia is associated with malignancy, prognosis depends on the course of tumor therapy (see below).

Basophilia Occurs in Allergic Reactions and Myeloproliferative Diseases

The basophil is the least abundant of all leukocytes. It differentiates in the bone marrow, circulates briefly in the blood and then passes into tissues. Its relationship to mast cells is controversial. Basophil granules contain several preformed inflammatory mediators, including histamine and chondroitin sulfate. When stimulated, these cells also synthesize leukotrienes and other mediators. Basophilia occurs most often in immediate-type hypersensitivity reactions and together with chronic myeloproliferative neoplasms. The major causes of basophilia are listed in Table 26-12.

Monocytosis Characterizes Both Malignant and Inflammatory Conditions

Monocytosis is defined as a peripheral blood monocyte count above 800/μL. The main causes include hematologic malignancies, immunologic and inflammatory conditions, infectious diseases and solid cancers. The former account for at least half of peripheral blood monocytoses. For example, monocytes may constitute a component of myeloproliferative neoplasms, or myelodysplastic/myeloproliferative neoplasms such as chronic myelomonocytic leukemia. In such cases, they may be either morphologically normal or immature and dysplastic cytologically. Peripheral blood monocytosis often occurs in neutropenic states, possibly as a compensatory mechanism. It may also accompany Hodgkin or non-Hodgkin lymphomas.

Proliferative Disorders of Mast Cells Release Inflammatory Mediators

Mast cell disorders are diverse and include many benign and malignant diseases. The benign, nonneoplastic, reactive conditions of mast cells are important to recognize and differentiate from the malignant syndromes. Mast cells derive from precursor cells in the bone marrow and are found in the connective tissues, usually in close proximity to blood vessels (see Chapter 2). Mast cell granules contain inflammatory mediators, such as histamine, heparin, eosinophil and neutrophil chemotactic factors and certain proteases. The symptoms of mast cell proliferative diseases are caused by release of these substances and include flushing, pruritus and hives. Secretion of heparin also causes bleeding from the nasopharynx or GI tract.

Reactive mast cell hyperplasia is a nonmalignant process that occurs in immediate- and delayed-type hypersensitivity reactions and in lymph nodes that drain the sites of

malignant tumors. It is also observed in Waldenström macroglobulinemia, in the bone marrow of women with postmenopausal osteoporosis, in myelodysplastic syndromes and after chemotherapy for leukemia.

Disorders of Hematopoietic Stem Cells

NONMALIGNANT STEM CELL DISORDERS

Disorders of HSC Failure May Manifest in Multiple Hematopoietic Series

Aplastic Anemia

Aplastic anemia is a disorder of pluripotential hematopoietic stem cells that leads to bone marrow failure. The marrow is hypocellular and all blood cell lineages are decreased **(pancytopenia)**.

PATHOPHYSIOLOGY AND ETIOLOGIC FACTORS: Aplastic anemia is a rare heterogeneous disease that results from injury to hematopoietic stem cells. In 50%–70% of cases, there is no identifiable etiology (Table 26-13). In 10%–20% of cases, it is due to a marrow insult. In the rest of the cases, aplastic anemia is inherited. The inciting insult can be a predictable, dose-dependent, toxic injury (e.g., certain chemotherapeutic drugs, chemicals and ionizing radiation). Marrow damage can result from an idiosyncratic, dose-independent, immunologic injury, as occurs with idiopathic cases or after certain drug or viral exposures. The most common inherited cause of aplastic anemia is Fanconi anemia, as discussed below. Depending on its cause, stem cell injury may or may not be reversible.

In some patients, stem cell injury is an immune phenomenon: it responds clinically to antithymocyte globulin or other immunosuppressive agents. Other cases probably reflect an intrinsic abnormality of stem cells, as suggested by subsequent evolution of clonal stem cell disorders (paroxysmal nocturnal hemoglobinuria, myelodysplasia, acute leukemia).

PATHOLOGY: The bone marrow in aplastic anemia shows variably reduced cellularity, depending on the clinical stage of the disease. Myeloid, erythroid and megakaryocytic lineages are decreased, with a relative increase in marrow lymphocytes and plasma cells. As marrow cellularity declines, there is a corresponding increase in fat (Fig. 26-34). Anemia, leukopenia (mainly granulocytopenia) and thrombocytopenia characterize aplastic anemia. Despite elevated EPO levels, reticulocytosis is absent, which underscores the underlying stem cell defect.

CLINICAL FEATURES: Patients with aplastic anemia show signs and symptoms due to pancytopenia (i.e., weakness, fatigue, infection and bleeding).

Fanconi anemia

For untreated aplastic anemia, the prognosis is grim, with a 3–6-month median survival. Only 20% live over 1 year. Immunosuppressive therapy often leads to transient remissions. Bone marrow or stem cell transplantation may be curative.

Fanconi Anemia

Fanconi anemia (FA) is the most common hereditary bone marrow failure syndrome. There are 15 associated genes known, labeled *FANC* (for Fanconi complementation group), followed by A, B, and so forth. The most commonly occurring mutants affect FANC genes A, C, G and D2. (FANCD1 is also BRCA2; see Chapters 5 and 25.) Affected patients may

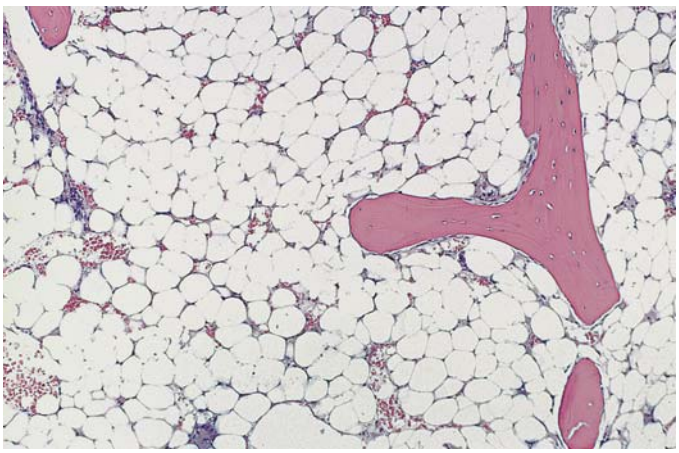

FIGURE 26-34. Aplastic anemia. The bone marrow consists largely of fat cells and lacks normal hematopoietic activity.

be obvious at birth or shortly afterward, as they often have abnormalities of their thumbs and radii, as well as cutaneous, renal and other malformations. Aggregate incidence of Fanconi anemia is less than 1 per 100,000 live births.

The underlying defect is in DNA repair, and in particular repair of cross-links between DNA strands, such as may occur during DNA duplication. Different members of the Fanconi gene family mediate key functions in this pathway and interact with other DNA damage/repair genes such as ATM, ATR and BRCA1 (see Chapter 5).

Aplastic anemia associated with Fanconi anemia usually occurs in the first decade and may be the sentinel event. All hematopoietic series are affected. It is important to distinguish FA patients from others with aplastic anemia, as Fanconi patients will not respond to immunosuppressive treatments used for people with idiopathic aplastic anemia. Androgens may be useful in treating bone marrow failure due to FA, but HSC transplantation is the treatment of choice. Unfortunately, the sensitivity of these patients to DNA damaging agents complicates pretransplant conditioning.

Long-term complications of Fanconi anemia, should patients survive hematopoietic failure events, include development of myelodysplastic syndromes and acute myelogenous leukemia (see below) during their teenage years or as young adults. As well, since the DNA repair defect affects all cells, FA patients are highly susceptible to developing epithelial tumors later in life.

Some HSC Disorders Affect One Series Preferentially

Pure Red Cell Aplasia

Pure red cell aplasia (PRCA) is selective marrow suppression of committed erythroid precursors. White blood cells and platelets are unaffected.

PATHOPHYSIOLOGY: PRCA most often results from immune suppression of red cell production, the etiology of which is unknown. On occasion, it is due to viral infection (parvovirus B19) or thymic lesions (e.g., thymoma, thymic hyperplasia). The P antigens on red cell membranes are receptors for parvovirus, which explains the restricted infection of erythroid precursors.

Diamond-Blackfan syndrome is a PRCA caused by de novo or inherited mutations in one of many ribosomal proteins. It manifests within the first 2 years of life with anemia, with or without physical abnormalities including cleft lip or palate, micrognathia, limb abnormalities and short stature. Anemia is caused by defective erythroid precursors that show a diminished response to erythropoietin and decreased erythroid burst- and colony-forming capacities.

PATHOLOGY: In PRCA, overall marrow cellularity is normal, but erythroid precursors are absent or are arrested at the erythroblast (pronormoblast) stage. In cases caused by parvovirus B19, proerythroblasts have intranuclear viral inclusions. Myeloid and megakaryocytic precursors are adequate in number and show normal maturation.

Patients with PRCA develop moderate to severe anemia, often with macrocytic indices. Despite increased EPO, there is no accompanying reticulocytosis.

CLINICAL FEATURES: Acquired PRCA manifests as an acute self-limited illness or a chronic relapsing process. **Acute self-limited PRCA** is often due to parvovirus B19. This condition may not be clinically apparent unless the patient suffers from an underlying chronic hemolytic anemia (e.g., hereditary spherocytosis, sickle cell anemia). Such cases may be complicated by an aplastic "crisis" (i.e., sudden worsening of anemia). Immunocompromised patients cannot clear parvovirus infection and anemia may be prolonged. **Chronic relapsing PRCA** may be idiopathic or associated with an underlying thymic lesion. In such cases, thymectomy may correct the anemia.

Diamond Blackfan syndrome is usually life-threatening owing to severe anemia and the gradual impact of iron overload. Some patients respond to glucocorticoids.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal stem cell disorder characterized by episodic intravascular hemolytic anemia due to increased RBC sensitivity to complement-mediated lysis.

MOLECULAR PATHOGENESIS: The underlying defect in PNH involves somatic mutation of the *phosphatidylinositol glycan-class A (PIG-A)* gene, on the short arm of the X chromosome (Xp22.1) in HSCs (Table 26-14). This mutation disrupts synthesis of GPI, which normally anchors many proteins (e.g., CD14, CD16, CD55, CD59) to RBC membranes. Consequent loss of **decay acceleration factor** (CD55) and, more importantly, **membrane inhibitor of reactive lysis** (CD59) from their surfaces makes red blood cells more susceptible to lysis by complement. Leukocytes and platelets derived from the abnormal stem cells also lose GPI-linked membrane proteins.

PNH may develop as a primary disorder or evolve from preexisting aplastic anemia. Because the defect is clonal, it may progress to **myelodysplasia** or overt **acute leukemia** (see below). Some patients have several abnormal clonal erythrocyte populations, with varying susceptibility to complement.

PATHOLOGY: During hemolytic episodes, patients develop varyingly severe normocytic or macrocytic anemia, with an appropriate reticulocyte response. Because the hemolysis is intravascular, hemoglobinuria is present, and iron deficiency may develop over time from recurrent iron loss in the urine. ***PNH is diagnosed by flow cytometric demonstration that blood cells lack GPI-anchored proteins.*** Leukopenia and thrombocytopenia are frequent, and sensitivity to complement may lead to inappropriate platelet activation.

CLINICAL FEATURES: Patients may have intermittent intravascular hemolysis, although only a minority have it at night. Venous and arterial thrombosis, notably Budd-Chiari syndrome (hepatic vein thrombosis; see Chapter 20), are increased in PNH because of complement-mediated platelet activation. Thrombocytopenia may lead to bleeding. Treatment is supportive; bone marrow transplantation is curative.

TABLE 26-14
COMMON GENETIC ABNORMALITIES ASSOCIATED WITH MYELOID PROLIFERATIONS

Disease	Associated Genetic/Chromosomal Abnormality	Importance
Paroxysmal nocturnal hemoglobinuria (PNH)	PIG-A mutations	Characteristic of PNH
Chronic myeloid leukemia (CML)	t(9;22)(q34;q11) (Philadelphia chromosome)	Largely defines CML
	Trisomy 8; trisomy 19; isochromosome 17q; second Philadelphia chromosome	Occur in some cases in blast phase of CML
Polycythemia vera	Trisomy 8 or 9; del 20q; del 13q; del 9p	Associated in some cases
	JAK2 V617F	Seen in 95% of polycythemia vera cases
Primary myelofibrosis (PMF)	del(13)(q12–22)	Associated in some cases
	der(6)t(1;6)(q21–23;p21.3)	Strongly associated in some cases
	JAK2 V617F	Seen in 50% of PMF
Essential thrombocythemia (ET)	del 20q; trisomy 8	Diagnostically helpful if present
	JAK2 V617F	Seen in 40% of ET cases
	MPL mutations	Seen in rare cases of ET
Myelodysplastic syndromes	5q–	Suggests favorable prognosis
	7q–	Suggests unfavorable prognosis
Acute myelogenous leukemia (AML)	t(8;21)(q22;q22); inv(16)(p13;q22); t(16;16)(p13.1;q22); t(9;11)(p22;q23); t(6;9)(p3;q34); inv(3)(q21;q26.2)	Seen in some cases of AML with recurring chromosomal abnormalities
Acute promyelocytic leukemia (APL)	t(15;17)(q22;q12)	Defines APL
Acute monocytic leukemia (AMoL)	del(11q); t(9;11); t(11;19)	Seen in some cases of AMoL
Acute myelomonocytic leukemia (AMML)	inv(16)(p13;q22); del(16q)	Seen in some cases of AMML
Acute megakaryoblastic leukemia	t(1:22)(p13;q13)	Seen in some cases, particularly in children
Myeloid sarcoma	Translocations involving (11q23), NPM mutations	Seen in some cases, not unique to myeloid sarcomas

LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Malignant leukocytes originate from either myeloid or lymphoid cells. Malignant proliferations of myeloid cells are derived from bone marrow cells and manifest as **acute myeloid leukemias, myelodysplastic syndromes** or **myeloproliferative neoplasms**. **Malignant lymphocytes** may arise anywhere there are lymphoid cells. World Health Organization (WHO) classifications are based on morphology, immunophenotype, cytogenetics and molecular abnormalities. In 2008, the WHO made significant changes to the classification of hematopoietic malignancies.

Myeloproliferative Neoplasms Are Clonal Stem Cell Disorders

Myeloproliferative neoplasms (MPNs) are clonal hematopoietic, stem cell disorders with unregulated, increased proliferation of one or more myeloid lineages (granulocytes, erythrocytes, megakaryocytes or mast cells). The WHO recognizes four well-established, and four additional, entities: **chronic myelogenous leukemia, *BCR-ABL1* positive; polycythemia vera; primary myelofibrosis; essential thrombocythemia; chronic neutrophilic leukemia; chronic eosinophilic leukemia; mastocytosis; and unclassifiable myeloproliferative neoplasm** (Table 26-15).

Myeloproliferative neoplasms typically affect adults 40–80 years old. They are relatively uncommon, with a yearly incidence of 6–10 cases per 100,000. Radiation and benzene exposure are implicated in a few cases, but the etiology is largely unknown. There is also evidence of inherited predisposition to develop MPNs. Characteristic features of all subtypes include bone marrow hypercellularity with effective hematopoietic maturation and increased numbers of red cells, granulocytes and/or platelets. Bone marrow fibrosis of different degrees and splenomegaly often accompany MPNs. Specific oncogene mutations and/or translocations are diagnostic of certain myeloproliferative neoplasms (see below).

TABLE 26-15
MYELOPROLIFERATIVE NEOPLASMS[a]

	Chronic Myelogenous Leukemia, BCR-ABL1 Positive	Polycythemia Vera	Primary Myelofibrosis	Essential Thrombocythemia
Clinical Features				
Peak age range (years)	25–60	40–60	50–70	50–70
Splenomegaly	90%	75%	100%	30% (slight)
Hepatomegaly	50%	40%	80%	40% (slight)
Acute leukemic conversion	80%	5%–10%	5%–10%	2%–5%
Median survival (years)	3–4	13	5	>10
Bone Marrow				
Histopathology	Panhyperplasia (predominantly granulocytic)	Panhyperplasia (predominantly erythroid)	Panhyperplasia with fibrosis	Large megakaryocytes in clusters
M:E ratio	10:1 to 50:1	≤2:1	2:1 to 5:1	2:1 to 5:1
Fibrosis	<10%	15%–20%	90%–100%	<5%
Laboratory Findings				
Hemoglobin	Mild anemia	>20 g/dL	Mild anemia	Mild anemia
RBC morphology	Slight aniso- and poikilocytosis	Slight aniso- and poikilocytosis	Immature erythrocytes and marked aniso- and poikilocytosis	Hypochromic microcytes
Granulocytes	Moderate to markedly increased with spectrum of maturation	Normal to mildly increased; may show a few immature forms	Normal to moderately increased; some immature WBCs	Normal to slightly increased
Platelets	Normal to moderately increased	Normal to moderately increased	Increased to decreased	Markedly increased with abnormal forms
Genetics	Philadelphia chromosome: *BCR/ABL* gene rearrangement	JAK2 activating mutation	JAK2 activating mutation	JAK2 activating mutation

M:E ratio = ratio of myeloid to erythroid; RBC = red blood cell; WBC = white blood cell.
[a]Other myeloproliferative neoplasms include chronic neutrophilic leukemia, chronic eosinophilic leukemia, mastocytosis and myeloproliferative neoplasm, unclassifiable.

Chronic Myelogenous Leukemia

CML is derived from an abnormal pluripotent bone marrow stem cell and results in prominent neutrophilic leukocytosis over the full range of myeloid maturation. A **Philadelphia chromosome,** or molecular or cytogenetic demonstration of the ***BCR/ABL* fusion gene,** is required to establish the diagnosis. CML is the most common myeloproliferative neoplasm and accounts for 15%–20% of all cases of leukemia.

MOLECULAR PATHOGENESIS: The cause of CML is usually unknown. Radiation exposure and myelotoxic agents, such as benzene, have been implicated in a small number of cases. The leukemic cells represent clonal pluripotent stem cells that can differentiate along myeloid or lymphoid pathways; however, most cases show mainly granulocytic differentiation. Conventional cytogenetic and/or fluorescence in situ hybridization (FISH) techniques identify a reciprocal balanced translocation in 95% of cases. This translocation involves exchange of genetic material between chromosomes 9 and 22, resulting in a Philadelphia chromosome [t(9;22)(q34;q11)] (Table 26-14 and Fig. 26-35A). This chromosome itself is a derivative (shortened) chromosome 22 [der(22q)]. The *BCR* (breakpoint cluster region) gene on chromosome 22 is fused to the *ABL* gene on chromosome 9 to form a *BCR/ABL* fusion gene. A small number of cases have cryptic translocations involving 9q34 and 22q11 that cannot be identified by conventional cytogenetics. In these cases, *BCR/ABL* fusion is detected by FISH (Fig. 26-35B) or using molecular techniques, such as reverse transcriptase polymerase chain reaction (RT-PCR).

In the vast majority of cases, the abnormal BCR/ABL fusion gene encodes a 210-kd fusion protein (p210), which is

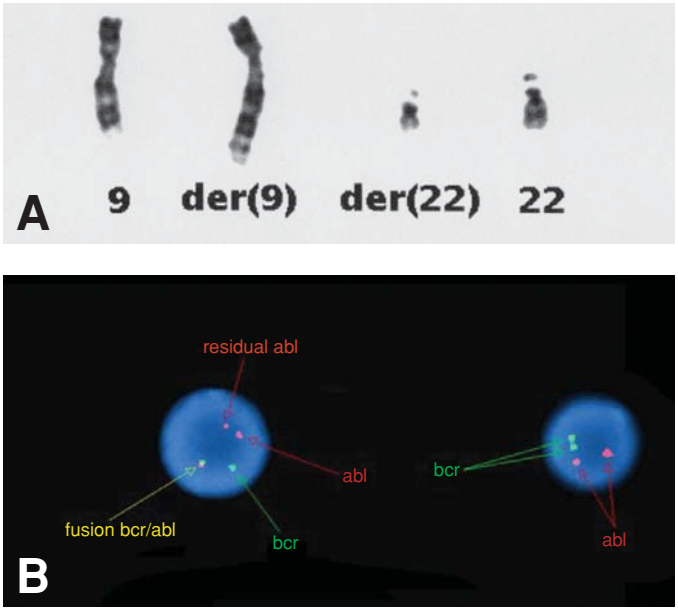

FIGURE 26-35. Chronic myelogenous leukemia. A. The Philadelphia chromosome der(22) is shown. **B.** Fluorescence in situ hybridization (FISH) in a patient with t(9;22) (Philadelphia chromosome)-positive chronic myeloid leukemia. *Right image.* A normal cell contains two separate bcr (chromosome 22) and abl (chromosome 9) genes. *Left image.* A leukemic cell with a fusion bcr/abl signal; residual abl signal; and two normal abl and bcr signals derived from normal chromosomes 9 and 22, respectively.

a constitutively active tyrosine kinase and is central to the pathogenesis of the neoplasm. This activated tyrosine kinase autophosphorylates and then activates downstream signaling pathways that trigger cell proliferation, differentiation, survival and adhesion. Much less commonly, the *BCR/ABL* fusion gene results from a breakage in the minor breakpoint cluster regions yielding alternative fusion proteins such as p190 and p230 (often associated with prominent neutrophilic maturation and/or thrombocytosis). While small amounts of p190 (often associated with monocytosis) fusion product occur in CML, this form of BCR/ABL is more often seen in **Philadelphia chromosome-positive acute lymphoblastic leukemia occurring outside the setting of CML.** RT-PCR can determine the specific BCR/ABL product fusion present in the leukemic cells and can quantitate the fusion product. The latter is useful for monitoring patient responses to therapy. If there are additional chromosomal abnormalities (e.g., second Philadelphia chromosome, trisomy 8, etc.), they usually herald disease progression to clinically more aggressive phases.

PATHOLOGY: CML may present in **chronic, accelerated** or **blast phase**.

- **CML, chronic phase (CP):** patients have leukocytosis, consisting of neutrophils in all stages of maturation with a peak of myelocytes and mature neutrophils. By definition, blasts make up less than 10% of circulating or bone marrow leukocytes. Basophilia and eosinophilia are common. Platelets are normal or increased and may exceed $10^6/\mu L$. Bone marrow biopsies show hypercellularity, usually with total effacement of the marrow space by mostly myeloid cells and their precursors (Fig. 26-36). Megakaryocytes often form clusters and show abnormal morphologic features, including micromegakaryocytes and nuclear hypolobation. Reticulin fibers are normal or moderately increased.
- **CML, accelerated phase (AP):** AP represents disease progression from CML-CP. CML-AP is defined by one of the following criteria: (1) persistent or increasing WBC count unresponsive to therapy, (2) persistent or increasing splenomegaly unresponsive to therapy, (3) persistent thrombocytopenia or thrombocytosis unresponsive to therapy, (4) additional chromosomal abnormalities, (5) 20% or more blood basophils and (6) 10%–19% blasts in the blood or bone marrow.
- **CML, blast phase (BP):** Blast phase represents the evolution to acute leukemia and features (1) 20% or more blasts in the blood or bone marrow, (2) extramedullary proliferation of blasts (skin, lymph nodes, spleen, bone, brain) and (3) clusters of blasts in the bone marrow. Blast phase heralds a poor prognosis. In 70% of blast crises, the leukemic blasts show myeloid morphology and immunophenotype; in 30%, they are lymphoblasts, usually of B-cell precursor lymphoblast immunophenotype (expressing

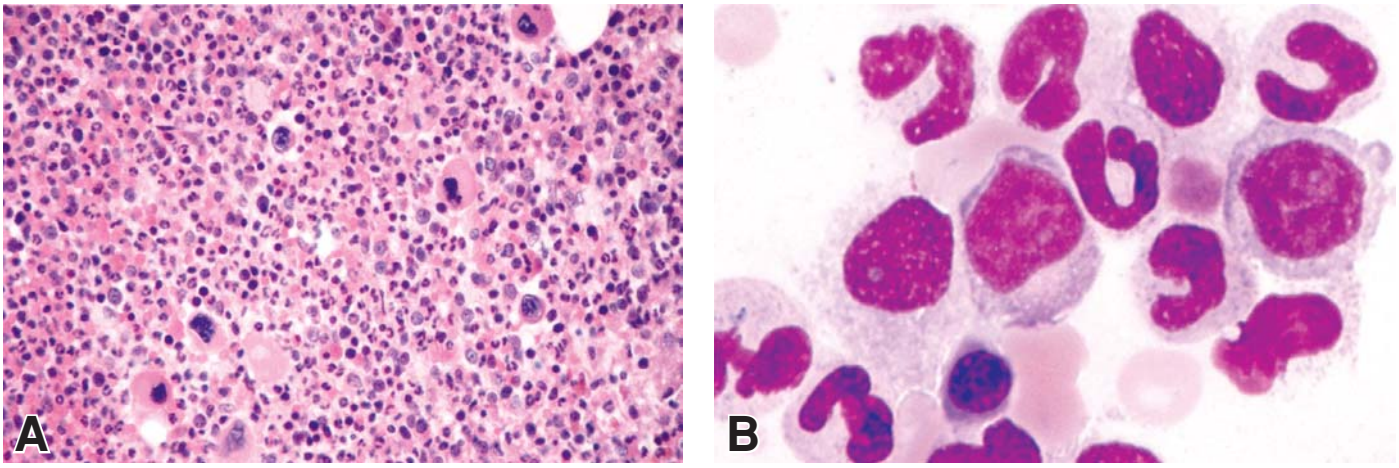

FIGURE 26-36. Chronic myelogenous leukemia. A. The bone marrow is conspicuously hypercellular because of an increase in granulocyte precursors, mature granulocytes and megakaryocytes. **B.** A smear of the bone marrow aspirate from the same patient reveals numerous granulocytes at various stages of development.

CD10, CD19, CD34 and terminal deoxynucleotidyl transferase [TdT]). In 80% of cases, transformation to accelerated phase or blast crisis entails additional cytogenetic alterations (Table 26-14).

CLINICAL FEATURES: Peak incidence is in the fifth and sixth decades, with a slight male predominance. Patients with CML report fatigue, anorexia, weight loss and vague abdominal discomfort caused by hepatosplenomegaly. Acute left upper quadrant pain is often a symptom of splenic infarction. Blood findings include mild to moderate anemia, leukocytosis and absolute basophilia. Peripheral granulocytes are markedly increased with a full maturation range with peaks in myelocytes and segmented neutrophils. Clinical deterioration often heralds blast phase.

CML is a model of targeted drug therapy in human malignancies. The drug imatinib, a tyrosine kinase inhibitor (TKI), blocks the ATP-binding site on *BCR/ABL* tyrosine kinase, and so inactivates it. Survival of 70%–90% is typical with imatinib. However, increasingly, subclones with point mutations within the ATP-binding pocket emerge and demonstrate resistance to imatinib. Second-generation TKIs and allogeneic bone marrow transplantation have greatly improved the outcome in CML patients.

Polycythemia Vera

PV is a myeloproliferative neoplasm arising from a clonal HSC and characterized by autonomous production of RBCs, not responsive to EPO. *It is a clonal proliferation not only of erythroid elements but also of megakaryocytes and granulocytes in the bone marrow.* As secondary polycythemia and other myeloproliferative neoplasms resemble PV both clinically and pathologically, the WHO established diagnostic criteria for polycythemia. A diagnosis of PV requires that both major criteria and one minor criterion, or the first major criterion and two minor criteria, be present. Major criteria include (1) increased RBC mass or Hgb greater than 18.5 g/dL in men or greater than 16.5 g/dL in women; and (2) V617F Janus kinase 2 (JAK2) mutation or a similar mutation of JAK2. Minor criteria include (1) no elevation of EPO; (2) hypercellular marrow with panmyelosis that includes erythroid, granulocytic and megakaryocytic hyperplasia; and (3) erythroid colony formation in vitro without growth factor stimulation (endogenous production).

PATHOPHYSIOLOGY AND MOLECULAR PATHOGENESIS: PV derives from malignant transformation of a single stem cell with primary commitment to the erythroid lineage. Proliferation of the neoplastic clone occurs mainly in the bone marrow but may involve such extramedullary sites as the spleen, lymph nodes and liver **(myeloid metaplasia)**.

EPO is the primary regulator of erythropoiesis (see above), and its synthesis by the kidney is triggered by tissue hypoxia. The neoplastic erythroid progenitor cells of PV are sensitive to EPO, like their normal counterparts. In culture, they form luxuriant clusters of erythroid cells (BFU-E) when exposed to EPO. However, at the more mature colony-forming stage (CFU-E), cultured PV neoplastic cells form erythroid colonies even without EPO stimulation. These autonomous erythroid colonies, "endogenous CFU-E," characterize PV throughout the disease and stand in contrast to normal erythroid progenitors, whose CFU-Es require added EPO ("exogenous CFU-E").

Autonomous (EPO-independent) proliferation of these PV cells gives them a proliferative advantage: the increased RBC mass suppresses EPO secretion and thus the proliferation of normal RBC progenitors. Serum EPO levels in PV are normal or low, while in secondary (functional) erythrocytosis EPO is increased.

Over 95% of patients with PV had a somatic mutation in JAK2 (V617F). This gain-of-function mutation occurs in the HSC and is found in all myeloid lineages. It makes daughter hematopoietic cells hypersensitive to growth factors and cytokines, including EPO. The JAK2 family of transcription factors plays a critical role in cytokine signaling in normal hematopoietic cells mainly by triggering signal transducers and activators of transcription (STAT) proteins. In vitro studies indicate that the activating JAK2 mutation confers proliferative and survival advantages to hematopoietic precursors. The JAK2 V617F mutation is not specific for PV: it occurs in other myeloproliferative neoplasms. Patients with the JAK2 mutation have a longer duration of disease and higher risk for bleeding complications and fibrosis.

Abnormal cytogenetic karyotypes occur in 20% of patients with PV, the most common of which are presented in Table 26-14. *The Philadelphia chromosome and BCR/ABL fusion protein do not occur in PV.*

PATHOLOGY: ***Bone marrow in PV is hypercellular, and all elements—erythroid, granulocytic, megakaryocytic—are hyperplastic*** (Table 26-15). Panmyelosis is characteristic but morphologic findings and clinical course vary, depending on the stage of disease. The three stages include prepolycythemic, overt polycythemic and postpolycythemic myelofibrosis phases. In pre- and polycythemic stages, erythroid precursors predominate, and the myeloid-to-erythroid ratio (M:E) is less than 2:1. Erythroid maturation is normal. The granulocyte series also shows normal maturation. Megakaryocytes are typically increased in number, are of variable size and tend to cluster. In over 95% of cases, marrow-stainable iron is decreased or absent. A mild to moderate increase in reticulin is common in the early stages. In the later stage of postpolycythemic myelofibrosis, or the "spent phase," erythropoiesis decreases and the marrow becomes replaced by reticulin and collagen fibrosis.

The spleen is typically enlarged, with prominent accumulation of erythrocytes in the red pulp cords and sinuses. In the polycythemic phase, there is minimal if any evidence of extramedullary hematopoiesis (EMH). However, EMH, with blood cell precursors outside the marrow, increases in the postpolycythemic myelofibrotic phase. Although the main site of extramedullary hematopoiesis is the spleen, liver and lymph nodes may also contain foci of erythroid precursors, immature granulocytes and megakaryocytes.

Blood hemoglobin concentrations may exceed 20 g/dL, and the Hct surpasses 60% (Table 26-14). Initially, there is

mild to moderate leukocytosis (10,000–25,000/μL) in 2/3 of cases, and mild to moderate thrombocytosis (400,000–800,000/μL) in 1/2 of cases, often with abnormal platelet morphology. Anemia characterizes the later, spent phase of PV. Hyperuricemia and secondary gout may occur and are due to rapid cell turnover.

Peripheral blood smears in the polycythemic phase show crowding of usual normochromic, normocytic RBCs. Hypochromia and microcytosis occur if there is iron deficiency. Iron-deficiency anemia is common in PV, since stored iron is diverted to the erythropoiesis or is lost to phlebotomy or bleeding from the GI tract. In the later stages of PV, anemia develops and the peripheral blood shows a leukoerythroblastic picture, poikilocytosis with teardrop-shaped RBCs.

CLINICAL FEATURES: In North America, 8–10 cases of PV per million present annually. The mean age at diagnosis is 60 years. Onset tends to be insidious, and symptoms are generally nonspecific, typically relating to the increased erythrocyte mass. Plethora and splenomegaly are early findings. Headache, dizziness and visual problems reflect hypertension and/or vascular disturbances in the brain and retina. Angina pectoris, from slowing of coronary blood flow, and intermittent claudication caused by sluggish peripheral blood flow in the lower extremities may be complaints. Gastric or duodenal ulcers may follow GI tract circulatory problems or, in part, histamine release by basophils. Major thrombotic complications, including stroke, myocardial infarction and deep vein thrombosis, occur in 20% of cases.

The clinical course of PV tends to proceed in the three phases described above. The **prepolycythemic phase** is the prodromal phase. It features borderline or mild erythrocytosis with mild erythroid hyperplasia, but not to the degree diagnostic of PV. The diagnosis can be rendered based on a low EPO level, JAK2 or similar mutation or endogenous erythroid colony formation. Later, when red cell mass is definitively increased, the polycythemic stage has been reached. In 10% of cases, the disease evolves to the postpolycythemic (spent) phase when excessive erythroid proliferation ceases, resulting in decreased erythrocyte mass and anemia. Another 10% of cases progress to myelofibrosis with extramedullary hematopoiesis, as in other MPNs **(postpolycythemic myelofibrosis)**. **Acute myelogenous leukemia (AML) or myelodysplasia** occurs in up to 15% of cases of PV and may in part be caused by treatment with ^{32}P or alkylating agents. Disease progression is often the result of karyotypic evolution and acquisition of complex chromosomal abnormalities.

Median survival with PV is 13 years. Specific causes of death related to the disease itself include thrombosis, hemorrhage, AML and the spent phase. Repeated phlebotomy or chemotherapy to reduce erythrocyte mass is effective management in most cases. JAK2 inhibitors have shown encouraging results.

Primary Myelofibrosis

Primary myelofibrosis (PMF) is a clonal myeloproliferative neoplasm in which prominent megakaryopoiesis and granulopoiesis accompany marrow fibrosis. Extramedullary hematopoiesis is present in fully developed disease.

MOLECULAR PATHOGENESIS: As in other MPNs, exposures to benzene or radiation have occasionally been implicated in primary myelofibrosis (chronic idiopathic myelofibrosis). The neoplastic megakaryocytes in PMF produce PDGF and TGF-β, both of which are powerful fibroblast mitogens. Ultimately, although fibroblasts are not part of the clonal stem cell disorder, their stimulation by those cytokines causes the entire marrow space to be replaced by connective tissue. In the fibrotic phase, clonal stem cells enter the circulation to cause EMH at multiple sites, especially the spleen. Half of patients with PMF have the JAK2 V617F mutation, which is important in the pathogenesis of the disease. A minority of cases have mutations of *MPL*, which encodes the TPO receptor. Some chromosomal abnormalities suggest, but do not prove, PMF (Table 26-14).

PATHOLOGY: PMF evolves through two stages, a prefibrotic and early stage, and a fibrotic stage. Most patients are diagnosed at the latter stage, but 30%–40% are first detected in a prefibrotic stage. The **prefibrotic stage** usually presents with unexplained thrombocytosis. The hypercellular bone marrow has minimal fibrosis and prominent neutrophilic and megakaryocytic proliferation. The megakaryocytes are densely clustered and atypically lobated with high a nuclear-to-cytoplasmic ratio. Some show "cloud-like" nuclei. In the **fibrotic stage,** the blood shows leukopenia or marked leukocytosis, with myeloid precursors and nucleated RBCs (leukoerythroblastosis) usually evident. The red cells exhibit poikilocytosis and teardrop forms (Fig. 26-37A). Bone marrow cellularity gradually decreases, and foci of hematopoiesis containing mostly atypical megakaryocytes alternate with hypo- or acellular regions. Conspicuous reticulin or collagen fibrosis in the marrow defines this stage (Fig. 26-37B). Extramedullary hematopoiesis leads to splenomegaly, hepatomegaly and lymphadenopathy, and may be seen in other organs.

The WHO requires 3 major criteria and 2 minor criteria for a diagnosis of PMF. Major criteria include megakaryocyte proliferation with or without fibrosis; absence of features of other well-defined MPNs; and a clonal genetic marker, such as *JAK2* mutation. Minor criteria include leukoerythroblastosis, elevated serum lactate dehydrogenase, anemia and splenomegaly.

CLINICAL FEATURES: The annual incidence of idiopathic myelofibrosis is 0.5–1.5 per 100,000. Its peak incidence is in the seventh decade. A quarter of patients with idiopathic myelofibrosis are asymptomatic at diagnosis, the disease being detected by splenomegaly on physical examination or by identifying teardrop red cells or thrombocytosis. Early clinical symptoms are nonspecific and include fatigue, low-grade fever, night sweats and weight loss. Platelet function may be impaired and associated with either increased platelet aggregation and thrombosis or decreased platelet aggregation with a bleeding diathesis. Transformation to AML occurs in 5%–30% of cases (Table 26-14).

Essential Thrombocythemia

Essential thrombocythemia (ET) is an uncommon myeloproliferative neoplasm in which megakaryocytes proliferate without restraint. Blood platelet counts remain increased

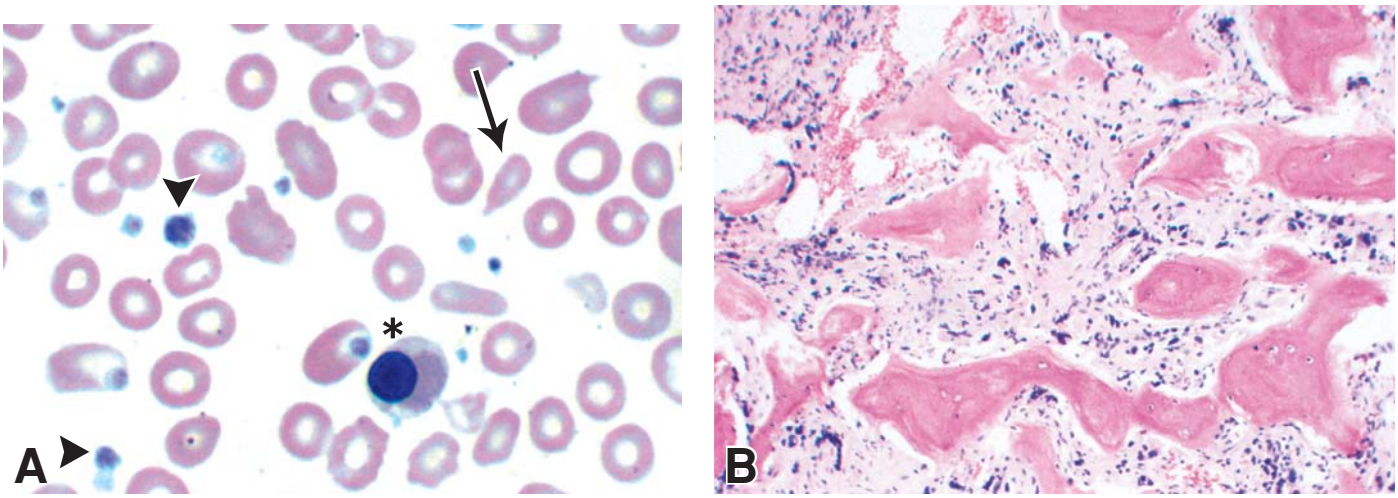

FIGURE 26-37. Chronic idiopathic myelofibrosis. A. Peripheral smear shows anisocytosis (red blood cells of different size), poikilocytosis with teardrop forms (*arrow*) and nucleated erythrocytes. Large to giant platelets are also present. **B.** A section of bone marrow shows collagenous fibrosis, osteosclerosis and numerous abnormal megakaryocytes.

(>450,000/μL), and recurrent episodes of thrombosis and hemorrhage are common. The disease affects middle-aged people, both genders equally (Table 26-14).

MOLECULAR PATHOGENESIS: ET is a clonal disorder believed to derive from neoplastic transformation of a single HSC with principal, but not exclusive, commitment to megakaryocytic lineage. The disease features a marked proliferation of megakaryocytes, with up to a 15-fold or greater increase in platelet production and consequent marked thrombocytosis (sometimes >10^6/μL). About 40%–50% have a *JAK2* V617F mutation or other functionally similar abnormality. One to 2% of cases have an *MPL* gene mutation. Chromosomal abnormalities include deletion 20q and trisomy 8 and are identified in approximately 5%–10% of cases.

PATHOLOGY: To diagnose ET, other chronic MPNs and reactive thrombocytosis must be excluded. Abnormalities of platelet function are common in primary thrombocythemia. Recurrent episodes of thrombosis in arteries or veins are attributed to severe thrombocytosis, and hemorrhage reflects defective platelet function. Thromboses in the spleen, with subsequent infarction, may cause splenic atrophy. Iron-deficiency anemia follows hemorrhage from GI or urogenital tracts. The bone marrow is normocellular or moderately hypercellular, with fewer fat cells (Fig. 26-38). Increased numbers of large, hyperlobulated, "stag-horn–shaped" megakaryocytes with abundant mature cytoplasm form cohesive clusters or sheets in the marrow. Marrow reticulin is normal or slightly increased. Post-ET myelofibrosis is rare. Iron stores are normal or low.

The spleen is mildly enlarged in 1/2 of cases of ET. Extramedullary hematopoiesis is common, but extensive myeloid metaplasia only occurs when myelofibrosis develops. The peripheral blood shows thrombocytosis.

CLINICAL FEATURES: The clinical course of ET is indolent, with median survival exceeding 10–15 years. In untreated cases, thrombosis of large arteries and veins is common, especially in the legs, heart, intestine and kidneys. Hemorrhage is less common, usually from mucosal surfaces, and is mild, not life-threatening. AML supervenes in up to 5% of cases. The disease is treated with platelet pheresis and myelosuppressive chemotherapy.

Mastocytosis

Mastocytosis is a clonal hematopoietic disorder in which neoplastic mast cells accumulate in certain tissues, mainly skin and bone marrow. Systemic neoplastic mast cell disorders are considered to be in the category of MPN. The distinct subtypes are characterized by tissue involvement and clinical manifestations.

CUTANEOUS MASTOCYTOSIS: This can present either as single or multiple lesions. In the former case, there is a tan-brown, cutaneous nodule in newborns; in the latter, there are several groups of skin nodules in young

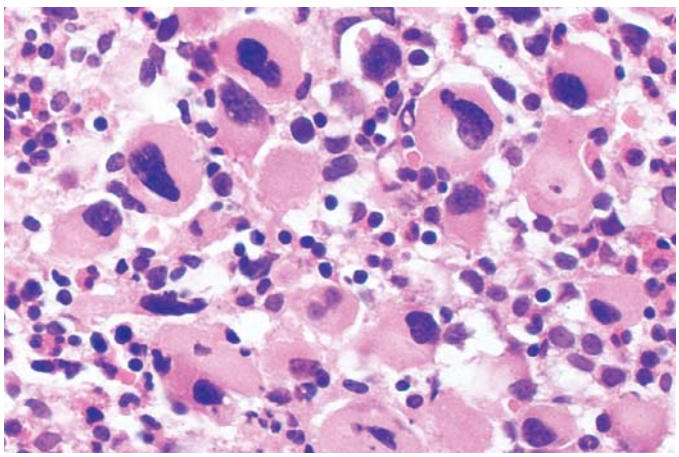

FIGURE 26-38. Essential thrombocythemia. A section of bone marrow exhibits a conspicuous increase in the number of megakaryocytes, which display atypical features and hypolobated forms.

children or disseminated brown-red macular or papular lesions. The most common type is **urticaria pigmentosa**. This presents as multiple, symmetrically distributed, tan-brown, cutaneous macules or papules, most commonly in infants and young children. The skin of the trunk is mostly affected, but any skin site may be involved. ***There is a disseminated perivascular and periadnexal dermal infiltrate of spindle-shaped mast cells.*** Spontaneous resolution usually occurs at puberty and systemic involvement does not happen.

SYSTEMIC MASTOCYTOSIS: This is a rare MPN, with mast cell infiltration of many organs, including the skin, lymph nodes, spleen, liver, bones, bone marrow and GI tract. Systemic mastocytosis has diverse manifestations, including an indolent form, a subtype associated with clonal hematologic non–mast cell lineage disease, an aggressive form and a leukemic form (mast cell leukemia). Transitions between these subtypes may occur. In most cases there is an activating mutation in the tyrosine kinase domain (D816V) of *c-kit* proto-oncogene. This underscores the neoplastic nature of this disorder. Skin lesions in the indolent form of systemic mastocytosis are clinically indistinguishable from those in cutaneous mastocytosis.

In mast cell leukemia, the bone marrow and peripheral blood show a significant increase in atypical mast cells (≥20% in the marrow) and depletion of fat and normal hematopoietic elements in the marrow. The circulating cells often exhibit cytologic atypia, including hypogranulation and/or nuclear irregularity, or less differentiated forms with blast-like morphology.

PATHOLOGY: In systemic mastocytosis, lymph nodes are rarely involved and initially show perifollicular and perivascular infiltration by mast cells (Fig. 26-39). Compact aggregates of mast cells within the paracortical areas can also be seen. The spleen shows nodular aggregates of mast cells with accompanying dense fibrosis in both red and white pulp. In the liver, portal triads are involved first. Involvement of the bone marrow may be peritrabecular, perivascular or diffuse, and there is often accompanying fibrosis and eosinophilia.

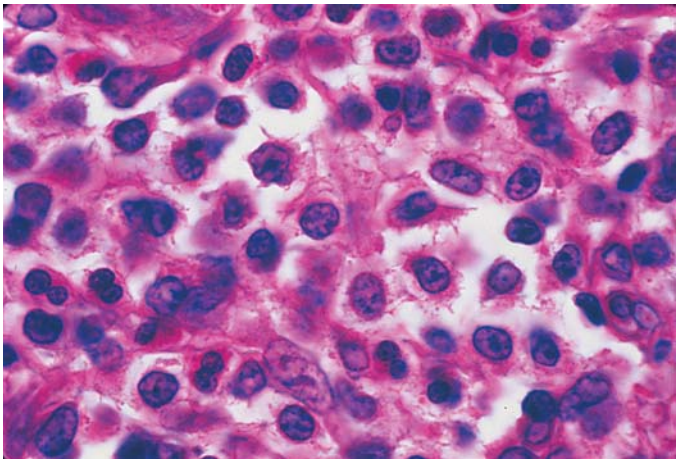

FIGURE 26-39. Mastocytosis. A section of lymph node shows effacement of the normal architecture by sheets of mast cells. The centrally situated nuclei are round to elongated, and occasionally indented. The cytoplasm is pale pink and finely granular.

CLINICAL FEATURES: Systemic mastocytosis occurs at any age, but adults in the 6th and 7th decades are most commonly affected. Patients' symptoms reflect the overproduction of a number of mediators normally made by mast cells and basophils, including histamine, prostaglandin D_2 and thromboxane B_2. Most people experience gastrointestinal pain and diarrhea. The serum **tryptase** levels are usually elevated. Anaphylactic episodes—with pruritus, flushing, hypotension and asthmatic symptoms—are common. Extensive mast cell infiltration of the bone marrow leads to secondary anemia, neutropenia and thrombocytopenia. Prognosis is variable, depending on subtype. The indolent form of systemic mastocytosis has a chronic course, and half of patients survive 5 years or more. Symptomatic relief is obtained, at least partially, with H_1- and H_2-receptor antagonists. There is no effective therapy for the underlying disease process.

Myelodysplastic Syndromes Are Clonal Disorders of Ineffective Hematopoiesis

In myelodysplastic syndromes (MDSs), peripheral blood cytopenias accompany a hypercellular marrow with ineffective hematopoiesis. The latter entails dysplastic morphologies in one or more hematopoietic lineages and carries increased risk of transformation to AML. *There is an apparent discrepancy between the paucity of peripheral blood elements and the hypercellularity in the bone marrow, which occurs because ineffective hematopoiesis leads to increased apoptosis in the marrow.*

There are several subtypes of MDS, depending on whether dysplasia involves one or more cell lineages and the percentage of blasts in the blood or bone marrow. ***All subtypes show refractory anemia and/or other cytopenia. Erythrocytosis, leukocytosis and thrombocytosis do not occur in MDS, unlike the MPNs (see above).*** In MDS, there are less than 20% blasts in the blood or bone marrow, which is different from acute leukemias, in which blood or bone marrow have 20% blasts or greater. Progression of MDS to AML (i.e., progression from ineffective hematopoiesis to a proliferative state) occurs in 30%–40% of cases that usually have genetic instability. This progression coincides with more genetic abnormalities. Some low-grade MDS subsets have more stable clinical courses and do not progress, or progress rarely, to AML.

ETIOLOGIC FACTORS: MDSs may be either primary (de novo) or secondary (therapy related). Patients with secondary MDSs usually have received radiation or chemotherapy (particularly alkylating agents or topoisomerase II inhibitors). Other risk factors include benzene exposure, cigarette smoking and congenital disorders such as Fanconi anemia or Kostmann syndrome.

PATHOLOGY: Subclassification of MDS is based on whether one or more of the hematopoietic lineages show **dysplasia,** and on the percentage of myeloblasts. Dysplasia is most often seen in erythroid precursors, which show megaloblastoid changes, multinucleation, nuclear budding, bridging between nuclei and karyorrhexis (Fig. 26-40). Erythroid precursors with iron-laden mitochondria around the nuclei **(ringed sideroblasts)** occur in several subtypes of MDS (Fig. 26-41A). Dysgranulopoietic features include nuclear hyposegmentation (pseudo-Pelger-Huët cells)

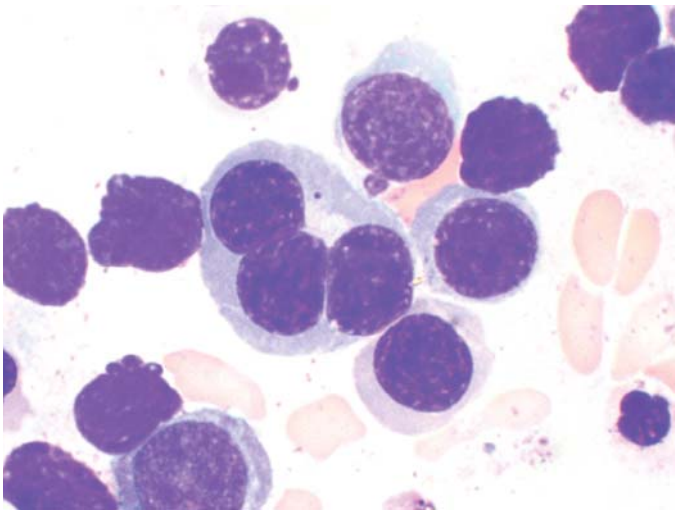

FIGURE 26-40. Myelodysplastic syndrome. Dysplastic, multinucleated, megaloblastoid erythroid precursors are shown.

and cytoplasmic hypogranulation. Dysplastic megakaryocytes may be mononuclear or hypolobated or show nuclear separation (Fig. 26-41B). Careful elucidation of the blast percentage is important in assigning an MDS subcategory and predicting the likely clinical course of the disease.

Cytogenetic and molecular studies are essential to diagnosing, treating and assessing prognosis of MDSs. Conventional cytogenetic tests identify clonal abnormalities in half of cases. If a patient has isolated deletion of the long arm of chromosome 5 (5q–), macrocytic anemia, megaloblastoid erythropoiesis with or without ringed sideroblasts and normal or increased platelets with monolobated megakaryocytes, that patient is likely to be an elderly woman and to have a more favorable prognosis. By contrast, deletion of chromosome 7 (7q–) has an unfavorable prognosis (Table 26-14). ***More chromosomal abnormalities augur less favorable outcomes.***

Other techniques have identified additional recurrent mutations. Most of these involve genes encoding components of the epigenetic regulation or RNA spliceosome machinery (see Chapter 5). These findings suggest that epigenetic factors play a large role in the pathogenesis of MDS.

CLINICAL FEATURES: MDS usually occurs in older patients, with a median age of 70. The WHO classification of MDS subtypes is beyond the scope of this discussion. ***However, in general, MDSs present with symptoms related to peripheral blood cytopenias: weakness in anemia, recurrent infections in neutropenia and bleeding in thrombocytopenia. Up to 40% of patients with MDS progress to AML.*** Progression to AML and overall prognosis depend on the morphologic subtype of MDS. Increased numbers of blasts, complex cytogenetic abnormalities, certain specific mutations and increased cytopenia confer a worse prognosis.

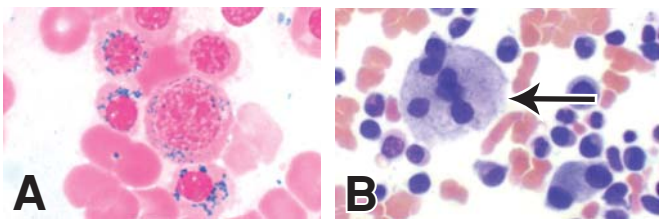

FIGURE 26-41. Myelodysplastic syndrome. A. Smear of a bone marrow aspirate stained with Prussian blue shows an erythroid precursor cell containing iron-laden mitochondria that encircle the nuclei (ringed sideroblast). **B.** Dysplastic megakaryocyte with nuclear separation (*arrow*).

Acute Myeloid Leukemia Is a Clonal Proliferation of Myeloblasts in the Marrow, with Their Subsequent Appearance in Blood and Possibly in Extramedullary Tissues

A diagnosis of AML requires greater than or equal to 20% myeloblasts in the blood or bone marrow. These criteria are relaxed in cases of several AML types with specific cytogenetic abnormalities (Table 26-14). AML with t(15;17)(q22;q12) is acute promyelocytic leukemia (APL). Such types are defined as AML regardless of blast cell count. If less than 20% blasts are present in AMLs without recurrent cytogenetic abnormalities, the disease should be classified in the MDS or MPN categories. There are 6 distinct types of AML (Table 26-16):

1. **AML with recurrent genetic abnormalities**
2. **AML with myelodysplasia-related changes**
3. **Therapy-related myeloid neoplasms**
4. **AML, not otherwise specified**
5. **Myeloid sarcoma**
6. **Myeloid proliferations related to Down syndrome**

Acute leukemias can derive from either myeloid (70%) or lymphoid (30%) lineages. The latter are discussed below under lymphoid malignancies.

ETIOLOGIC FACTORS: Most cases of AML are of unknown etiology. Some cases are attributed to prior radiation, cytotoxic chemotherapy or benzene exposure. AML increased after the detonation of atomic bombs in Hiroshima and Nagasaki. Cigarette smoking doubles the risk for AML (see Chapter 8).

PATHOLOGY: Malignant myeloblasts of AML are present in the bone marrow and, usually, in the blood. Typically, the malignant cells pack the bone marrow and displace normal hematopoietic cells (Fig. 26-42). Myeloblasts are medium-sized to large cells with round or slightly irregular nuclei and immature nuclear chromatin. Some cases show eosinophilic, slender cytoplasmic inclusions, ***Auer rods***, which are coalesced primary granules (Fig. 26-43). Auer rods are specific for the myeloid lineage and preclude a diagnosis of lymphoblastic leukemia.

Immunophenotyping by flow cytometry, chromosomal analysis (cytogenetic studies) and molecular studies are essential for correct classification of AML. Myeloid antigens frequently expressed include CD13, CD15, CD33 and CD117 (*c-kit*), in addition to the progenitor cell marker CD34. AML with megakaryoblastic differentiation may show the platelet/megakaryocyte markers CD41 and CD61 (platelet Gp IIb/IIIa complex).

In addition, cytochemical staining, including myeloperoxidase, Sudan black and nonspecific esterase (NSE), remain helpful in classifying AML cases.

TABLE 26-16
WHO CLASSIFICATION OF ACUTE MYELOID LEUKEMIA (AML)

Acute Myeloid Leukemia with Recurrent Genetic Abnormalities
AML with t(8;21)(q22;q22); RUNX1-RUNX1T1
AML with abnormal bone marrow eosinophils inv(16)(p13q22) or t(16;16)(p13;q22); CBFβ/MYH11
Acute promyelocytic leukemia [AML with t(15;17)(q22;q12)(PML/RARα] and variants **(M3)**
AML with (9;11)(p22;q23); MLLT3-MLL
AML with t(6;9)(p23:q34); DEK-NUP214
AML with inv(3)(q21q24.2) or t(3;3)(q21;126.2); RPN1-EVI1
AML (megakaryoblastic) with t(1;22)(p13;q13); RBM15-MKL1
AML with gene mutations (NPM1, CEBPA, FLT3, etc.)
Acute Myeloid Leukemia with Myelodysplasia-Related Changes
Following a myelodysplastic syndrome or myelodysplastic syndrome/myeloproliferative disorder
Without antecedent myelodysplastic syndrome
Therapy-Related Myeloid Neoplasms
Alkylating agent related
Topoisomerase type II inhibitor related (some may be lymphoid)
Other types
Acute Myeloid Leukemia Not Otherwise Categorized
AML minimally differentiated **(M0)**
AML without maturation **(M1)**
AML with maturation **(M2)**
Acute myelomonocytic leukemia **(M4)**
Acute monoblastic and monocytic leukemia **(M5)**
Acute erythroid leukemia **(M6)**
Acute megakaryoblastic leukemia **(M7)**
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid Sarcoma
Myeloid Proliferations Related to Down Syndrome

PML = promyelocytic leukemia; RAR = retinoic acid receptor; WHO = World Health Organization.

CLINICAL FEATURES: ***Most cases of AML occur in adults, with a median age of 67 at onset. The major problems associated with AML reflect progressive accumulation in the marrow of immature myeloid cells that cannot differentiate and mature further.*** Although leukemic myeloblasts divide more slowly than do normal hematopoietic precursor cells, they also undergo spontaneous cell death less often than normal cells. The expanded pool of abnormal leukemic blasts overwhelms the marrow and suppresses normal hematopoiesis. ***As a result, the major clinical problems in AML are leukopenia, thrombocytopenia and anemia.*** Infections, especially with opportunistic organisms (e.g., fungi), are common, as are cutaneous bleeding (petechiae and ecchymoses) and serosal hemorrhages over viscera. Untreated AML has a dismal prognosis. Chemotherapy leads to remission in over half of patients, but relapses are common and overall 5-year survival is under 30%. Bone marrow transplantation is a common mode of treatment for high-risk forms of AML and for AML in relapse.

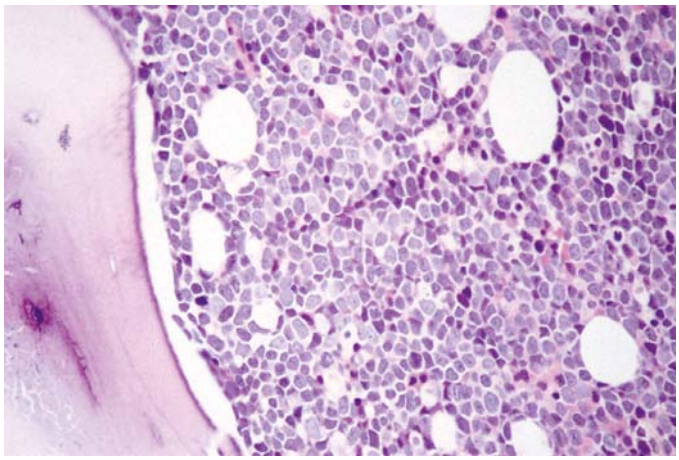

FIGURE 26-42. Acute myelogenous leukemia. A bone marrow section is hypercellular, resulting from effacement of the normal architecture by myeloblasts.

Selected Acute Myeloid Leukemia Subtypes

AML WITH RECURRENT GENETIC ABNORMALITIES: There are multiple cytogenetic abnormalities associated with this category of AML (Table 26-14). These include AML with mutated *NPM1* or *CEBPA*.

AML with t(15;17)(q22;q12), which is **APL**, ***is defined by a translocation involving the*** promyelocytic leukemia 1 (***PML1***) ***gene at 15q22 and the retinoic acid receptor-α (RARA) gene at 17q12.*** APL mainly affects middle-aged patients and accounts for 5%–10% of AMLs.

APL is a paradigm for a molecularly defined disease in which the underlying genetic defect determines the type of treatment. The translocation results in the *PML/RARA* fusion gene that encodes a functional retinoic acid receptor. The

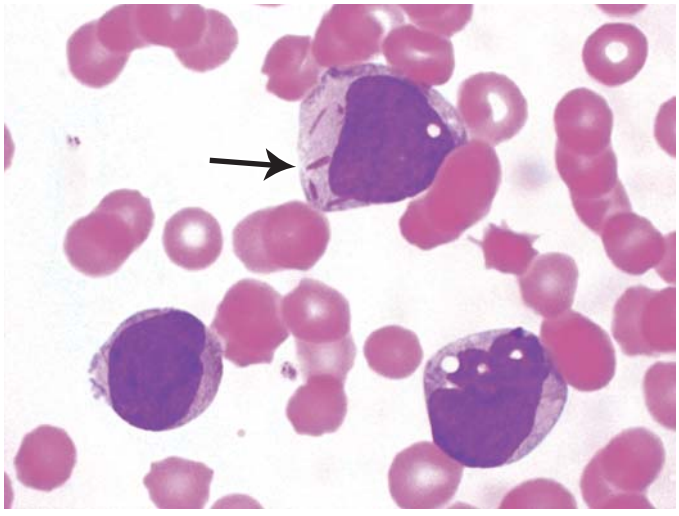

FIGURE 26-43. Acute promyelocytic leukemia. Auer rods are prominent (*arrow*).

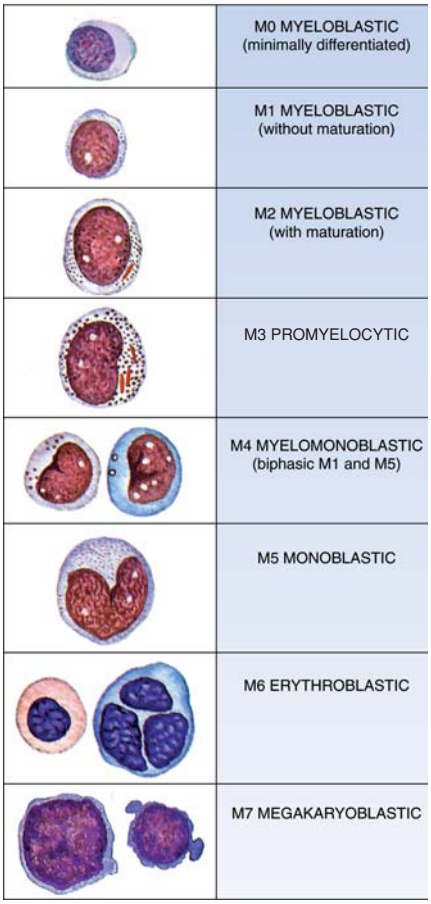

FIGURE 26-44. Morphology of acute myeloid leukemia (AML) in the traditional French-American-British (FAB) classification, now within the framework of the World Health Organization (WHO) classification "AML-not otherwise specified."

receptor can be targeted by all-*trans*-retinoic acid (ATRA), which causes tumor cells to mature. The bone marrow is packed with tumor cells with promyelocytic morphologic features. Auer rods may be abundant. Leukemic cells react strongly for myeloperoxidase or Sudan black. ***Patients with APL frequently present with DIC.*** Senescent leukemic cells degranulate and activate the coagulation cascade. Treatment with ATRA induces maturation of the tumor cells and prevents both degranulation and DIC. The prognosis for APL is more favorable than for all other AMLs.

THERAPY-RELATED MYELOID NEOPLASMS: Cytotoxic radiation or chemotherapy for a prior malignancy can induce mutational changes that lead to secondary hematopoietic neoplasms one to several years after treatment. This category includes AMLs, MDSs and MPNs related to prior mutagenic therapies. Alkylating agents and radiation most often give rise to myelodysplasia and subsequent AML after 5–10 years. In contrast, topoisomerase II inhibitors (epipodophyllotoxins) lead to overt AML with latencies of 1–5 years. Nearly all therapy-related MPNs have cytogenetic abnormalities and poor prognoses.

ACUTE MYELOID LEUKEMIA, NOT OTHERWISE SPECIFIED: This set of leukemias does not meet the characteristics of any of the other subtypes of AML. They are thus grouped based on the older French-American-British (FAB) classification. The WHO classification incorporates the FAB scheme (Fig. 26-44):

- **AML with minimally differentiation:** The leukemic cells are immature myeloblasts with no defining morphologic or cytochemical criteria of the myeloid lineage. Immunophenotyping by flow cytometry establishes the myeloid nature of the tumor cells. The prognosis is unfavorable.
- **AML without maturation:** Less than 10% of the myeloid cells are promyelocytes or more mature myeloid cells. This disease occurs most often in middle-aged people.
- **AML with maturation:** More than 10% maturing myeloid cells (promyelocytes and later) are present.
- **Acute myelomonocytic leukemia (AMML):** This tumor is composed of a mixture of neutrophils and their precursors, plus monocytes and their precursors. The latter make up 26%–80% of tumor cells. AMML accounts for 5%–10% of AMLs.
- **Acute monoblastic/monocytic leukemia (AMoL):** At least 80% of myeloid leukemic cells have monocytic differentiation, including monoblasts, abnormal promonocytes and monocytes. AMoL constitutes 5%–8% of AMLs and is seen in younger patients.
- **Acute erythroid leukemia:** Acute erythroid leukemias feature prominent erythroid proliferation. There are 2 subtypes. Erythroleukemia is defined by erythroid precursors making up greater than 50% of all nucleated cells in the bone marrow, and at least 20% of the remaining nonerythroid population are myeloblasts. The second type, pure erythroid leukemia, is characterized by neoplastic immature cells committed to erythroid lineage making up greater than 80% of the bone marrow nucleated cells. A rare, more chronic form of this disease **(erythremic myelosis** or **di Guglielmo syndrome)** has pure erythroblasts.
- **Acute megakaryoblastic leukemia (AMegL):** At least 50% of the blasts show a megakaryocytic immunophenotype.

MYELOID SARCOMA: **Myeloid sarcoma is an extramedullary solid tumor of myeloblasts or monoblasts** (Fig. 26-45).

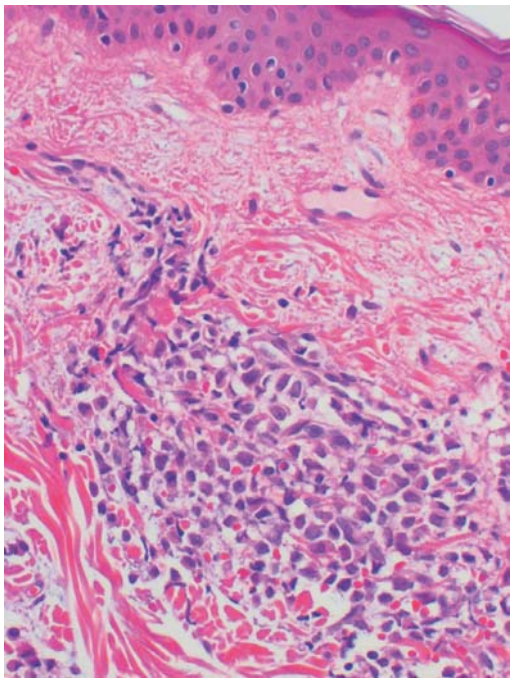

FIGURE 26-45. Myeloid sarcoma. The skin from a patient with acute monoblastic leukemia (leukemia cutis) shows neoplastic myeloid cells.

This entity is sometimes called a **chloroma** because of its greenish color, **granulocytic sarcoma** or **monoblastic sarcoma. Monoblastic differentiation** is uncommon and is most commonly associated with translocations involving the myelomonocytic leukemia (*MML*) gene (11q23). Myeloid sarcoma may evolve de novo or in association with AML, or it may represent the blast phase in myeloproliferative neoplasms. Prognosis is determined by the underlying leukemic process.

Disorders of the Lymphoid System

NORMAL LYMPH NODES AND LYMPHOCYTES

The lymphoid system consists of circulating T and B lymphocytes, natural killer cells (NK cells) and the secondary lymphoid organs, which mainly include the lymph nodes, spleen and thymus. In addition to the tonsils in the oro- and nasopharynx (Waldeyer ring), aggregates of organized lymphoid tissue known as mucosa-associated lymphoid tissue (MALT) are also present in extranodal sites, such as the gut, lungs and skin. Peyer patches in the terminal ileum are a prototypic example of MALT.

Lymphocytes in tonsils and Peyer patches arrive in those sites by migration through the tall endothelial cells of vessels, which are comparable to the postcapillary venules in lymph nodes. ***MALT plays an important role in immunologic protection of the host in areas vulnerable to potential invaders.*** IgA secretion is a key facet of this protection.

All three major types of lymphocytes (T cells, B cells and NK cells) develop from lymphoid stem cells in the bone marrow (Fig. 26-2). T cells mature and differentiate in the thymus. B cells undergo activation, transformation and selection in the lymph nodes and spleen. NK cells do not go through a thymic or lymph node education phase, but rather are released into the peripheral circulation, where they appear as large granular lymphocytes. All lymphocyte development entails a tightly controlled sequence of gene expression and silencing that leads to sequential gain and loss of nuclear material and changes cytoplasmic and/or surface antigen expression. ***Patterns of antigenic expression identify the lineage and maturation stage of normal and neoplastic lymphoid cells*** (see below and Chapter 4).

LYMPH NODES: Lymph nodes are located along lymphatic vessels throughout the body. Normal lymph nodes are typically round to bean shaped, and less than 1 cm. Larger nodes are considered clinically enlarged and may be abnormal microscopically. Lymph nodes are organized in regional collections, called chains or groups (e.g., cervical lymph node chain). Sometimes many nodes within a chain or group may be enlarged and/or matted together, often a feature of malignancy. Staging malignancies depends on identifying lymph node chains involved by tumor.

Individual lymph nodes are surrounded by a thin fibrous capsule with internally radiating trabeculae, which provides structural support (Fig. 26-46). Subjacent to the fibrous capsule sits the subcapsular sinus, which receives lymph fluid (potentially containing antigens) from **afferent lymphatic vessels** that penetrate the node at several points along the outer capsule. The **subcapsular sinus** extends along the penetrating fibrous trabeculae, forming trabecular sinuses, which ultimately connect to the efferent lymphatic vessels. The sinuses are lined by macrophages, which are involved in antigen presentation (see Chapter 4). The arrangement of the sinuses maximizes exposure to foreign antigens present in the lymph to macrophages and immunoreactive lymphocytes in the lymph nodes.

Lymph nodes are composed of an **outer cortex** and an **inner medulla** (Fig. 26-46). The cortex is subdivided into a follicular area (which contains mostly B cells) and a paracortical area (predominantly T cells, plus many postcapillary venules). Lymphocytes from the circulation enter the lymph node cortex by migrating through the tall endothelial cells of the postcapillary venules in the **paracortex**. T cells tend to remain in the paracortex, while B lymphocytes home to the **follicle germinal centers**.

The B-cell–rich cortex contains two types of follicles: (1) immunologically inactive follicles, called **primary follicles;** and (2) immunologically active follicles, called **secondary follicles**. Primary follicles are cohesive aggregates of small lymphocytes without well-defined germinal centers or mantle zones. Secondary follicles contain germinal centers in which large noncleaved lymphocytes **(centroblasts)** mingle with small and larger lymphocytes with cleaved nuclei **(centrocytes)**.

The germinal centers also include scattered macrophages with phagocytized nuclear and cytoplasmic debris ("tingible body" macrophages) and **follicular dendritic cells (FDCs)** that are stellate cells with long cytoplasmic processes. FDCs present antigens to follicular lymphocytes. Macrophages, and to a lesser extent dendritic cells, provide growth factors for activated B cells.

The T-cell–rich paracortex, also known as the deep cortex or parafollicular area, is both between the B-cell follicles and deep to them. In addition to T cells, scattered macrophages and **interdigitating dendritic cells (IDCs)** are present in the paracortex. IDCs process and present antigens to T lymphocytes.

B-LYMPHOCYTE DEVELOPMENT: Normal **B-cell progenitor cells** arise in the bone marrow (Fig. 26-47) (called hematogones), where they are present in relatively low numbers. They have a similar phenotype to the cells of **precursor B-cell acute lymphoblastic leukemia (B-ALL):** both hematogones and B-ALL cells express the early B-cell surface antigens **CD10** (called common acute leukemia/lymphoma antigen [CALLA]) and **CD19,** and the nuclear enzyme **terminal deoxynucleotidyl transferase**. These cells largely lack CD20, a marker present at high levels on the more mature B-cell populations, and they also lack cell membrane Ig light (L) chains. Hematogones increase in number during viral infections and in bone marrow recovery after chemotherapy or stem cell transplantation.

A fraction of the bone marrow-derived progenitor B cells leave the marrow and home to lymph node germinal centers, where further development and selection occurs. Specifically, B cells with sufficient affinity for antigen survive the germinal center reaction and eventually leave the follicle compartment. As B lymphocytes mature, the genes for Ig heavy (H) chains are rearranged, leading to the synthesis of IgM antibodies. In precursor (progenitor) B cells, IgM is expressed in the cytoplasm. Mature B cells express the pan B-cell antigens CD19, CD20 and CD22, and surface Ig light and heavy chains. After activation and clonal expansion in

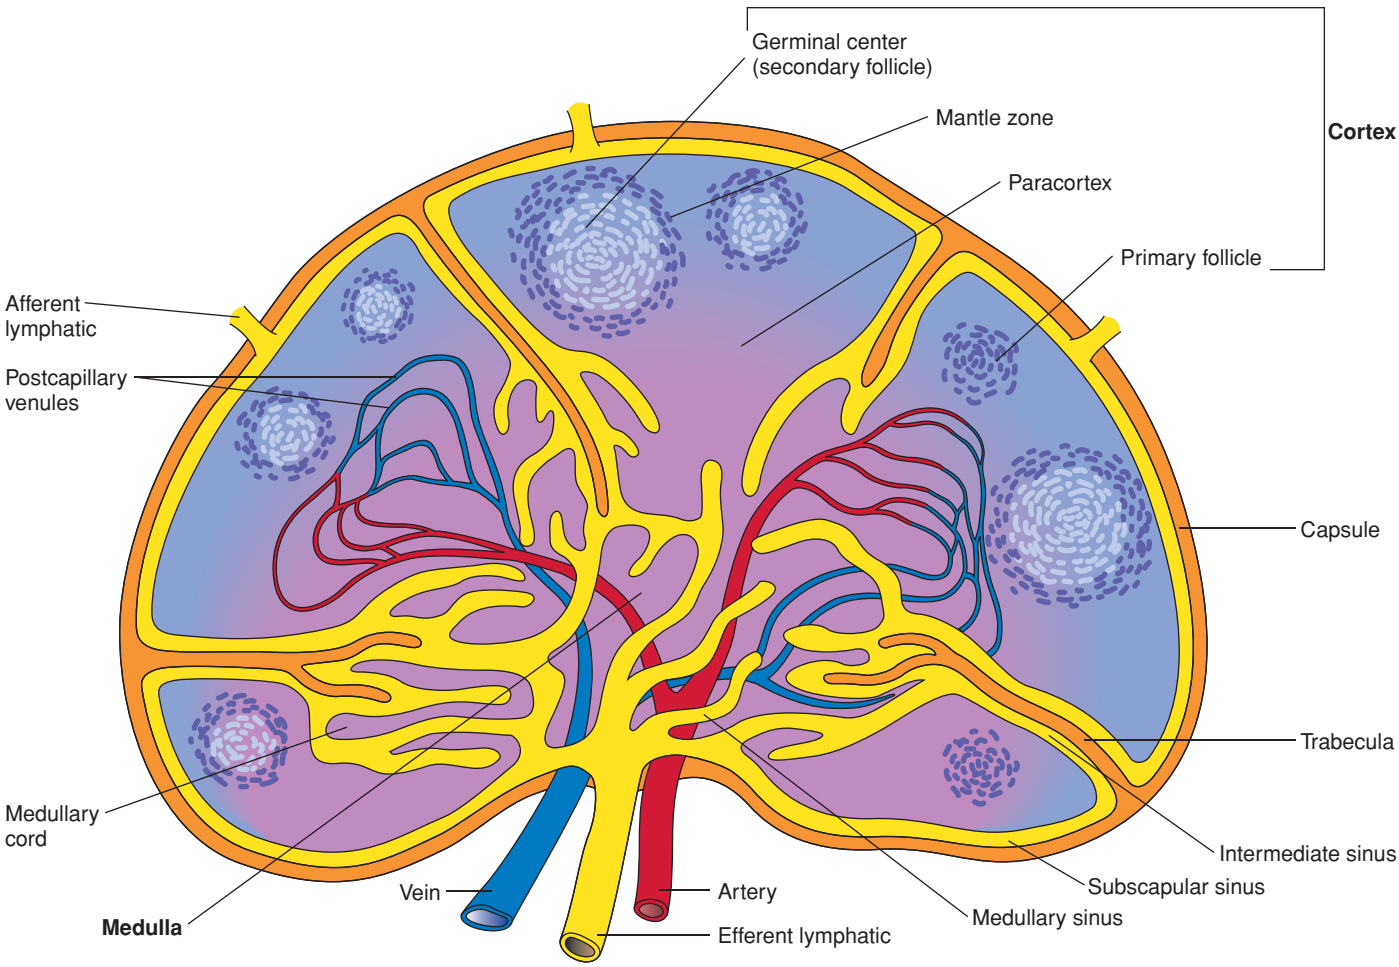

FIGURE 26-46. Structure of normal lymph node.

germinal centers, B cells migrate to the B-cell–dependent medullary cords of the lymph nodes. There, they become Ig-secreting **plasma cells,** or they exit the lymph nodes as **memory B cells**.

Plasma cells have eccentric nuclei with clumped chromatin marginated at the nuclear membrane, traditionally described as "clock-face chromatin." In their abundant blue-purple cytoplasm, plasma cells often have a clear paranuclear clear zone representing the Golgi complex. Plasma cells no longer normally express CD20 or surface Ig.

T LYMPHOCYTES: The lymphoid stem cells that migrate from the bone marrow to the thymus are exposed to a number of thymic hormones that induce sequential expression of pan T-cell surface antigens such as CD2, CD3, CD5 and CD7, and CD4 or CD8 (Fig. 26-48). ***Recombination of T-cell receptor genes generates a diverse population of T cells, each of which can recognize a single antigen.*** T cells that cannot bind a foreign antigen with high affinity and T cells that recognize self-antigens are eliminated via apoptosis. Once mature and educated, T cells leave the thymus to lymph nodes, spleen and peripheral blood to become **postthymic T cells**.

When exposed to foreign (nonself) receptor-specific antigen in the context of major histocompatibility complex (MHC) class II molecules, the $CD4^+$ T cells become activated via release of mitogenic growth factors, such as IL-1 and IL-2. The antigens presented to T-helper cells are peptide fragments derived from partial digestion of foreign proteins by macrophages and/or other antigen-presenting cells. The T-helper cells in turn interact with B lymphocytes that express the same antigenic specificity and induce the latter to proliferate and differentiate into plasma cells. The latter produce antigen-specific antibody.

$CD8^+$ cells are activated when their receptors recognize peptide antigens presented in association with MHC class I human leukocyte antigen (HLA) molecules. They then become suppressor/cytotoxic cells. $CD8^+$ cells limit expansion of activated B cells and stop their immune response in a negative feedback response loop.

NATURAL KILLER AND CYTOTOXIC LYMPHOCYTES: A small subset of lymphocytes lack the usual T- or B-cell antigens. These are **natural killer cells**. NK cells are cytotoxic effectors that do not require antigen recognition to initiate their killing function. They are large lymphocytes with granular cytoplasm (i.e., **large granular lymphocytes**) (Fig. 26-49). They differ from mature T cells in that they lack surface CD3 and possess other surface antigens, such as CD16 and CD56.

Lymphocytes have diverse morphologies in stained peripheral blood and bone marrow smears, as well as in tissue sections. Like other blast cells, immature lymphoid cells have high nuclear-to-cytoplasmic ratios, fine chromatin and visible nucleoli. During maturation and differentiation,

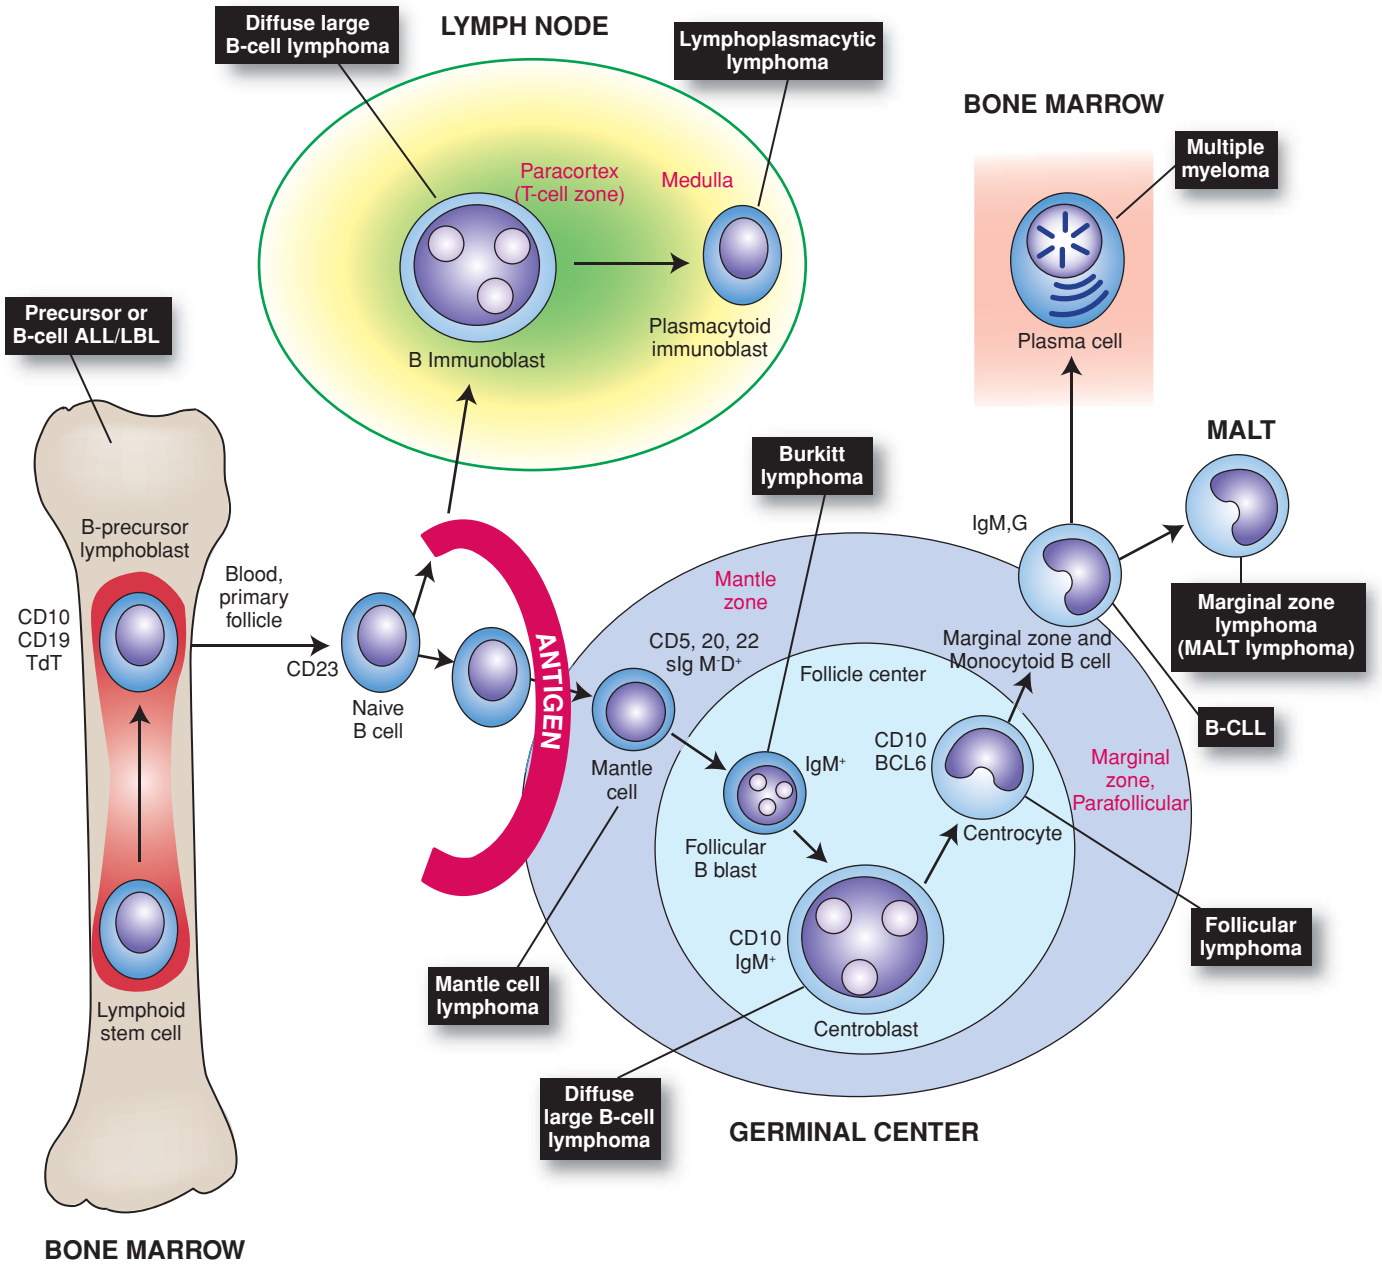

FIGURE 26-47. Pathway of normal B-cell differentiation and corresponding B-cell neoplasms. Following the lymphoid stem cell and precursor stage in the bone marrow, B cells mature into naive B lymphocytes and home to the secondary lymphoid organs (primarily lymph nodes). The germinal-center reaction represents an important turntable for immunoglobulin variable-region gene mutations, Ig heavy-chain switch and differentiation into plasma cells and memory B cells. Cluster designation (CD) markers are shown. B-cell immunoblasts and plasmacytoid immunoblasts reside in the T-cell–rich paracortex and medulla, respectively. Marginal zone B cells home to mucosa-associated lymphoid tissue (MALT) sites and bone marrow. Neoplastic transformation occurs at all phases of B-cell differentiation. *ALL/LBL* = acute lymphoblastic leukemia/lymphoma; *B-CLL* = B-cell chronic lymphocytic leukemia; *Ig* = immunoglobulin.

lymphoid cells can range from large to small, but they generally show more clumped nuclear chromatin and variable amounts of cytoplasm (with or without granules) compared to the immature (blast-like) cells. While a variety of cell sizes (including many large transformed or activated cells) are normally present in the secondary lymphoid organs, the lymphocytes that circulate in the blood and those in the bone marrow are mainly small and heterogeneous (Fig. 26-49).

In peripheral blood smears, transformed cytotoxic T cells are **variant lymphocytes** (sometimes called **"atypical lymphocytes"**). Variant lymphocytes tend to have abundant blue-gray cytoplasm and multiple nucleoli in Wright-Giemsa–stained smears. The same cells in tissue sections stained with hematoxylin and eosin have round to oval nuclei, one to several eosinophilic nucleoli apposed to their nuclear membranes and abundant clear to purple cytoplasm. ***T and B cells appear identical in routinely stained smears or tissue sections. Precise identification and characterization of lymphoid cells requires flow cytometric or immunohistochemical analysis***. In the blood, 60%–80% of circulating lymphocytes are T cells, 10%–15% are B cells and the rest are NK cells.

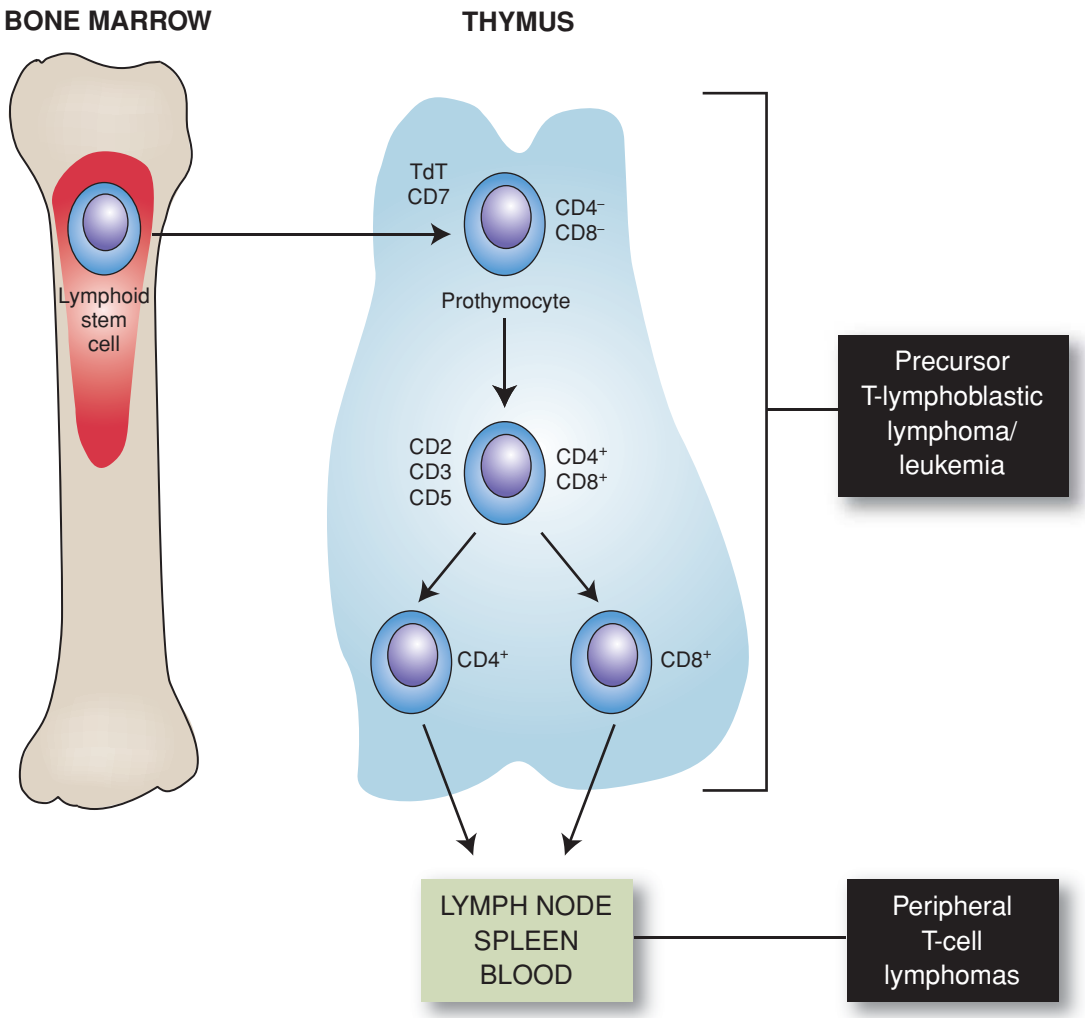

FIGURE 26-48. Pathways of normal T-cell development and corresponding T-cell neoplasms. *CD* = cluster designation; *TdT* = terminal deoxynucleotidyl transferase.

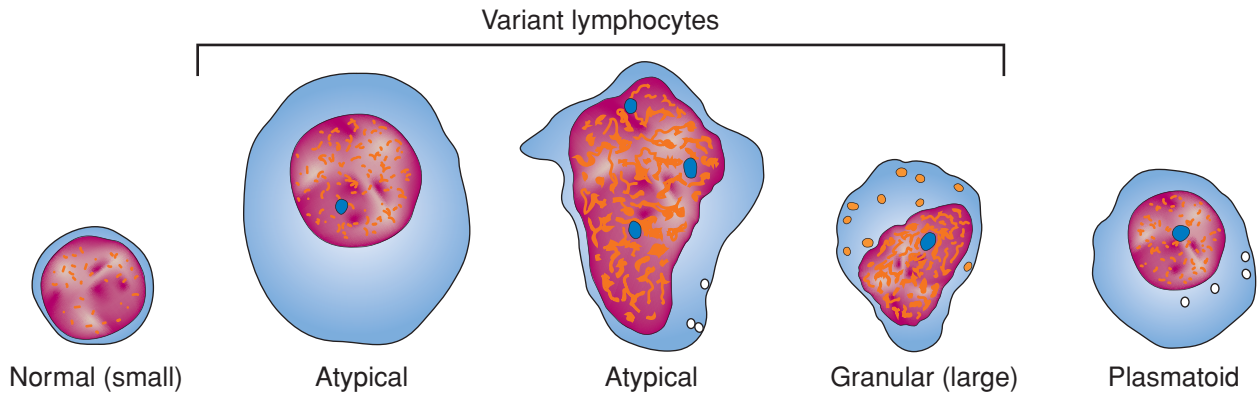

FIGURE 26-49. Lymphocyte morphology. The term "variant lymphocytes" covers atypical lymphocytes and large granular lymphocytes. **Atypical lymphocytes** are large and exhibit deep blue to pale gray cytoplasm; they are seen in benign reactive processes. **Large granular lymphocytes** are medium to large lymphoid cells with some pink cytoplasmic granules. They are suppressor T lymphocytes, some with natural killer (NK) function, and may be increased in benign or malignant disorders. **Plasmacytoid lymphocytes** have abundant blue cytoplasm and are seen in some reactive disorders.

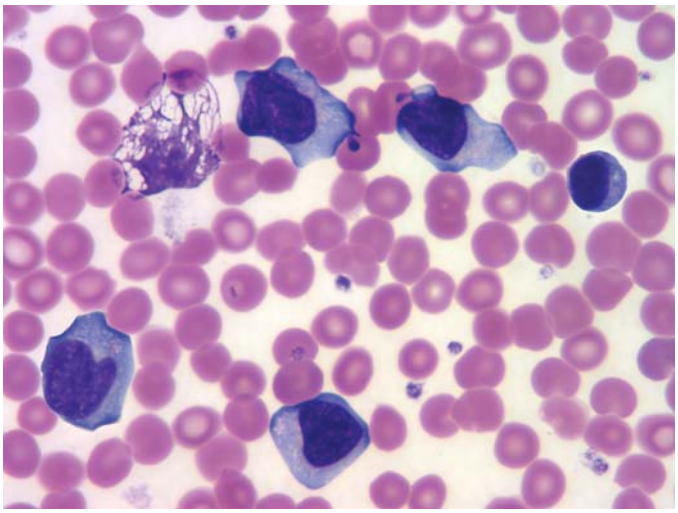

FIGURE 26-50. Infectious mononucleosis. An absolute lymphocytosis caused by a heterogeneous population of small and larger lymphoid cells, including atypical lymphocytes, is characteristic of this Ebstein-Barr virus–driven disorder.

BENIGN DISORDERS OF THE LYMPHOID SYSTEM

In Benign Lymphocytosis, Absolute Numbers of Circulating Lymphocytes Are Transiently Increased

The upper limits of normal are 4000/μL in adults, 7000/μL in children and 9000/μL in infants. Lymphocytes in benign lymphocytoses are usually reactive appearing and morphologically heterogeneous, but atypical lymphocytes may also be seen (Figs. 26-49 and 26-50). Infectious mononucleosis due to EBV infection is the most common cause of reactive lymphocytosis, but other viral infections can produce similar syndromes (e.g., CMV). Other less common causes of reactive lymphocytosis include pertussis, chronic bacterial infections such as tuberculosis and brucellosis, stress and cigarette smoking. Persistent absolute lymphocytosis, greater than 4000/μL, particularly in adults, raises suspicion for a lymphoproliferative disorder and deserves further evaluation.

Bone Marrow Plasmacytosis May Signify a Plasma Cell Disorder

- **Plasma cells in peripheral blood:** It is uncommon to find plasma cells in the blood. When seen, they are usually part of the spectrum of lymphoid cells in infectious mononucleosis–like syndromes caused by viruses other than EBV. The presence of circulating plasma cells in the blood of an adult raises suspicion for a plasma cell neoplasm, such as plasma cell myeloma (see below).
- **Reactive bone marrow plasmacytosis:** Plasma cells normally account for less than 3% of hematopoietic cells in the bone marrow. If they make up greater than 3% of bone marrow cells, plasmacytosis is diagnosed, and it may be polyclonal or monoclonal. In children and young adults, most plasmacytoses are caused by reactive conditions such as chronic infections or systemic inflammatory disorders. Autoimmune diseases are a particularly common cause of bone marrow plasmacytosis, especially in women. A plasmacytosis can also accompany a metastatic neoplasm in the bone marrow. ***Bone marrow plasmacytosis greater than 10% is typically associated with a plasma cell neoplasm.*** In both reactive and neoplastic plasma cell proliferations, immunoglobulin may accumulate in the cytoplasm to form prominent eosinophilic globules, known as Russell bodies. Similarly, benign and neoplastic plasma cells may contain nuclear pseudoinclusions (Dutcher bodies), which represent immunoglobulin invaginated into the nucleus and seen in cross-section.

Lymphocytopenia Usually Reflects a Decrease in T-Helper Lymphocytes

Peripheral blood lymphocytopenia is defined as a blood lymphocyte count less than 1500/μL in adults or less than 3000/μL in children. Since the predominant lymphocytes in the blood are T-helper ($CD4^+$) cells, lymphocytopenia generally means decreased $CD4^+$ T cells. There are several mechanisms by which lymphocytopenia occurs:

- **Decreased lymphocyte production:** Several congenital and acquired immunodeficiency syndromes entail reduced generation of lymphocytes. Impaired T-cell production also occurs with some lymphomas, such as classical Hodgkin lymphoma, particularly in advanced stages.
- **Increased lymphocyte destruction:** Certain therapies, such as irradiation, chemotherapy, administration of antilymphocyte globulin, adrenocorticotropic hormone (ACTH) and corticosteroids, destroy lymphocytes. Some viral infections, particularly HIV, cause T-cell death, with resultant lymphopenia.
- **Loss of lymphocytes:** Disorders associated with damage to intestinal lymphatics can lead to loss of lymph fluid and lymphocytes into the gut lumen. Such diseases include protein-losing enteropathies, Whipple disease and conditions of increased central venous pressure (e.g., right-sided heart failure, chronic constrictive pericarditis). Immunologic damage to lymphocytes may occur in collagen vascular diseases, such as systemic lupus erythematosus.

Reactive Lymphoid Hyperplasia Is a Response to Diverse Stimuli, Including Infections, Inflammation and Tumors

Lymph nodes may undergo hyperplasia of all cellular components, or any combination of B cells, T cells and mononuclear phagocytes, in response to a variety of infectious, inflammatory and neoplastic disorders (Fig. 26-51).

The histology and magnitude of lymph node enlargement in reactive hyperplasia are functions of the age of the patient (children tend to show greater immunoreactivity than do adults), the immunologic competence of the host and the inciting stimulus.

Acute suppurative and necrotizing lymphadenitis occurs in lymph nodes that drain sites of acute bacterial or fungal infections. Such nodes enlarge rapidly because of edema and hyperemia, and are usually tender because the capsule becomes distended. Lymph node sinuses and stroma are infiltrated by neutrophils and variable numbers of bland macrophages. Well- or poorly defined granulomas are common, and necrosis can be focal and

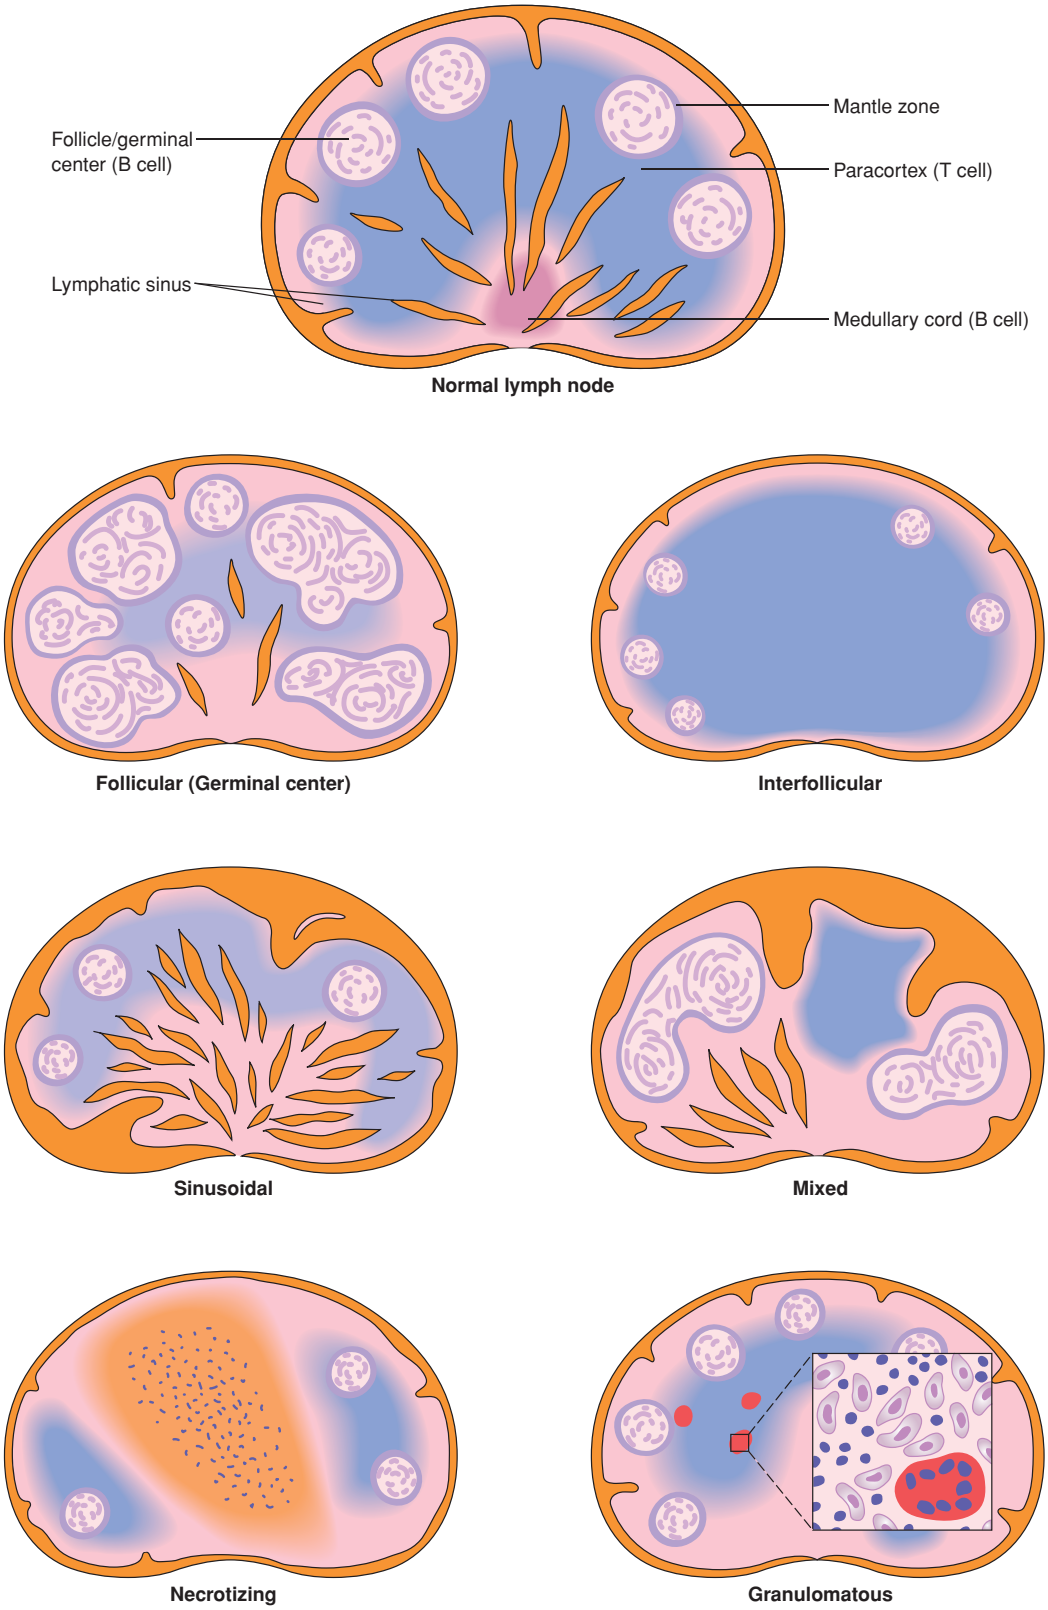

FIGURE 26-51. Patterns of reactive lymphadenopathy. The major patterns of reactive hyperplasia are contrasted with the architecture of a normal lymph node. **Follicular hyperplasia,** with an increased number of enlarged and irregularly shaped follicles, is characteristic of B-cell immunoreactivity. **Interfollicular hyperplasia** with expansion of the paracortex is typical of T-cell immunoreactivity. The **sinusoidal pattern** is typified by expansion of sinuses by bland macrophages. This patten is seen in reactive proliferations of the mononuclear–phagocyte system. A **mixed pattern** of follicular, interfollicular and sinusoidal hyperplasia is common in a variety of complex immune reactions. In **necrotizing lymphadenitis,** variable zones of necrosis are found within the lymph nodes, with or without the presence of neutrophils. Cohesive clusters of macrophages and occasional multinucleated giant cells are characteristic of the **granulomatous inflammation pattern**.

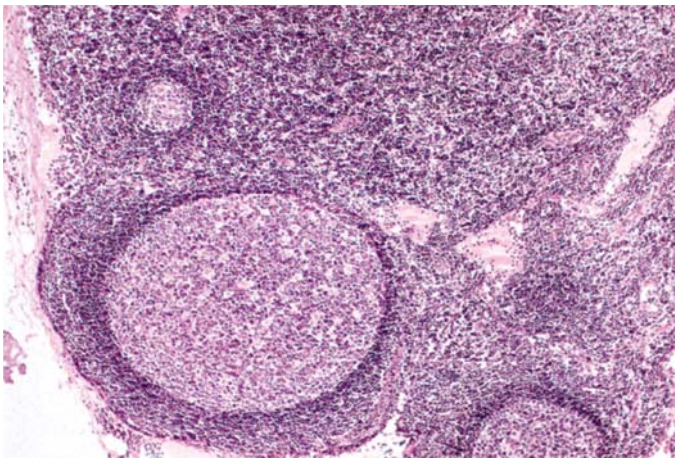

FIGURE 26-52. Lymph node with reactive follicular hyperplasia. A section of a hyperplastic lymph node shows prominent follicles (germinal centers) containing numerous macrophages with pale cytoplasm.

geographic or extensive. The location of the nodes involved in reactive lymphadenopathy often provides a clue to its cause. For example, posterior auricular lymph nodes are commonly enlarged in rubella infection; occipital lymph nodes in scalp infections; posterior cervical lymph nodes in toxoplasmosis; axillary lymph nodes in infections of the arms or chest wall; and inguinal lymph nodes in venereal infections and infections of the legs. Generalized lymphadenopathy may occur in systemic infections, hyperthyroidism, drug hypersensitivity reactions and autoimmune diseases.

Follicular Hyperplasia

Hyperplasia of secondary follicles (germinal centers) and plasmacytosis of medullary cords indicate B-cell immunoreactivity. In **nonspecific reactive follicular hyperplasia,** prominent hyperplastic follicles occur mainly in the cortices of the lymph node (Figs. 26-51 and 26-52). Follicles are round or irregularly shaped and may be fused or confluent. The activated B cells in these follicles range from small cells with irregular, cleaved nuclei to large immunoblasts. Many mitoses reflect rapid proliferation of activated B lymphocytes. Scattered benign macrophages, with abundant pale cytoplasm containing pyknotic nuclear and cytoplasmic debris, impart a characteristic "starry sky" pattern to benign follicle centers. A well-defined mantle of normal small B cells surrounds the follicles, sharply separating them from interfollicular regions.

The cause of nonspecific reactive follicular hyperplasia is often unknown, although a virus, drug or inflammatory process is often likely. The clinical course involves rapid and complete resolution of lymphadenopathy after the inciting stimulus disappears.

Reactive lymphadenopathy (either localized or generalized) due to follicular hyperplasia and interfollicular plasmacytosis is common in rheumatoid arthritis. It also occurs early in HIV infection. It is worth noting here that the lymph nodes in patients with HIV/AIDS show a high incidence of superimposed lymphomas (such as diffuse B-cell lymphoma, Burkitt lymphoma and classical Hodgkin lymphoma), Kaposi sarcoma or opportunistic infection (e.g., with atypical mycobacteria or CMV).

Interfollicular Hyperplasia

Interfollicular or diffuse hyperplasia of the deep cortex or paracortex is characteristic of T-lymphocyte immunoreactivity.

Nonspecific reactive interfollicular hyperplasia (Fig. 26-51) is most commonly caused by viral infections or immunologic reactions. Although the precise cause is often unknown, the condition usually resolves promptly. Interfollicular lymph node hyperplasia is common in viral diseases, including infectious mononucleosis, varicella-herpes zoster infection, measles and CMV lymphadenitis.

Systemic lupus erythematosus (SLE) is often associated with lymphadenopathy characterized by interfollicular hyperplasia with prominent immunoblasts and plasma cells, and variably pronounced necrosis. Arteriolitis with fibrinoid necrosis of vessel walls is common. Unlike acute suppurative and necrotizing lymphadenitis, neutrophils are absent in SLE-related lymphadenitis.

Mixed Patterns of Reactive Lymph Node Hyperplasia

Some infectious diseases are associated with mixed patterns of lymphoid hyperplasia, in which several different features are prominent. For example, in **toxoplasmosis,** one sees prominent follicular hyperplasia and small collections of epithelioid macrophages in interfollicular regions and around the hyperplastic follicles (Figs. 26-51 and 26-53). **Cat-scratch disease** elicits follicular hyperplasia and suppurative granulomas with a stellate appearance (Fig. 26-54). Lymphadenitis caused by **lymphogranuloma venereum** and **tularemia** (see Chapter 9) resembles that seen in cat-scratch disease.

Sinus Histiocytosis Is an Increase in Macrophages Lining Nodal Sinuses

In sinus histiocytosis, tissue macrophages in nodal subcapsular and trabecular sinuses are more prominent (Figs. 26-51 and 26-55). Sinus histiocytes derive from blood monocytes. Sinus histiocytosis is common in lymph nodes draining

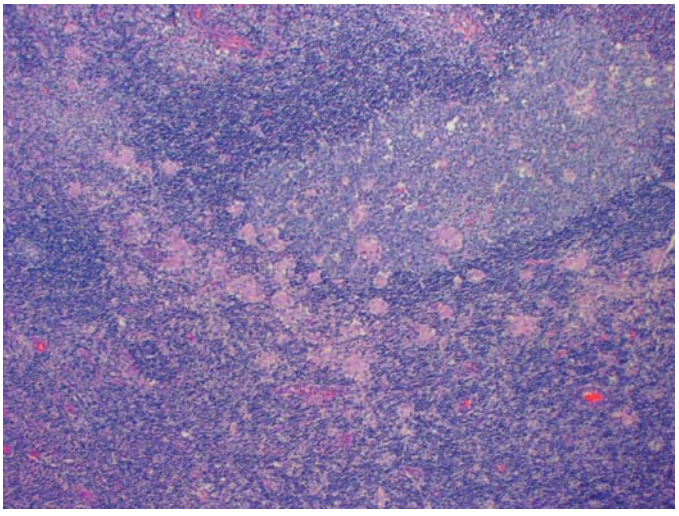

FIGURE 26-53. Toxoplasmosis. A section of a lymph node displays clusters of pink epithelioid macrophages and follicular hyperplasia.

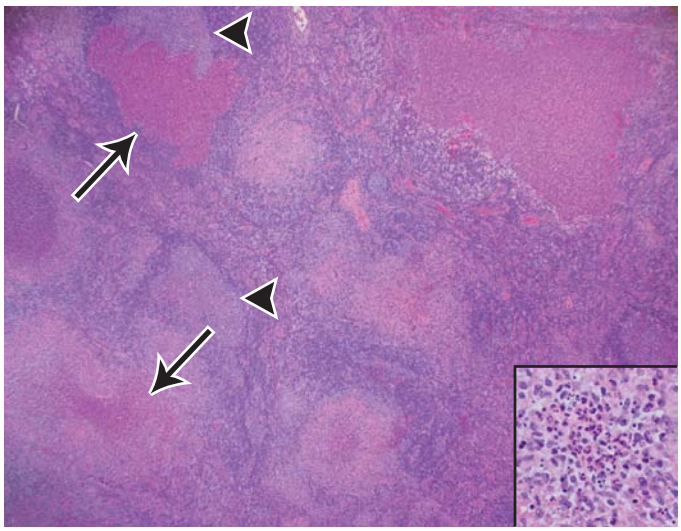

FIGURE 26-54. Cat-scratch disease. Follicular hyperplasia (*arrowheads*) is punctuated by irregularly shaped granulomas (*arrows*), which occasionally impinge on the germinal centers. **Inset.** The granulomas are composed of central cores of neutrophils with surrounding macrophages.

carcinomas and, less often, inflammatory and infectious foci. The nature of the phagocytic debris in the cytoplasm of such macrophages helps identify the origin of the process. For example, anthracotic pigment accumulates in macrophages in mediastinal lymph nodes showing sinus histocytosis. Macrophages containing erythrocytes and hemosiderin pigment characterize autoimmune hemolytic anemias and sites draining hemorrhages.

Sinus histiocytosis may or may not cause lymph node enlargement. Common sinus histiocytosis should not be confused with **sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease),** in which prominent bilateral (usually cervical) lymphadenopathy reflects a marked expansion of lymph node sinuses by histocytes that have ingested intact lymphocytes (emperipolesis). Most

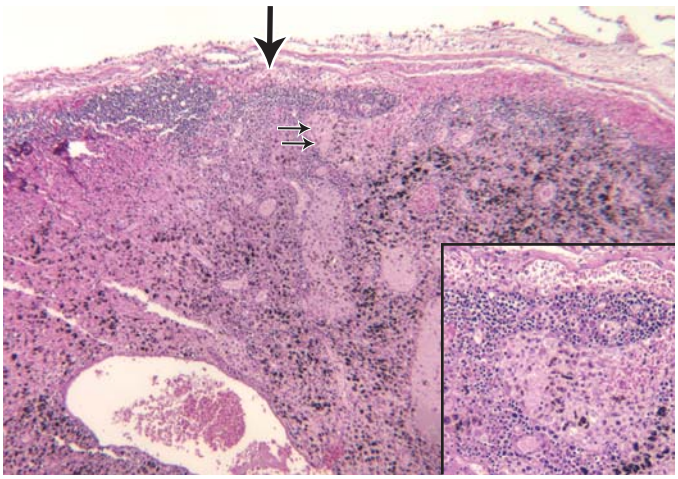

FIGURE 26-55. Sinus histiocytosis. In this hilar lymph node, macrophages are prominent in the subcapsular sinus (*single arrow*) and also in draining sinuses (*double arrows*). **Inset.** A higher-power view demonstrates the large, pink macrophages both at the bottom of the subcapsular sinus and in the draining sinus.

cases of Rosai-Dorfman disease occur in the second decade of life, and the disease is often associated with systemic findings including fever, leukocytosis and hypergammaglobulinemia.

Dermatopathic Lymphadenopathy Occurs in Chronic Dermatoses

Dermatopathic lymphadenopathy refers to paracortical T-cell proliferation caused by certain chronic skin diseases. Lipid, melanin and hemosiderin drain from the affected skin to the regional lymph nodes. The draining lymph nodes show an immune reaction to antigenic material arriving there from the skin, and mainly accumulating in paracortical macrophages. A heterogeneous cell population expands the paracortex. It consists of Langerhans cells, interdigitating reticulum cells and macrophages whose cytoplasm contains lipid or granular, brown, melanin pigment.

MALIGNANT LYMPHOMAS

Lymphomas are malignant proliferations of lymphocytes. B-cell, T-cell and NK-cell lymphomas may be **immature** (derived from precursor cells; lymphoblasts) or **mature** (derived from mature effector cells). The latter are more common. While all lymphomas are malignant, they show a wide spectrum of clinical behavior: some follow an indolent clinical course (and may not even require treatment), while others are very aggressive (and can cause death in a short time, if untreated).

Lymphomas mostly affect lymph nodes, but any tissue or organ may be involved (e.g., GI tract, thyroid, liver, skin, lungs, brain). If lymphoma cells are present in the peripheral blood and/or bone marrow, the tumor is "leukemic" or "peripheralized."

Beyond the broad categories of B-cell, T-cell and NK-cell types, lymphomas are further classified by their postulated cells of origin, normal cellular counterparts, immunophenotypes, molecular/genetic alterations, clinical features and morphology. Further, Hodgkin lymphomas (HLs) are classified separately from non-Hodgkin lymphomas (NHLs). The WHO classification of lymphoid tumors takes all of these parameters into account and is currently used by pathologists and clinicians alike. The major recognized types of B-, T-, and NK-cell lymphomas are shown in Tables 26-17 and 26-18. Selected examples are discussed in the following sections.

Precursor B-Cell Acute Lymphoblastic Leukemia/Lymphoma Is a Malignancy of B Lymphoblasts

The malignant cells in precursor B-ALL and B-cell lymphoblastic lymphoma (B-LBL) are immature (precursor) cells, or **lymphoblasts**. If the B-lymphoblast proliferation involves the bone marrow and/or peripheral blood, it is **acute lymphoblastic leukemia**. But if it mainly involves extramedullary tissues (e.g., lymph nodes), it is called a **lymphoblastic lymphoma**.

EPIDEMIOLOGY: ***Precursor B-cell ALL is the most common childhood leukemia.*** Although the disease can present at any age, 75% of cases occur in children younger than age 6. The incidence of B-cell ALL

is 1–4.75 per 100,000 people per year worldwide, and 1.65 per 100,000 people per year in the United States. Several environmental and genetic factors have been inculpated in the genesis of ALL, including Down syndrome, Bloom syndrome, ataxia-telangiectasia, neurofibromatosis type I, in utero exposure to ionizing radiation and solvents such as benzene. Most cases of precursor B-cell ALL are leukemic rather than lymphomatous at presentation, in contrast to its T-cell counterpart.

MOLECULAR PATHOGENESIS: Chromosomal abnormalities are present in most cases of precursor B-cell ALL, including both numerical and structural abnormalities (Table 26-19). Translocations are common, including those involving chromosomes 9 and 22 (*BCR/ABL* fusion; Philadelphia chromosome), which tends to generate a smaller protein (p190) in childhood B-ALLs than in adult B-ALLs and CML (p210). Other chromosomal changes may impact prognosis (Table 26-19).

PATHOLOGY: Lymphoblasts are small to medium-sized cells with high nucleus-to-cytoplasm ratios, fine chromatin, inconspicuous nucleoli and agranular cytoplasm (Fig. 26-56). The lymphoblasts typically make up greater than or equal to 20% of bone marrow cellularity, and variable numbers of blast cells circulate in the blood. Flow cytometry immunophenotyping is

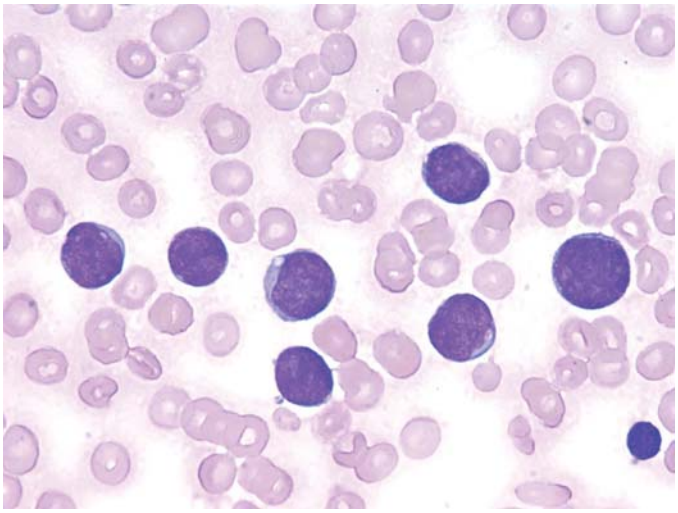

FIGURE 26-56. Acute lymphoblastic leukemia. The lymphoblasts in peripheral blood have irregular and indented nuclei with fine nuclear chromatin, visible nucleoli and variable amounts of agranular cytoplasm.

TABLE 26-19
COMMON GENETIC ABNORMALITIES ASSOCIATED WITH PROLIFERATIONS OF LYMPHOID CELLS

Disease	Associated Genetic/Chromosomal Abnormality	Importance
B-lymphoblastic leukemia/lymphoma	t(9;22) translocations involving *MLL* at 11q23	Children often make p190 bcr/abl, while adults make p210 bcr/abl from t(9;22)
	Hyperdiploidy	Better prognosis
	Hypodiploidy	Worse prognosis
T-lymphoblastic leukemia/lymphoma	TCR genes translocate to sites involving *MYC, TAL1, RBTN1, RBTN2, HOX11*	Disturbed transcriptional regulation results
B-cell chronic lymphocytic leukemia/ small lymphocytic lymphomas	del 13q12-14; frequent IgVH gene rearrangements	
	del 11q; trisomy 12; del 17p	17p locus encodes p53; these changes imply worse prognosis
Follicular lymphoma	t(14;18)(q32;q21)	Characteristic, leads to overexpression of Bcl-2
	Inactivation of p53; activation of *MYC*	Transformation to more aggressive phenotype
Mantle cell lymphoma	t(11;14)(q13;q32)	Primary genetic event, upregulates cyclin D1
	Mutation at 11q22-23	Inactivates *ATM*
Marginal zone lymphoma	t(11;18); t(1;14)	No longer responds to antibiotic treatment alone
	Mutations of IgV region genes; trisomy 3	
Diffuse large B-cell lymphoma	Rearrangements involving 3q27	3q27 carries *BCL6* locus
	t(14;18) rearrangements involving *MYC*	Tend to portend worse prognosis
Burkitt lymphoma	Rearrangements involving *MYC:* t(8;14) or t(2:8) or t(8;22)	Characteristic rearrangement
Plasma cell myeloma	Clonal rearrangements involving Ig H and L genes	
	Abnormalities of chromosome number	Poor prognosis
	IgH translocations with *cyclin D1, C-MAF, FGFR3, cyclin D3, MAFB;* monosomy or partial deletion of chromosome 13	
	t(4;14); t(14;16); t(14;20); del 17p	Poorer prognosis
Anaplastic large cell lymphoma	t(2;5) (involving anaplastic lymphoma kinase and *NPM* genes)	Tends to occur in younger patients, upregulates *ALK,* better prognosis

H = heavy; Ig = immunoglobulin; L = light; TCR = T-cell receptor.

needed to confirm the diagnosis. All cases show evidence of B-lymphoblast differentiation, but immunophenotypic patterns in precursor B-cell ALLs are variable and reflect the different stages of early B-cell maturation (Fig. 26-47). The earliest antigens that indicate B-cell differentiation are CD10, CD19 and TdT. B-cell neoplasms that express surface Ig are not considered precursor neoplasms since surface Ig expression is a feature of mature B cells.

CLINICAL FEATURES: The leukemic cells of precursor B-cell ALL proliferate in the bone marrow and displace the normal marrow elements, resulting in anemia, thrombocytopenia and neutropenia. Organomegaly and central nervous system (CNS) involvement are common as the disease disseminates from the bone marrow. The rapidly growing tumor cells in the bone marrow cause bone pain and arthralgias, which may be the earliest presenting symptoms in children.

The prognosis for childhood precursor B-cell ALL is generally excellent with complete remission rates of greater than 90%. Among other variables, age younger than 1 year or older than 12 years, older adult onset and/or the presence of certain cytogenetic abnormalities [e.g., t(9;22), t(1;19), t(4;11), hypodiploidy] are poor prognostic indicators. All

translocations involving the *MLL* gene at 11q23 are associated with a poor prognosis regardless of age.

The treatment includes chemotherapy or stem cell transplantation for patients with high-risk features or who are unresponsive to chemotherapy.

Precursor T-Cell Acute Lymphoblastic Leukemia/Lymphoma Is a Neoplasm of T Lymphoblasts

Precursor T-cell acute lymphoblastic leukemia (T-ALL) and T-cell lymphoblastic lymphoma (T-LBL) are immature T-cell neoplasms. As with precursor B-ALL, the decision whether to call the tumor **leukemia** or **lymphoma** is often arbitrary.

EPIDEMIOLOGY: Precursor T-cell ALL occurs at any age. It accounts for 15% of childhood ALL and affects adolescents more commonly than younger children. T-ALL is more common in males than females. In adults, 25% of acute lymphoblastic leukemias are precursor T-cell ALLs. Compared to its B-cell counterpart, precursor T-cell ALL is more likely to have a lymphomatous presentation.

MOLECULAR PATHOGENESIS: The genes encoding the four T-cell receptor chains (α-, β-, γ-, δ-chains) often participate in chromosomal translocations with genes encoding transcription factors (Table 26-19). Juxtaposition of T-cell receptor loci to transcription factor genes often leads to disturbed transcriptional regulation.

PATHOLOGY: The morphology of T lymphoblasts is like that of B lymphoblasts (Fig. 26-56). Immunophenotype in T-ALL reflects normal T-cell differentiation and maturation in the bone marrow and thymus (Fig. 26-48). The earliest T-cell antigen is CD7, followed by CD2 and CD5. During thymic differentiation, T cells become positive for CD1a and cytoplasmic CD3 (cCD3; CD3ε), CD4 and CD8. Like precursor B-cell ALL, lymphoblasts in most cases of T-cell ALL express TdT.

CLINICAL FEATURES: The blood and bone marrow are almost always involved in precursor T-cell ALL. Presenting white blood cell counts are usually high, and a mediastinal mass or other tissue mass (lymphoma) is often present. Lymphadenopathy and organomegaly are common, as are pleural effusions. **Mediastinal adenopathy** occurs particularly often in adolescent males. The tumor usually grows rapidly, and patients with mediastinal involvement may present with respiratory distress because of compression of the central airways or superior vena cava syndrome. In general, precursor T-cell ALL has a worse prognosis than precursor B-cell ALL in children, but it has a slightly better outcome than B-ALL in adults.

Mature B-Cell Lymphomas Are the Most Common Type of Lymphoma in the Western World

Mature B-cell malignancies are clonal proliferations of differentiated B cells. As B cells progress through the steps of differentiation and maturation from naive B lymphocytes to plasma cells, lymphomas may arise at any point along the way (Fig. 26-47).

EPIDEMIOLOGY: Mature B-cell lymphomas make up greater than 90% of lymphoid neoplasms worldwide. They are more common in developed countries, particularly the United States, Australia, New Zealand and western Europe, and their incidence is increasing. In the United States, the incidence of all lymphoid neoplasms is 34 cases per year per 100,000 people, of which B-cell lymphomas alone account for 26 per year per 100,000 people. The frequency of the specific types of B-cell lymphoma varies in different parts of the world. For example, Burkitt lymphoma is endemic in equatorial Africa (where it is the most common childhood malignancy), but it accounts for only 1%–2% of lymphomas in industrialized nations. Similarly, follicular lymphoma occurs more frequently in the United States and western Europe, compared to South America, eastern Europe and Asia. ***Worldwide, the most common lymphomas are follicular lymphoma (29%) and diffuse large cell lymphoma (37%), exclusive of Hodgkin lymphoma and plasma cell myeloma (Table 26-20).***

Most mature B-cell lymphomas occur in the sixth and seventh decades of life. A variant of diffuse large B-cell lymphoma, mediastinal large B-cell lymphoma, is an exception, with a median age of 35. Mature B-cell lymphomas, other than Burkitt and diffuse large B-cell lymphomas, are distinctly uncommon in children.

Risk factors for development of B-cell lymphoma include abnormalities of the immune system (e.g., immunodeficiencies like AIDS or iatrogenic immunosuppression, and autoimmune diseases), certain infectious agents (e.g., EBV, hepatitis C, *Helicobacter pylori* and *Chlamydia*), environmental exposures (e.g., herbicides and pesticides) and even genetic polymorphisms in a number of immunoregulatory genes.

TABLE 26-20
FREQUENCY OF B- AND T-/NK-CELL LYMPHOMAS

Diagnosis	% of Total Cases
Diffuse large B-cell lymphoma	30.6
Follicular lymphoma	22.1
MALT lymphoma	7.6
Mature T-cell lymphomas (except ALCL)	7.6
Chronic lymphocytic leukemia/small lymphocytic lymphoma	6.7
Mantle cell lymphoma	6.0
Mediastinal large B-cell lymphoma	2.4
Anaplastic large cell lymphoma	2.4
Burkitt lymphoma	2.5
Nodal marginal zone lymphoma	1.8
Precursor T-cell lymphoblastic lymphoma	1.7
Lymphoplasmacytic lymphoma	1.2
Other types	7.4

ALCL = anaplastic large cell lymphoma; MALT = mucosa-associated lymphoid tissue; NK = natural killer.

PATHOPHYSIOLOGY: Most peripheral B-cell lymphomas occur without apparent cause; however, impairment of the immune system and certain infectious agents may give rise to certain types of lymphoma (Table 26-21). Immunodeficiency caused by HIV infection and therapeutic **immunosuppression in allograft recipients** favors development of large B-cell lymphoma or Burkitt lymphoma. Low-grade B-cell lymphomas tend to develop in patients with certain **autoimmune diseases**. For example, patients with Sjögren disease or Hashimoto thyroiditis (see Chapters 11, 27 and 29) may develop extranodal marginal zone B-cell lymphoma (MALT lymphoma). **Epstein-Barr virus** is linked to endemic Burkitt lymphoma, HIV-associated lymphomas and immunosuppression-related lymphomas. Human herpesvirus 8 (HHV-8) and hepatitis C virus also predispose to B lymphomas—primary effusion lymphoma and lymphoplasmacytic lymphoma associated with type 2 cryoglobulinemia, respectively. MALT lymphomas are often associated with gastric *H. pylori* infections (see Chapter 19) and often regress after antibiotic treatment.

As discussed earlier, lymphomas are classified according to their respective normal lymphocyte counterparts (Fig. 26-47). After the precursor stage, B cells undergo immunoglobulin *VDJ* gene rearrangements and mature to surface IgM- and IgD-positive naive B cells that often express CD5. These cells give rise to **mantle cell lymphoma**. Large activated B cells **(centroblasts)** home to germinal centers where they mature into smaller cells with cleaved nuclei **(centrocytes)**. Centroblasts and centrocytes express germinal center cell markers BCL-6 and CD10 and lack expression of Bcl-2 antiapoptotic protein. **Follicular lymphomas** derive from germinal center B cells and contain a mixture of centroblasts and centrocytes that overexpress Bcl-2, which gives them a survival advantage. **Burkitt lymphoma** and some diffuse large **B-cell lymphomas** also come from germinal center lymphocytes, with the latter known as germinal center–type B-cell lymphomas.

Late-stage memory B cells reside in marginal zones, the outermost compartment of lymphoid follicles. **Marginal zone lymphomas** include **splenic marginal zone lymphoma, nodal marginal zone lymphoma** and **MALT lymphomas**. The latter, particularly, involve extranodal sites such as the stomach and other mucosal tissues. Late-stage memory B cells can also give rise to a subset of chronic lymphocytic leukemia/small lymphocytic lymphomas **(CLL/SLL)**. Ultimately, some B cells differentiate into plasma cells. These are the only B cells to secrete antibodies, although they lack detectable cell surface immunoglobulins. Plasma cells home to the bone marrow, where they may give rise to **multiple myeloma**.

Celiac disease
Hodgkin lymphoma (posttreatment)

EBV = Epstein-Barr virus; HHV = human herpesvirus; Ig = immunoglobulin.

CLINICAL FEATURES: The various types of mature B-cell lymphoma may evolve aggressively, slowly or in between. Their behavior generally reflects their morphology, immunophenotype, genetic lesions and clinical presentation (including stage). ***Usually, and with a few exceptions, mature B-cell lymphomas contain small lymphocytes and follow an indolent clinical course, while other B lymphomas, composed of mostly large cells, follow an aggressive course that would be rapidly fatal if untreated.*** Examples of indolent mature B-cell lymphomas include (but are not limited to) B-cell CLL/SLL, follicular lymphoma, extranodal marginal zone B-cell lymphoma (MALT lymphoma) and lymphoplasmacytic lymphoma; aggressive mature B-cell lymphomas include diffuse large B-cell lymphoma, Burkitt lymphoma and mantle cell lymphoma (MCL). The latter represents an important exception to the general rule of small cell morphology predicting indolent behavior (see below).

Ironically, although indolent lymphomas follow a prolonged clinical course, they are usually incurable using standard therapy. In contrast, aggressive lymphomas progress rapidly, but many are curable with conventional therapies. Unfortunately, not all lymphomas fall unequivocally into either category.

Our subsequent discussion of B-cell lymphomas follows the B-cell development paradigms outlined in Fig. 26-47.

B-Cell Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

B-cell CLL/SLL is a common, mature $CD5^+$ B-cell tumor with a monomorphic population of mostly small lymphocytes with round to slightly irregular nuclear contours mixed with less abundant larger cells that have round nuclei and single basophilic nucleoli. These latter are called prolymphoyctes (in the blood) or paraimmunoblasts (in

tissue). B-cell CLL/SLL may involve the blood, bone marrow, lymph nodes and/or extranodal sites. When the disease only affects the blood and bone marrow (leukemia), the term **CLL** is preferred. If, instead, lymphadenopathy or solid tumor masses predominate, **SLL** is the more fitting name. Since these two presentations are morphologically, phenotypically and genetically indistinguishable, they are often considered one entity, B-cell CLL/SLL. This tumor generally follows an indolent clinical course. MCL, another mature B-cell tumor that also expresses CD5, is more aggressive.

EPIDEMIOLOGY: B-cell CLL is the most common form of leukemia in adults in the Western world. Its overall annual incidence is 2–6 cases per 100,000 people, but the incidence increases with age to 12.8 per 100,000 at age 65, which is the average age at diagnosis. Men develop CLL/SLL more frequently than women. SLL accounts for 7% of all non-Hodgkin lymphomas in tissue biopsies.

MOLECULAR PATHOGENESIS: The vast majority of B-cell CLL/SLL tumors have cytogenetic abnormalities. The most common are shown in Table 26-19. Half of B-CLL cases do not show somatic mutations in Ig variable-region genes (i.e., unmutated *IgVH*), and so have the genotype of naive B cells. The other half have undergone *IgVH* gene rearrangement (i.e., mutated) and resemble postgerminal center B cells. Cases with unmutated immunoglobulin segments tend to behave more aggressively, for unknown reasons.

PATHOLOGY: Lymph nodes involved by B-cell CLL/SLL are effaced by a proliferation of mostly small lymphocytes in a vaguely nodular or pseudofollicular to diffuse pattern (Fig. 26-57A). The blood shows absolute lymphocytosis composed mostly of small monotonous lymphocytes with round to slightly irregular nuclear contours and scant blue-gray cytoplasm (Fig. 26-57B). Peripheral smears also contain a large number of disrupted cells (smudge cells; Fig. 26-57B). The nuclear chromatin is clumped and often has a blotchy appearance resembling cracked mud; nucleoli are absent in the small cells.

In addition to the small cells, all cases also have some larger cells with round nuclear contours, less condensed chromatin, and a single prominent central nucleolus; these cells are known as prolymphocytes in the blood, and they usually account for less than 10% of total lymphocytes. In order to establish a diagnosis of B-CLL in the absence of tissue-based disease, the total number of circulating monoclonal B cells must exceed 5000/μL.

The vaguely nodular pattern of B-cell CLL/SLL (with noticeably light and darker staining areas) is most apparent at low magnification. Further examination of lighter-staining zones reveals so-called proliferation centers, which contain a small number of large cells called paraimmunoblasts (Fig. 26-57C). Large confluent sheets of paraimmunoblasts or other large lymphoid cells may represent transformation to diffuse large B-cell lymphoma (see below). B-cell CLL/SLL infiltrates the splenic white and red pulp and portal areas of the liver. Bone marrow involvement ranges from complete effacement of the marrow space to patchy interstitial or nonparatrabecular infiltrate of varying degree.

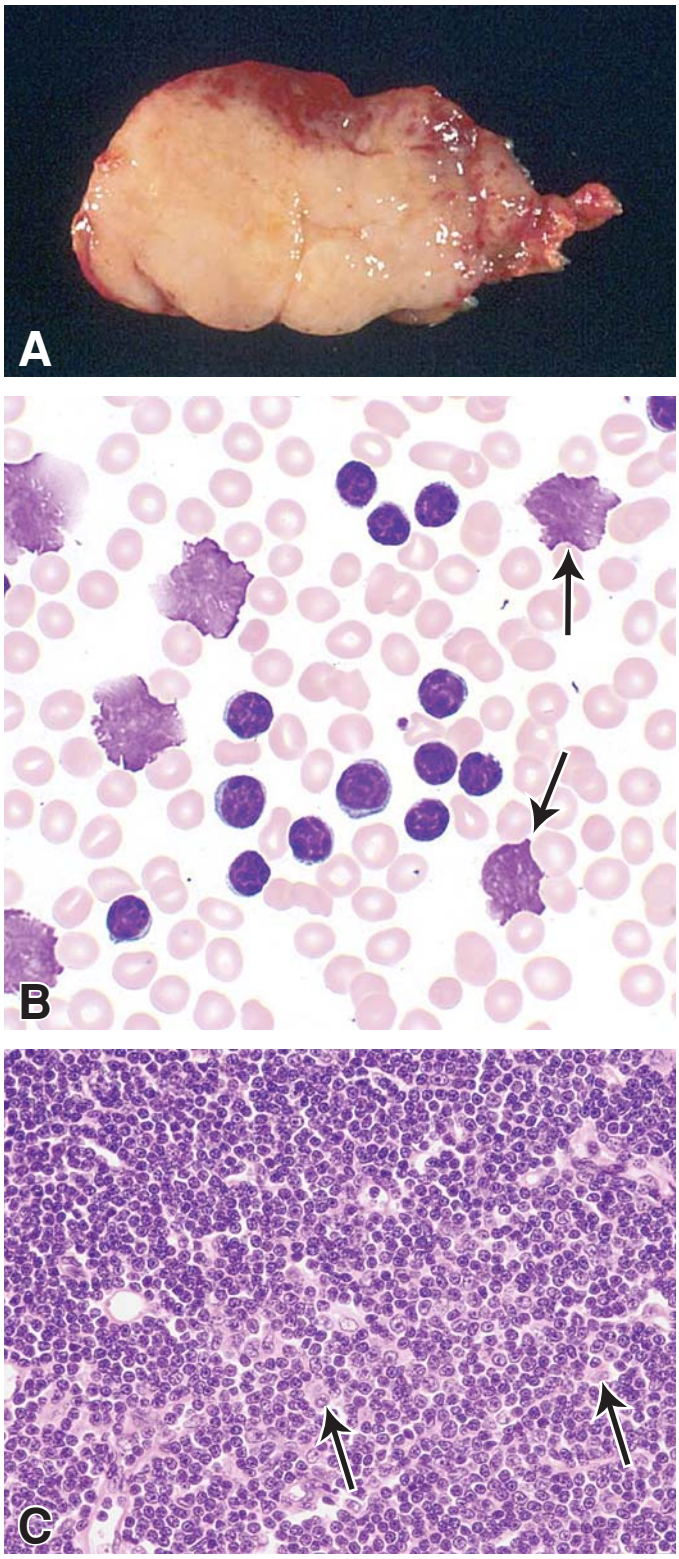

FIGURE 26-57. B-cell small lymphocytic lymphoma/chronic lymphocytic leukemia. A. Gross image of a bisected, enlarged lymph node shows the characteristic uniform, glistening, fish-flesh appearance seen in tissues involved by lymphoma. **B.** A smear of peripheral blood exhibits numerous small to medium-sized lymphocytes with clumped nuclear chromatin. Scattered smudge cells (osmotically fragile cells) are present (*arrows*). **C.** On microscopic examination, the nodal architecture is replaced by a diffuse proliferation of small lymphocytes admixed with a low number of larger cells known as paraimmunoblasts (*arrows*) found in scattered proliferation centers.

The immunophenotype of B-cell CLL/SLL is distinct. The neoplastic cells express pan B-cell antigens, including CD19, CD20, CD22 and CD79, as well as CD5, CD23 and surface immunoglobulin light chain. It is important to note that B-cell CLL/SLL cells show weaker CD20 and immunoglobulin light-chain expression compared to other mature B-cell neoplasms including mantle cell lymphoma, and these findings are diagnostically useful. B-cell CLL/SLL is negative for cyclin D1 and CD10. Some cases of B-cell CLL/SLL express CD38 and/or ZAP-70, and these markers serve as prognostic indicators often used in conjunction with other molecular and FISH tests to help predict individual patient outcome.

CLINICAL FEATURES: Most patients with B-cell CLL/SLL are asymptomatic, and many cases are diagnosed incidentally. Often the first hint of the disease is an abnormal complete blood count showing absolute lymphocytosis. The total lymphocyte count is variable, but an absolute monoclonal B-cell count of at least 5000 cells/μL is needed to establish a diagnosis of CLL in the blood. Flow cytometry of the peripheral blood is sufficient to establish the diagnosis in most cases. The other peripheral counts may be normal or abnormal, and findings such as platelet count and hemoglobin level are used to stage the disease. Erythrocyte and platelet counts are initially normal, but as the disease advances, severe anemia, thrombocytopenia and even neutropenia can develop. A positive Coombs test occurs during the course of disease in up to 20% of patients and may be associated with immune-mediated hemolytic anemia. A small monoclonal paraprotein may be present in some patients, most of which are of the IgM heavy-chain type (in contrast to patients with multiple myeloma, who most often have IgG paraproteinemias).

Immune deficiencies, mainly of B cells but also of T cells, are common. The cause of B-cell dysfunction is unknown. Hypogammaglobulinemia occurs in 50%–75% of cases at some point during the disease; the degree of hypogammaglobulinemia generally correlates with disease stage and is responsible for infectious complications. Patients with B-CLL also have increased peripheral blood T cells (>3000/μL). $CD8^+$ T cells are increased, and $CD4^+$ cells correspondingly decreased, so that the $CD4^+/CD8^+$ ratio is low. The T cells, though increased in number, often show impaired delayed-type hypersensitivity reactivity, which may contribute to the increased risk of infection. The most common complicating infections are bacterial, then viral and fungal.

Median survival of patients with B-CLL/SLL is 4–6 years (untreated), but the disease course and prognosis are highly variable. For instance, patients with low disease burden can survive over 10 years, while others with extensive disease or poor prognostic features show rapid progression and may not survive more than 2 or 3 years. Certain molecular lesions suggest a worse prognosis (Table 26-19).

The survival of patients with B-CLL/SLL also reflects the risk of transformation or progression to a more aggressive B-cell tumor. ***Transformation to prolymphocytic leukemia occurs in 15%–30% of cases and is the most common form of progression.*** This type of transformation is heralded by worsening cytopenias, increasing splenomegaly and progressive increases in prolymphocytes in the blood or paraimmunoblasts in lymph nodes or other tissues.

Transformation to diffuse large B-cell lymphoma, **Richter syndrome,** occurs in 10% of cases. This form of progression is marked by the appearance of a rapidly enlarging mass, worsening of systemic symptoms and a high lactate dehydrogenase level in the serum. Other rare forms of transformation also occur, including a Hodgkin lymphoma or Hodgkin-like transformation, the latter occurring more frequently in patients treated with certain chemotherapeutic drugs. Most patients who undergo prolymphocytic or Richter transformation survive less than 1 year.

Asymptomatic patients with B-CLL/SLL who have stable lymphocyte counts may not need treatment. Multiagent chemotherapy and/or treatment with humanized monoclonal antibodies (e.g., Rituxan) is used in patients with high-stage or aggressive disease, but the disease generally remains incurable.

Follicular Lymphoma

Follicular lymphoma (FL) is a mature B-cell lymphoma of follicle center B cells (germinal center cells). FLs must have at least a partially follicular architecture to meet diagnostic criteria. The neoplastic cells are heterogeneous, with a mixture of small and large cleaved cells and centroblasts. This tumor's behavior may vary from indolent to aggressive. This largely reflects the histologic grade, which depends on the number of centroblasts in the neoplastic follicles.

EPIDEMIOLOGY: FL is the second most common lymphoma worldwide, but it is the most common non-Hodgkin lymphoma in the United States, where it constitutes 20% of all adult lymphomas. It is mainly a disease of adults with a peak incidence in the sixth decade. It only rarely occurs in people under age 20, and is more common in women than men.

MOLECULAR PATHOGENESIS: The t(14:18) is the characteristic genomic abnormality in FL. It occurs in up to 90% of grades 1 and 2 FLs (so-called low-grade follicular lymphomas; Table 26-19). It puts expression of the antiapoptotic protein, Bcl-2, under control of the IgH promoter, and results in Bcl-2 overexpression. ***Bcl-2 protein is an inhibitor of apoptosis and provides a survival advantage to the lymphoma cells.*** In addition to the *Bcl-2/IgH* rearrangement, several other genetic alterations have been found in FL, and some of them are associated with progression/transformation from the low-grade indolent forms to the more aggressive higher-grade form or diffuse large B-cell lymphoma (DLBCL) (Table 26-19).

PATHOLOGY: Lymph nodes (or other tissues) involved by follicular lymphoma have a distinctly nodular (follicular) pattern or a combination of nodular and diffuse architectural patterns (Fig. 26-58). The neoplastic follicles are present in high density, and are often in a back-to-back arrangement with little intervening paracortex. The neoplastic follicle centers (germinal centers) contain a mixture of small and large cells with irregular nuclear contours (centrocytes/cleaved cells) and scattered centroblasts, which have round nuclear contours and multiple nucleoli attached to the nuclear membrane.

Histologic grade helps to predict prognosis in FL. There are 3 such grades of FL, distinguished by the number of centroblasts per high-power field (Fig. 26-59). Diffuse areas occur in FL but generally do not affect prognosis unless they are composed of large B cells, in which case a diagnosis of concurrent DLBCL is made. The bone marrow is involved

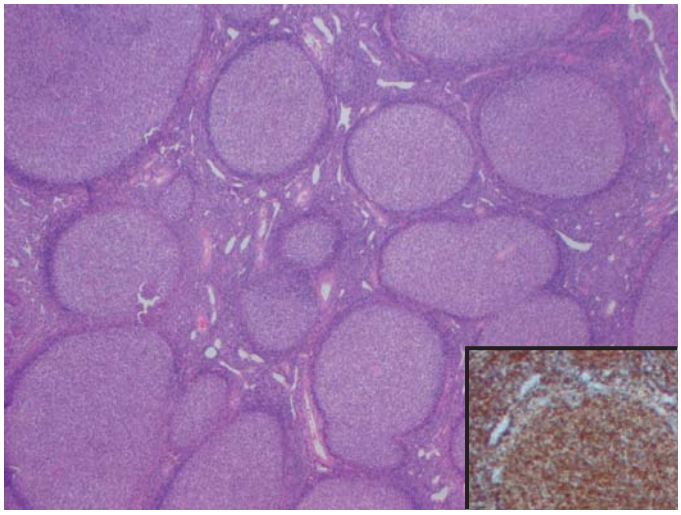

FIGURE 26-58. Follicular lymphoma. The normal lymph node architecture is replaced by malignant lymphoid follicles in a back-to-back pattern. **Inset.** Malignant lymphoid follicle germinal centers can be distinguished from normal/reactive germinal centers using immunohistochemistry for Bcl-2.

in 40%–60% of cases, in a characteristic paratrabecular pattern in most positive bone marrow core biopsies. Circulating follicular lymphoma cells are present in the blood in 10% of cases; they show prominent nuclear irregularity and deep nuclear clefts.

Follicular lymphomas express pan B-cell antigens including CD19, CD20, CD22, CD79a, PAX-5 and cell surface Ig, which in most cases contains only one type of light chain (κ or λ). In addition, FLs also express the germinal center cell markers CD10 and Bcl-6, as would be expected given that they originate from follicle centers. Unlike mantle cell lymphoma and B-cell CLL/SLL, FLs do not express CD5. Follicular lymphoma cells express Bcl-2 protein in over 90% of cases (Fig. 26-58, **inset**). The latter finding may help to distinguish FL from follicular hyperplasia, since the latter is negative for Bcl-2.

CLINICAL FEATURES: Most patients with follicular lymphomas present with generalized adenopathy. Over 80% have stage III or IV disease at the time of initial diagnosis. Extranodal presentations are relatively uncommon, compared to other B-cell lymphomas. The lymphadenopathy is painless and may have followed a waxing and waning course before the patient seeks medical attention. Some patients will report having fevers, fatigue and night sweats (B symptoms).

Most cases of FL follow an indolent clinical course. Therefore, and because the disease is usually incurable, treatment is not always needed at diagnosis. Overall median survival is 7–9 years, which does not improve dramatically with high-dose chemotherapy. As discussed above, the clinical course is linked to histologic grade, and progression/transformation to more aggressive disease may occur in 50% of cases.

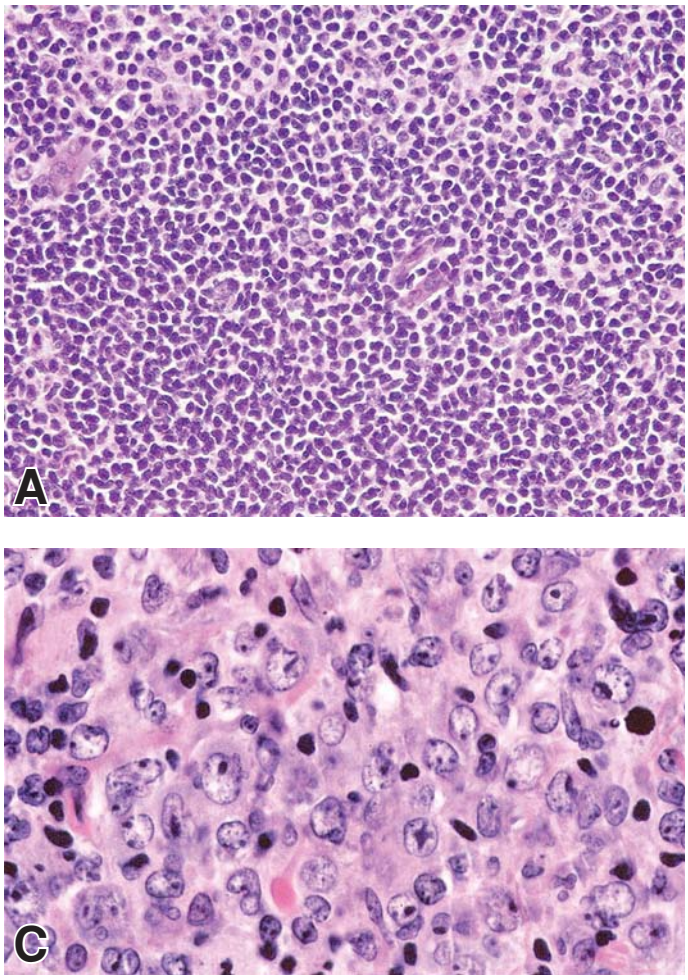

FIGURE 26-59. Follicular lymphoma grading. A. Follicular lymphoma, grade 1. The neoplastic follicles are composed of predominantly small cleaved cells (centrocytes) and only a few scattered centroblasts are present. **B. Follicular lymphoma, grade 2.** The neoplastic follicle shows a mixture of small and large cleaved cells and centroblasts characterized by multiple nucleoli (*arrows*). **C. Follicular lymphoma, grade 3.** The neoplastic follicle shows a predominance of centroblasts with only rare admixed centrocytes. The persistence of a follicular pattern helps distinguish this entity from diffuse large B-cell lymphoma.

Mantle Cell Lymphoma

Lymphomas of mantle cells (MCL) are $CD5^+$ mature B-cell tumors presenting a picture of monotonous small- to medium-sized lymphocytes with irregular nuclear contours, like the normal lymphocytes of the mantle zone around germinal centers.

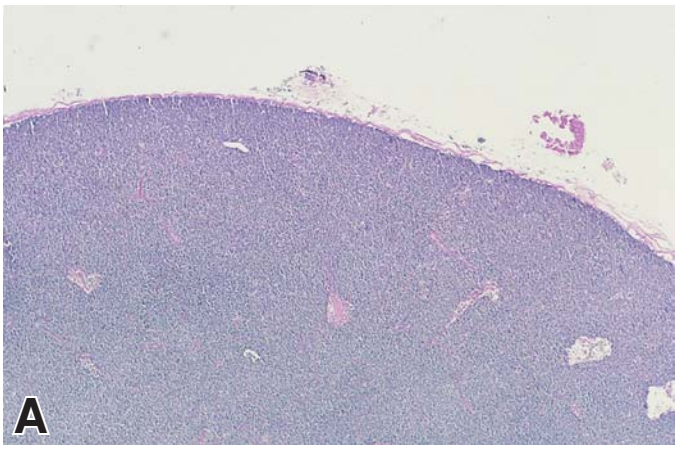
EPIDEMIOLOGY: MCLs account for less than 10% of B-cell lymphomas. This is a disease of adults, with a median age of 60. MCL affects men twice as often as women; it does not occur in children.

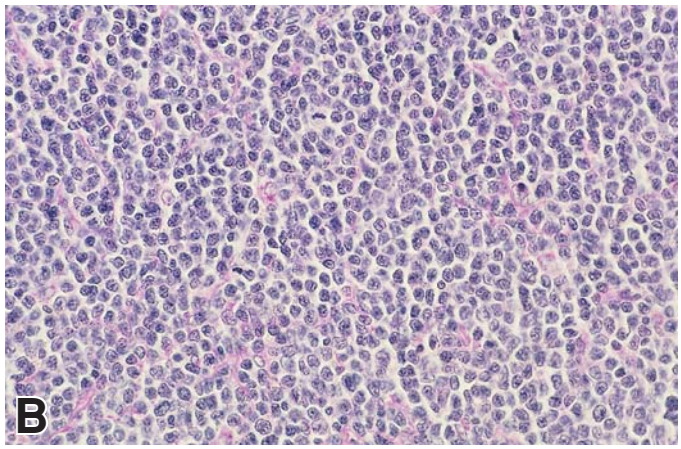
MOLECULAR PATHOGENESIS: The reciprocal chromosomal translocation t(11;14) is considered the primary genetic event in nearly all cases of MCL (Table 26-19). It causes overexpression of cyclin D1. Cyclin D1 drives cell cycle progression at the G_1-to-S-phase transition, by binding to Cdk4/6. This event leads to phosphorylation of retinoblastoma (Rb) and subsequent activation of transcription factors promoting cell cycle progression from the G_1 to S phase (see Chapter 5). Several other oncogenic changes may occur in MCL and are listed in Table 26-19.

PATHOLOGY: Lymph nodes involved by MCL show a diffuse to vaguely nodular lymphoid infiltrate composed of small to medium-sized B cells with irregular nuclear contours. In some cases, MCL lymphocytes are round and resemble the cells of B-cell CLL/SLL, which is often in the differential diagnosis, especially since they also both aberrantly coexpress CD5. One of the characteristic features in typical cases of MCL is the striking monotony of the lymphoma cells with respect to size and shape (Fig. 26-60A). Unlike many other small B-cell lymphomas, large transformed cells and/or centroblasts are absent or rare. The presence of scattered epithelioid histiocytes and hyalinized small blood vessels completes the picture of typical cases.

There are 2 major variants: one with a more nodular-appearing pattern where the lymphoma cells surround the germinal centers (**mantle zone pattern**) and another where the cells are larger and resemble lymphoblasts (**blastic/blastoid variant**). The mantle zone pattern is thought to behave less aggressively than the typical type, while the blastic/blastoid variant is more aggressive. MCL is mainly a nodal-based disease, but it involves many different tissues and organs, particularly the spleen, bone marrow and GI tract. Multifocal mucosal involvement of the gut (mostly small intestine and colon) may produce a pattern known as **lymphomatous polyposis**.

Mantle cell lymphomas express the B-cell markers CD19 and CD20 and show surface light-chain restriction. The lymphoma cells are also positive for CD5, but they are negative for CD10 and CD23. ***Importantly, MCL cells are positive for cyclin D1*** (Fig. 26-60B). This immunophenotype, combined with the morphologic features, helps distinguish MCL from other small B-cell lymphomas with a more indolent course.





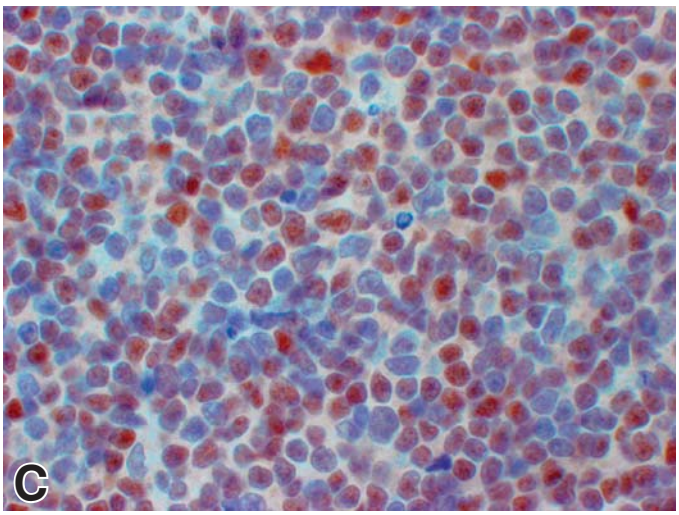


FIGURE 26-60. Mantle cell lymphoma (MCL). A. Lymph node architecture is completely effaced by a small lymphocytic infiltrate. **B.** At closer examination, the population of lymphocytes consists of monotonous, small cells with irregular nuclei. Unlike small lymphocytic lymphomas, MCL has very few admixed larger cells. **C.** A nuclear stain for Bcl-1 (cyclin D1) is positive. This finding correlates with the presence of t(11;14), the typical translocation in MCL.

CLINICAL FEATURES: Most patients with MCL present with high-stage disease (III or IV). About 1/3 have peripheral blood involvement at diagnosis. Despite its small cell morphology, MCL is clinically aggressive and is considered incurable by standard chemotherapy. The median survival is 5 years for the typical type of MCL, and 3 years for the blastic/blastoid variant.

Marginal Zone Lymphomas

The marginal zone lymphomas are a heterogeneous group of mature B-cell tumors that arise in lymph nodes, spleen and extranodal tissues. The lymphoma cells are thought to arise from the marginal zone of the lymphoid follicle, which contains memory B cells that have gone through the germinal center reaction (postgerminal center). Regardless of the primary site of involvement, all marginal zone lymphomas share similar morphologic and immunophenotypic features. The prototypical marginal zone lymphomas are the extranodal marginal zone B-cell lymphomas arising in the mucosa-associated lymphoid tissues and called **MALT lymphomas** or **MALTomas**.

MALTomas are indolent B-cell lymphomas composed of a heterogeneous population of small B cells including centrocyte-like cells (marginal zone cells), monocytoid lymphocytes, small lymphocytes and scattered larger lymphoid cells resembling centroblasts and immunoblasts. These tumors often occur at extranodal sites, such as the GI tract, salivary glands, ocular adnexa, lungs and skin. Plasma cell differentiation is present in a variable proportion of cases.

EPIDEMIOLOGY: MALT lymphomas account for 5%–10% of B-cell lymphomas and are the most common type of gastric lymphoma. Most cases occur in adults with a median age of 60; they are rare in children and young adults. There is a slight female predominance in part because they may occur at sites of autoimmune diseases (e.g., Sjögren syndrome, Hashimoto thyroiditis). Immunoproliferative small intestinal disease (IPSID), also called α-chain disease or **Mediterranean lymphoma,** is a subtype of MALT lymphoma that produces α heavy chains.

PATHOPHYSIOLOGY AND MOLECULAR PATHOGENESIS: MALT lymphomas are monoclonal B-cell tumors that arise in the setting of chronic inflammation, most often due to autoimmunity or infection. What begins as a benign polyclonal reaction acquires mutations and/or chromosomal lesions in B cells. T lymphocytes are necessary to maintain growth and survival of the neoplastic B cells. ***The prototypical infection-driven MALToma is gastric lymphoma associated with* H. pylori *gastritis*** (see Chapter 19). Gastric MALT lymphomas at their earliest phases of development may regress with antibiotic therapy to eradicate *H. pylori.* MALTomas that have progressed to acquire other chromosomal translocations (Table 26-19) no longer respond to antibiotic therapy alone. Dissemination to distant sites and/or transformation to diffuse large B-cell lymphoma occur as additional genetic lesions accrue. Similar progression, from polyclonal to monoclonal lymphoid infiltrates, occurs in EBV-related lymphomas.

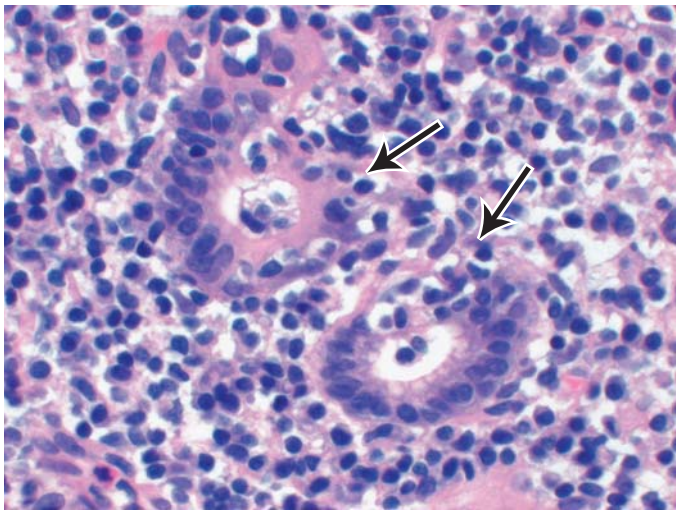

FIGURE 26-61. Mucosa-associated lymphoid tissue (MALT) lymphoma. A stomach biopsy showing the characteristic lymphoepithelial lesions seen in MALT lymphomas (*arrows*). The infiltrating lymphocytes are B cells.

PATHOLOGY: Early-stage MALT lymphomas show increased marginal zone lymphocytes surrounding and infiltrating reactive B-cell follicles. The malignant B cells are heterogeneous and include varying proportions of small angulated lymphocytes, medium-sized monocytoid lymphocytes with abundant cytoplasm, plasmacytoid lymphocytes and even admixed clonal plasma cells. The tumor cells invade glandular epithelium or epithelia of mucosal surfaces, resulting in **lymphoepithelial lesions** (Fig. 26-61). Indolent MALT lymphomas may occasionally transform into large cell B-cell lymphomas.

MALTomas have no specific immunophenotype. Most tumor cells express IgM and show light-chain restriction. They express B-cell–associated antigens and are negative for CD5, CD23 and cyclin D1, which distinguishes them from B-CLL/SLLs and mantle cell lymphomas. Unlike follicular lymphomas, MALTomas do not express CD10.

MALT lymphomas typically show somatic mutation of variable-region genes. Common cytogenetic abnormalities are listed in Table 26-19 and, along with clonal *IgH* gene rearrangements, may help to establish the diagnosis if gastric infiltrates are subtle.

CLINICAL FEATURES: Most MALT lymphomas involve the stomach or other mucosal sites, including the respiratory tract. They may also occur in the salivary glands, ocular adnexa, skin, thyroid and breast. These tumors may remain localized for prolonged periods and tend to follow an indolent clinical course. MALT lymphomas of the skin are sensitive to radiation therapy, and gastric MALTomas related to *H. pylori* infection often respond to antibiotic therapy alone. Transformation to diffuse large B-cell lymphoma may occur and is associated with more aggressive disease often requiring chemotherapy.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphomas (LPLs) are relatively rare mature B-cell neoplasms containing small lymphocytes, plasmacytoid lymphocytes and plasma cells. They mainly

involve the bone marrow, and occasionally spleen and lymph nodes. LPLs overlap considerably morphologically and immunophenotypically with MALT lymphomas, and distinction often depends in part on the site of involvement. Most LPLs produce a sizeable monoclonal serum paraprotein (usually of the IgM type), but such a finding is not required for diagnosis. A subset of patients with LPLs (and sometimes MALT lymphomas) develop the clinical syndrome of **Waldenström macroglobulinemia,** which can be associated with a **hyperviscosity syndrome**. The disease usually occurs in adults in their fifth to sixth decades, and there is a slight male predominance.

PATHOLOGY: Bone marrows involved by LPL show a variably dense heterogeneous lymphoid infiltrate of small lymphocytes, plasmacytoid lymphocyte and mature plasma cells, in a diffuse and nonparatrabecular pattern. A few large transformed lymphoid cells are present in some cases. Lymphoplasmacytic cells with nuclear immunoglobulin pseudoinclusions (Dutcher bodies; see above) are common in tissue sections. Stained bone marrow aspirate smears show the cytologic features to advantage and also usually contain increased numbers of normal mast cells. Lymphoplasmacytic lymphoma cells may be present in the blood, but absolute lymphocytosis like CLL/SLL is rare. Affected lymph nodes show an interfollicular pattern of involvement, and nodal architecture is generally preserved.

Lymphoplasmacytic lymphomas express pan B-cell antigens and are negative for CD5, CD10, CD23 and cyclin D1. The plasma cell component expresses the plasma cell marker CD138. Plasma cell clonality is demonstrable in tissue sections using immunostains for κ and λ light chains. No specific chromosomal or oncogenic abnormalities are associated with LPL.

CLINICAL FEATURES: Fatigue, weakness and weight loss are the most common presenting complaints of people with LPL. These nonspecific findings are usually related to anemia caused by marrow infiltration or immune-mediated hemolysis. About half of patients have lymphadenopathy and/or organomegaly at diagnosis. Most have a serum IgM paraprotein, although some may have a different isotype paraprotein (IgG, IgA) or none at all. Increased blood viscosity due to macroglobulinemia occurs in 30% of patients, and serum hyperviscosity may cause visual impairment, neurologic problems, bleeding and cryoglobulinemia. Therapeutic plasma exchange (plasmapheresis) is often necessary to control the complications of hyperviscosity syndrome until the patient receives more definitive therapy.

Lymphoplasmacytic lymphoma is an indolent disease that follows a progressive course. Median survival is 5–10 years. Like other small B-cell lymphomas, LPL is currently incurable. Transformation to diffuse large B-cell lymphoma may occur in a small proportion of patients and shortens survival considerably.

Hairy Cell Leukemia

Hairy cell leukemia (HCL) is a clonal B-cell neoplasm of small to medium-sized lymphocytes (with abundant pale cytoplasm and hair-like cell cytoplasmic protrusions) involving bone marrow and peripheral blood (Fig. 26-62A). The neoplastic cell is thought to arise from a postgerminal center–stage peripheral B cell (late activated memory B cell).

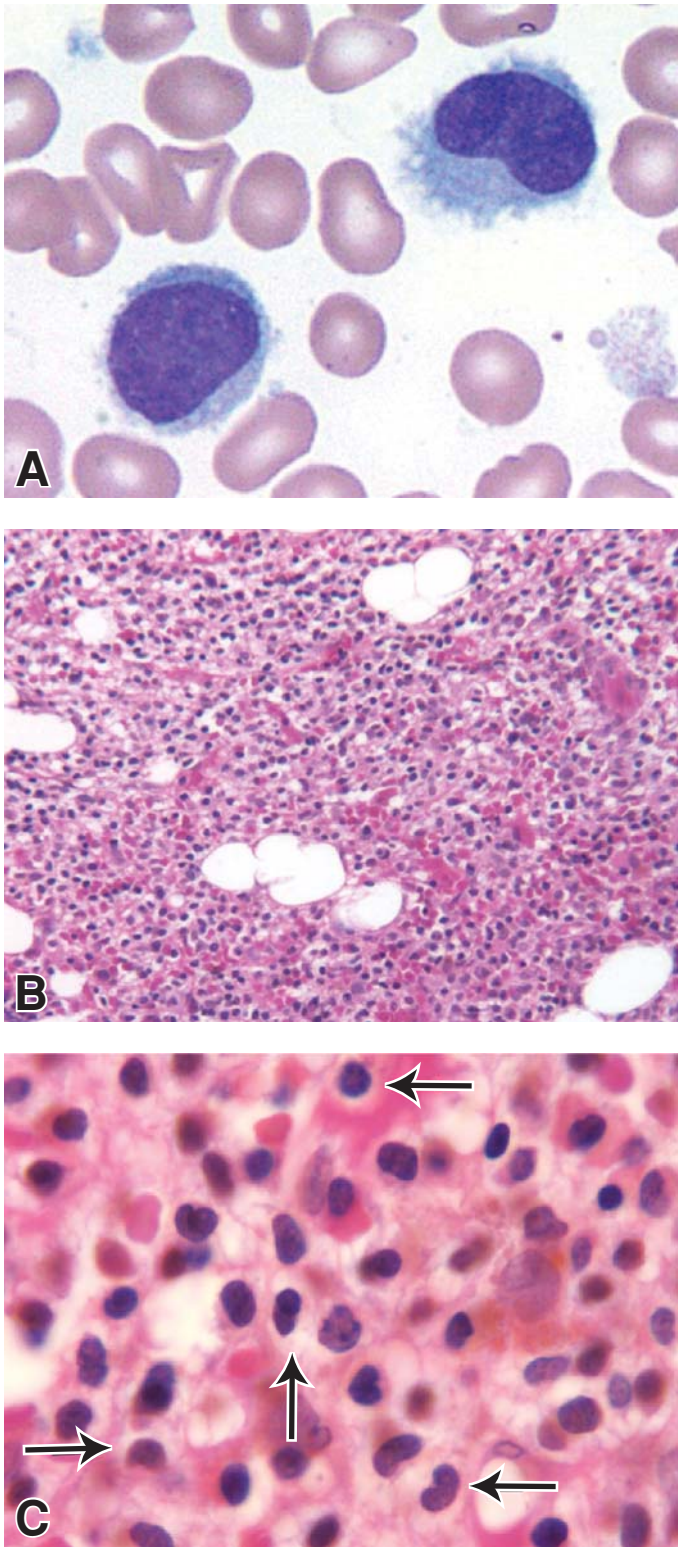

FIGURE 26-62. Hairy cell leukemia. A. Peripheral smear demonstrating "hairy" appearance of the leukemic cells in hairy cell leukemia. B. Bone marrow biopsy, showing infiltration of bone marrow by small to medium-sized lymphocytes with oval to reniform nuclei and pale cytoplasm with circumferential hair projections seen in peripheral blood and bone marrow aspirate smears. **C. Higher-power photomicrograph of the lymphocytes infiltrating the bone marrow in hairy cell leukemia.** Typical "fried egg" cells, with round-oval to kidney-shaped nuclei, are shown (*arrows*).

Hairy cell leukemia is uncommon and affects mainly middle-aged to elderly men, with a male-to-female ratio of 5:1. Marked splenomegaly at presentation is common.

PATHOLOGY: Hairy cell leukemia shows subtle interstitial infiltrates that do not disturb the normal bone marrow architecture. The cells have abundant clear cytoplasm, compared to normal small lymphocytes, which gives them a "fried egg" appearance in tissue sections (Fig. 26-62B, C). HCL generally spares lymph nodes but involves both liver and spleen prominently. The immunophenotypic features of HCL are characteristic, allowing distinction from other small B-cell neoplasms. Hairy cells express the pan B-cell antigens CD19 and CD20, as well as CD11c, CD22, CD25 and CD103. Some cases may show variable expression of CD5, CD10 and even cyclin D1. The tumor cells produce tartrate-resistant acid phosphatase (TRAP), but immunophenotyping has largely replaced such cytochemical analysis in clinical practice. No specific cytogenetic abnormalities have been found in HCL.

CLINICAL FEATURES: Most patients with HCL present with splenomegaly, leukopenia and monocytopenia or sometimes pancytopenia. Hepatomegaly is less common, and peripheral lymphadenopathy is rare. Infections are frequent, occurring in 1/3 of patients during their clinical course. HCL is otherwise indolent, and purine analogs such as deoxycoformycin or 2-chlorodeoxyadenosine (2-CDA) may provide complete and durable remissions.

Diffuse Large B-Cell Lymphoma

DLBCLs are a heterogeneous group of aggressive—but potentially curable—B-cell tumors. Their heterogeneity is evident at the morphologic, immunophenotypic, genetic and clinical levels. While some cases of DLBCL arise de novo, others represent transformation or progression from a more indolent type of lymphoma.

EPIDEMIOLOGY: Diffuse large B-cell lymphomas are the most common B-cell lymphoma worldwide. They have been the single largest factor in the increasing incidence of non-Hodgkin lymphomas during the past few decades. Diffuse large B-cell lymphomas occur at all ages, but are most prevalent between the ages of 60 and 70. They are slightly more common in males than females.

PATHOPHYSIOLOGY AND MOLECULAR PATHOGENESIS: The cause of DLBCL is unknown, but altered immune function is important, since a number of cases are associated with viral infections, such as EBV, HIV and rarely HHV-8. The frequency of EBV-positive cases is highest in immunosuppressed patients and in those older than age 50. Diverse pathogenetic mechanisms contribute to the development of DLBCL. A number of chromosomal rearrangements are seen in DLBCLs (Table 26-19). Some of these involve genes that directly or indirectly impair apoptosis and have substantial influence in prognosis. Some translocations overlap with characteristic FL rearrangements (Table 26-19).

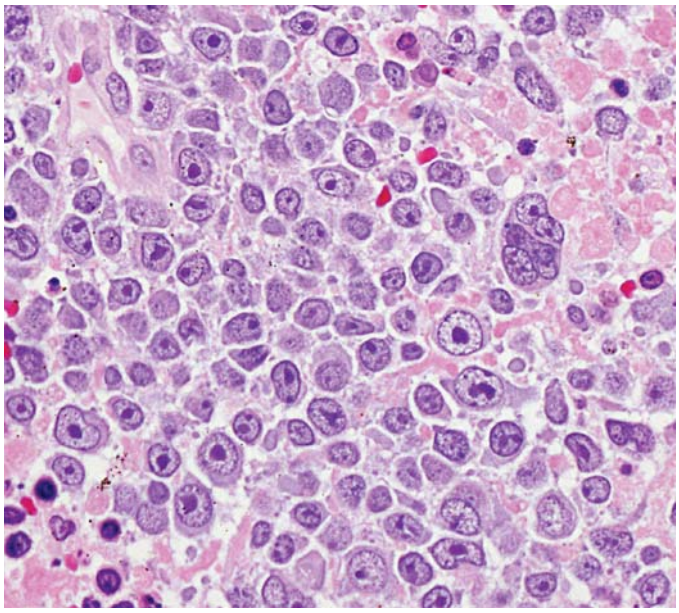

FIGURE 26-63. Diffuse large B-cell lymphoma. Sheets of large lymphoma cells with prominent nucleoli are present.

PATHOLOGY: DLBCLs show diffuse proliferation of large neoplastic B cells (Fig. 26-63). The large lymphoma cells are comparable in size to the nucleus of a histiocyte (macrophage) or roughly twice the size of a normal lymphocyte. Morphologic variants include centroblastic, immunoblastic, T-cell/histiocyte rich and others. The malignant cells of DLBCL are sometimes pleomorphic and/or anaplastic appearing, or they may resemble cells seen in other malignant tumors, such as carcinoma, melanoma or seminoma. Immunohistochemical stains are therefore often necessary to establish the nature of the tumor. ***While DLBCL most often involves lymph nodes, it commonly presents at extranodal sites, especially the GI tract.***

The immunophenotype of the malignant cells of DLBCL varies. Often, the cells express pan B-cell antigens, such as CD19 and CD20. However, owing to complete aberrant loss, downregulation or treatment effect, the lymphoma cells may not necessarily express these common markers. In that event, additional markers of B-cell differentiation such as CD22, CD79a and PAX-5 may be useful to distinguish DLBCL from other morphologically similar neoplasms. DLBCL cells may or may not express CD10 and BCL-6, markers of germinal center cell differentiation. They sometimes express CD5. Surface Ig light-chain restriction occurs most of the time. All cases are negative for TdT and cyclin D1, which distinguishes DLBCLs from B-cell lymphoblastic lymphoma (TdT positive) and MCL (cyclin D1), respectively.

CLINICAL FEATURES: Patients with DLBCL most often present with a rapidly growing tumor in nodal and/or extranodal sites. One or more sites may be involved, but half of patients have limited disease (stage I or II) at presentation. Bone marrow involvement may occur but is usually a late event in this disease. Tumor cells rarely appear in the peripheral blood. Symptoms reflect the site(s) of involvement. For example, a large mass in the colon can cause obstruction or bowel perforation, while a rapidly growing mediastinal mass can impinge on the superior vena cava (SVC) to cause SVC syndrome. Systemic

manifestations such as fever, fatigue and night sweats ("B symptoms") are not uncommon in patients with DLBCL.

These are aggressive neoplasms and are rapidly fatal if left untreated. Because these tumors generally proliferate quickly, however, they are sensitive to chemotherapeutic agents that target rapidly dividing cells. Complete remissions are achieved in 60%–80% of patients. The ultimate outcome depends on tumor stage: patients with limited disease at diagnosis do better compared to those with widespread (high-stage) disease.

Burkitt Lymphoma

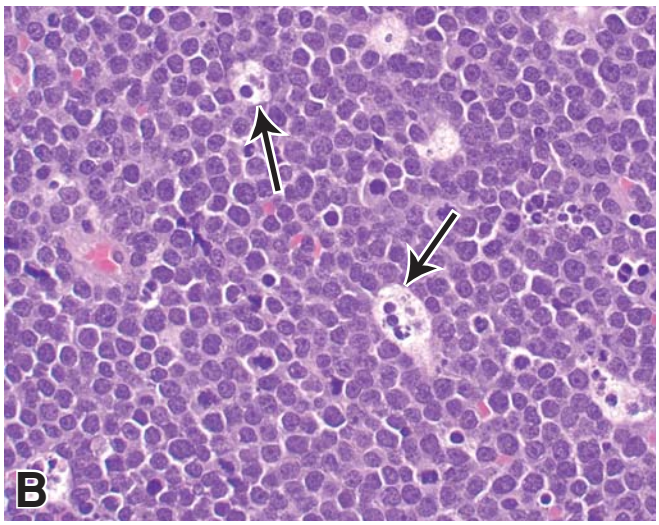
Burkitt lymphoma (BL) is one of the most rapidly growing malignancies known. It is defined by a chromosomal translocation that activates the *MYC* oncogene (see Chapter 5). BLs often present at extranodal sites, contain a monomorphic population of medium-sized cells and tend to show involvement of the blood and/or bone marrow. The MYC translocation is highly characteristic, but is not specific to BL, and a combination of other diagnostic features is required to confirm the diagnosis.

EPIDEMIOLOGY: BL occurs in three distinct variants, each with different clinical presentations, morphology and pathogenesis. In equatorial Africa and Papua, New Guinea, **endemic Burkitt lymphoma** is the most common childhood malignancy. Its peak incidence is in 4- to 7-year-olds, and it commonly involves the jaw, other facial bones and the abdominal viscera. **Sporadic BL** occurs worldwide and mainly affects children and young adults. In the Western world, BL is uncommon (1%–2% of lymphomas overall), but it accounts for 30%–50% of childhood lymphomas. The median age for adult patients is 30. Like most other B-cell lymphomas, BL afflicts males more than females. Unlike endemic BL, sporadic BL often presents as an abdominal mass involving the ileocecum. **Immunodeficiency-associated BL** mainly occurs in HIV-infected people and may be the initial manifestation of AIDS.

MOLECULAR PATHOGENESIS: All cases are associated with translocations that upregulate expression of *c-MYC* oncogene on chromosome 8, either by placing it under the control of IgH [t(8;14)] or IgL [t(2;8 for κ) or t(8;22 for λ)] promoters (Table 26-19). In endemic cases, the breakpoint on chromosome 14 occurs in the heavy-chain–joining region, as seen in early B cells. In sporadic BL, the translocation occurs in the Ig switch region, which is more characteristic of mature B lymphocytes. In these cases, expression of *MYC* gene driven by the Ig heavy-chain promoter leads to uncontrolled tumor cell growth (see Chapter 5).

EBV is present in virtually all cases of endemic BL but is responsible for less than 30% of sporadic and immunodeficiency-related cases. EBV-positive sporadic BL is associated with lower socioeconomic status. Many patients experience prodromal polyclonal B-cell activation caused by bacterial, viral or parasitic infections (e.g., malaria).

CLINICAL FEATURES AND PATHOLOGY: BL typically produces extranodal tumors rather than lymphadenopathy. All variants of this lymphoma have a high risk for CNS involvement. The classic presentation for endemic BL is a destructive tumor in the jaws or other facial bones (Fig. 26-64A). Patients with sporadic BL typically present with abdominal



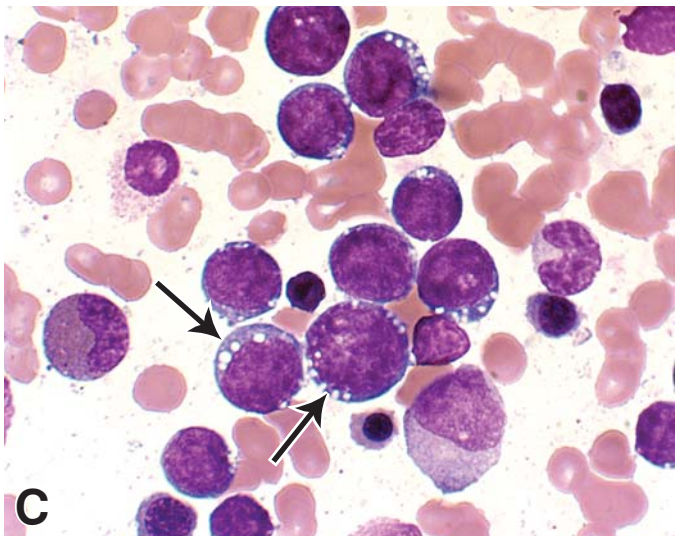


FIGURE 26-64. Burkitt lymphoma. A. A tumor of the jaw distorts the child's face. **B.** Lymph node is effaced by neoplastic lymphocytes with several starry-sky macrophages (*arrows*). **C.** Bone marrow aspirate smear showing typical cytologic features of Burkitt lymphoma. Note the deeply basophilic cytoplasm and lipid vacuoles (*arrows*).

masses. All types may involve ovaries, kidneys and breast. Patients with sizable bulky tumors sometimes present with Burkitt leukemia and extensive bone marrow involvement.

BL cells are medium sized and lack significant cytologic atypia. Tissue sections reveal abundant mitotic figures, reflecting the extremely high proliferative rate in this tumor. Macrophages ingesting the cellular debris of apoptotic tumor cells are scattered throughout the tumor, imparting a "starry sky" microscopic appearance to the tumor (Fig. 26-64B). Aspirate smears stained with Wright-Giemsa show lipid vacuoles in the deeply basophilic tumor cell cytoplasm (Fig. 26-64C).

BL cells express surface IgM and immunoglobulin light chain and are positive for common B-cell antigens (CD19, CD20, CD22). They also express CD10 and BCL-6, which suggests that they originate from germinal centers. BL cells do not express TdT, helping to distinguish these tumors from precursor B-cell acute lymphoblastic leukemia/lymphoma (see above).

All variants of BL are highly aggressive, and most patients have bulky extranodal tumors, high tumor burdens and disseminated disease (stage III or IV) at presentation. Because of its high proliferative rate, BL responds to intensive chemotherapy. Thus, up to 90% of people with early stage disease and 60%–80% of those with high-stage disease may be cured. Children and young adults with BL tend to fare better than adults. Tumor lysis syndrome can occur when therapy begins, as a result of rapid tumor cell death. This is a potentially lethal complication of treatment.

Plasma Cell Neoplasia

Plasma cell neoplasms result from clonal expansion of plasma cells, that is, terminally differentiated B lymphocytes that can produce a monoclonal paraprotein (**monoclonal gammopathy**). The major plasma cell neoplasms include monoclonal gammopathy of undetermined significance (MGUS), plasma cell myeloma (multiple myeloma), plasmacytoma, immunoglobulin deposition disease (amyloidosis and light-chain disease) and osteosclerotic myeloma (**POEMS disease:** polyneuropathy, organomegaly, endocrine disorders, myeloma and skin lesions). These almost exclusively affect adults. Further discussion will be limited to MGUS and plasma cell myeloma.

ETIOLOGIC FACTORS: Known risk factors for plasma cell neoplasia are:

- **Genetic predisposition** is suggested by the increased incidence of multiple myeloma in first-degree relatives of patients with plasma cell neoplasia and the higher frequency of multiple myeloma in blacks.
- **Ionizing radiation** may be involved in the etiology of plasma cell neoplasia. Long-term survivors of the bombing of Hiroshima and Nagasaki had a 5-fold greater incidence of multiple myeloma.
- **Chronic antigenic stimulation** may be a risk factor. Some cases of multiple myeloma follow chronic infections, such as HIV and chronic osteomyelitis, and with chronic inflammatory disorders (e.g., rheumatoid arthritis). Antigenic stimulation leads to reactive, polyclonal proliferation of B cells, which may render them susceptible to a later mutagenic event, establishing a single malignant clone.

Monoclonal Gammopathy of Undetermined Significance

MGUS occurs in about 3% of people older than age 50 and in greater than 5% who are older than 70. Criteria for diagnosing MGUS include (1) monoclonal paraproteinemia of less than 3.0 g/dL; (2) less than 10% plasma cells in the bone marrow; (3) lack of end-organ damage (CRAB: hypercalcemia, renal insufficiency, anemia, bone lesions); and (4) exclusion of other B-cell neoplasms or diseases known to produce a monoclonal paraprotein (M-protein).

IgM MGUS is most often associated with a clone of immunoglobulin-secreting B cells and can progress to a small B-cell lymphoma with plasma cell differentiation such as lymphoplasmacytic lymphoma. Non-IgM MGUS is most often associated with clonal plasma cells and may progress to a bona fide malignant plasma cell neoplasm. Although non-IgM MGUS entails an expanded clone of antibody-secreting plasma cells with genetic lesions similar to those in multiple myeloma, it is a preneoplastic condition that becomes overt plasma cell neoplasia (e.g., multiple myeloma) in about 1% of affected patients per year.

Plasma Cell Myeloma

Plasma cell myeloma (PCM) is a malignancy of plasma cells, in which the serum and/or urine contain an M-protein. The disease is primarily bone marrow based and tends to be multifocal. PCM varies from asymptomatic and indolent to highly aggressive with leukemic involvement. Diagnosis requires a combination of clinical and laboratory findings, including radiographic studies.

EPIDEMIOLOGY: PCM accounts for 10% of hematologic malignancies, with 22,000 cases reported annually in the United States. Its overall incidence is about 6 cases per 100,000 people. Men are more affected than women, and the disease is proportionately twice as common in blacks as in whites. Incidence of PCM increases with age, with the median age at diagnosis being 69 years. Over 90% of cases occur in people older than age 50. PCM does not affect children and is extremely rare in adults under age 30. There is a familial predisposition: people who have a first-degree relative with PCM have a 4-fold greater risk of developing the disease.

PATHOLOGY: Plasma cell myeloma produces multifocal destructive bone lesions with a lytic or "punched out" radiographic appearance throughout the skeleton. The vertebral column, ribs, skull, pelvis, femurs, clavicles and scapulae are most commonly affected. Plasma cells focally fill the medullary cavity, erode cancellous bone and eventually destroy the bony cortex, causing pathologic fractures. The affected bone contains gelatinous red-brown soft tissue masses that are sharply demarcated from the surrounding normal tissue (Fig. 26-65). If the tumors breach the bony cortex, they may spread beyond the medullary cavity into surrounding soft tissues.

Pathologic examination of the bone marrow is essential in diagnosing PCM and shows interstitial clusters, distinct nodules and/or confluent sheets of plasma cells in bone marrow core biopsies. Because malignant plasma infiltrates in PCM affect the bone patchily, variable amounts of normal bone marrow are often present. Such marrow reserves are not, however, seen in all cases, and are less likely in advanced disease. PCM is likely if plasma cell infiltrates involve over 30% of the marrow volume and/or there are large confluent

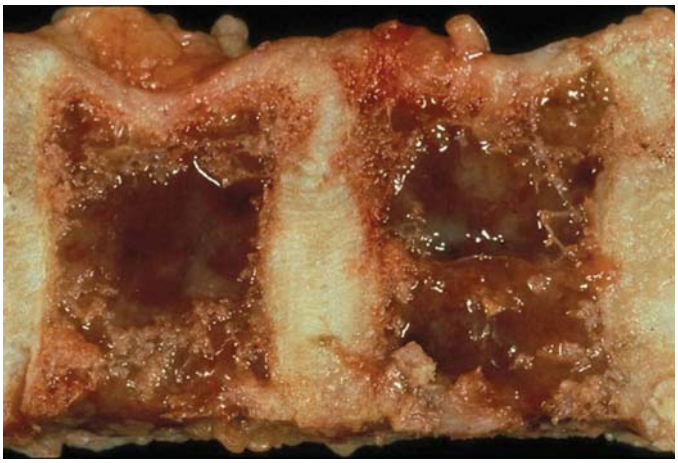

FIGURE 26-65. Plasma cell myeloma. Multiple lytic bone lesions are present in the vertebra. Bones such as this are prone to pathologic fracture.

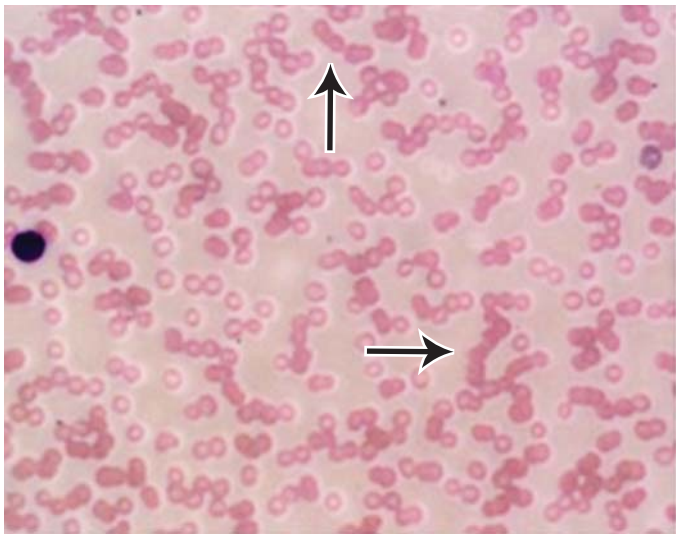

FIGURE 26-67. Plasma cell myeloma, rouleaux in peripheral blood. In plasma cell myeloma, the peripheral blood commonly shows red blood cells seemingly stacked on each other, like coins in a roll. These are rouleaux (*arrows*).

masses of plasma cells without admixed normal hematopoietic cells, even if other typical clinical and pathologic findings are absent.

Immunohistochemical stains for plasma cells (e.g., CD138) are very useful in assessing the degree and pattern of marrow infiltration. Bone marrow aspirate smears stained with Wright-Giemsa show variable plasmacytosis in PCM, again in part because the disease involves the marrow spottily. Myeloma plasma cells may resemble normal plasma cells (Fig. 26-66A), or they may show immature, plasmablastic or pleomorphic features (Fig. 26-66B). Cytoplasmic and nuclear inclusions, representing accumulated or partially degraded immunoglobulin, are occasionally present.

Erythrocyte rouleaux (Fig. 26-67) in peripheral blood smears reflect the type and quantity of circulating paraprotein. High levels of M-protein cause red blood cells to stick together end on end, like a stack of coins. Plasma cells may circulate in the blood in a minority of cases. Marked peripheral blood plasmacytosis establishes a diagnosis of plasma cell leukemia. Renal disease occurs in more than 50% of cases (see Chapter 22).

Plasma cells in PCM usually express the B-cell marker CD79a, plasma cell markers CD38 and CD138 and monotypic *cytoplasmic* immunoglobulin. Unlike normal plasma cells, myeloma cells usually lack CD19, and unlike mature B cells, they do not express CD20. Aberrant expression of various markers such as CD56, CD117, CD52, CD10 and CD20 can occur in some cases. Occasional PCMs express cyclin D1 and have t(11;14) translocations; such cases must be distinguished from MCL. In most cases, the heavy chain in the monoclonal paraprotein is IgG or IgA. Rarely, it is IgD or IgE.

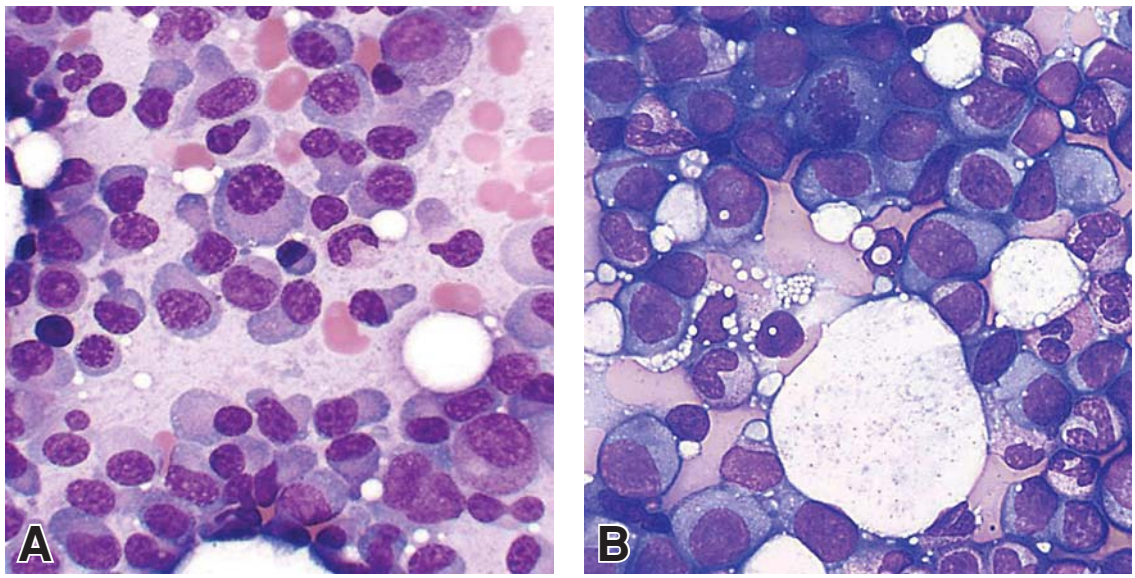

FIGURE 26-66. Plasma cell myeloma (PCM). Neoplastic plasma cells can show variable cytologic features ranging from normal-appearing cells **(A)** to cells resembling blasts **(B)**. Total number, clonality and clinicopathologic findings help distinguish PCM from other plasma cell proliferations.

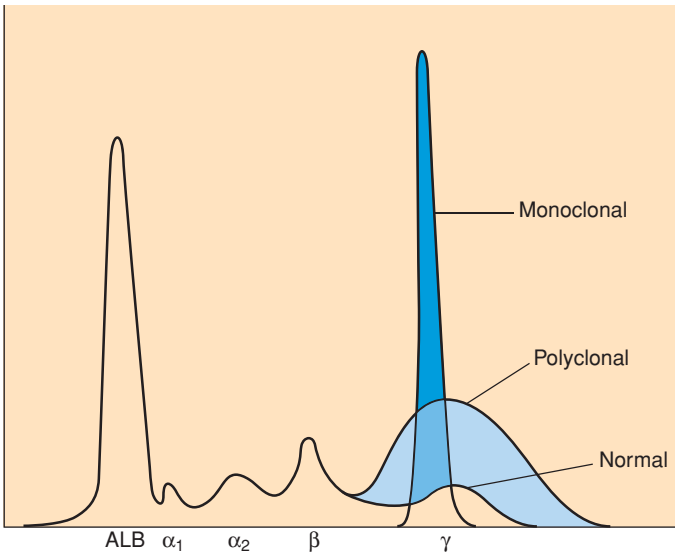

FIGURE 26-68. Abnormal serum protein electrophoretic patterns contrasted with a normal pattern. Polyclonal hypergammaglobulinemia, characteristic of benign reactive processes, shows a broad-based increase in immunoglobulins as a result of immunoglobulin secretion by myriad reactive plasma cells. Monoclonal gammopathy of unknown significance (MGUS) or plasma cell neoplasia shows a narrow peak, or spike, as a result of the homogeneity of the immunoglobulin molecules secreted by a single clone of aberrant plasma cells. *ALB* = albumin.

Immunoglobulins produced in 85% of cases are whole antibody molecules. However, the remaining 15% of myelomas only secrete light chains (**light-chain disease**). In some cases there is no detectable serum or urine paraprotein (nonsecreting myelomas). Laboratory assessment for monoclonal gammopathy entails serum (or urine) protein electrophoresis followed by immunofixation if a restricted protein (spike) is found (Fig. 26-68). The immunofixation test confirms the spike to be monoclonal κ or λ, and also identifies the heavy-chain type. IgGs account for 50% of cases, followed by IgA (20%), light chains only (20%) and IgD, IgE and biclonal (<10% combined). The type of M-component determines the course of the disease and its prognosis.

MOLECULAR PATHOGENESIS: All cases show clonal rearrangement of the Ig L- and H-chain genes. The pattern of somatic hypermutation in the variable regions of Ig heavy chains is consistent with the postgerminal center origin of the neoplastic cells in PCM. Both numerical and structural chromosomal abnormalities occur in PCM. The IgH gene frequently participates in translocations, involving diverse oncogenes (Table 26-19) and affecting 40% of cases. Loss or partial loss of one chromosome 13 occurs in 50% of cases and is thought to be an early genetic event in plasma cell neoplasia.

CLINICAL FEATURES: As stated above, diagnosis of PCM rests on a constellation of clinical and pathologic findings. The most important disorder to consider in the differential diagnosis of PCM is MGUS, which is a more common entity.

Symptomatic myeloma is characterized by end-organ damage (CRAB) in patients with serum or urine M-proteins plus clonal populations of plasma cells in the marrow. Radiography reveals lytic bone lesions in 70% of cases; these lesions are often associated with bone pain and hypercalcemia. Pathologic bone fractures are common presenting manifestations of PCM. Bone destruction in multiple myeloma results from both progressive tumor growth and secretion of osteoclast-activating factor by malignant plasma cells. Osteoclasts may also be activated by IL-6, which is also increased in patients with PCM. Calcium released from injured or resorbed bone may precipitate in the kidneys (nephrocalcinosis) and impair renal function.

Monoclonal light-chain proteinuria can damage renal tubular epithelium and lead to kidney failure. M-proteins can suppress normal antibody responses, and so predispose to infectious complications. Anemia develops in 70% of patients, both because the neoplastic plasma cells displace normal bone marrow and because renal injury limits erythropoietin production. The serum and/or urine have detectable M-proteins in 97% of patients (see above), the isotype of which predicts disease progression:

- **IgG myelomas** are "typical" PCMs. Mean survivals are 3–4 years. Infectious complications are common.
- **IgA myelomas** cause serum hyperviscosity because IgA tends to form dimers.
- **IgD myelomas** are aggressive and tend to occur in middle-aged men. Mean survival is 1 year.
- **IgE myelomas** are uncommon and aggressive, and tend to occur in young adult men.
- **Light-chain disease** is an aggressive variant in which only κ or λ light chains are made. κ-Chain disease is twice as common as λ-chain disease, reflecting the normal ratio of κ and λ light chains in plasma cells. The serum protein pattern is normal until secondary renal disease prevents glomerular filtration of light chains.

While nonspecific, the finding of rouleaux in peripheral blood smears sometimes leads to initial serum protein analysis and subsequent diagnosis of a plasma cell disorder. ***Additional findings and complications associated with PCM include amyloidosis, hyperviscosity syndrome, coagulation abnormalities, humoral immune deficiency and treatment-related myeloid malignancies (e.g., myelodysplasia and AML).***

Plasma cell myeloma remains an incurable disease; however, targeted therapies such as bortezomib, a proteasome inhibitor, portend increasingly better prognoses. Median survival is 3.75 years but is highly variable, ranging from less than 6 months to more than 10 years. Total disease burden (as reflected in serum β_2-microglobulin and albumin levels) and genetic abnormalities (Table 26-19) are the most accurate predictors of outcome.

Clinical Variants of Plasma Cell Myeloma

- **Asymptomatic myeloma** is a condition in which the diagnostic criteria for PCM are met, but the patient lacks detectable end-organ damage. This condition is like MGUS, which also shows a lack of clinical manifestations (i.e., CRAB), but it is more likely to progress to symptomatic PCM. Of patients who develop PCM, 8% were asymptomatic at first and so fall into this disease category.
- **Nonsecretory myeloma** accounts for 3% of cases of PCM. These patients lack detectable serum or urine M-protein. This occurs because the malignant plasma cells produce but cannot secrete immunoglobulin (85% of cases) or they simply do not synthesize any immunoglobulin at all (15%

of cases). Free Ig L chains are made in most of these cases, indicating that they are minimally secretory. The clinical features of nonsecretory PCM are otherwise similar to secretory PCM.

- **Plasma cell leukemia (PCL)** is an aggressive variant of PCM plasma cells and is represented by greater than 20% of circulating WBCs. At presentation, these patients often have widespread extramedullary involvement, especially of lymph nodes, spleen, liver, body cavities and cerebrospinal fluid. PCL may be the first presentation of a plasma cell tumor (primary), or it may evolve as a late complication of PCM (secondary). Many cases of PCL are IgD, IgE or light chain only. Abnormal cytogenetic karyotypes are common in PCL, as is the incidence of unfavorable genetic lesions. Plasma cell leukemia is therefore usually an aggressive disease with a short survival.
- **Solitary plasmacytoma of bone (osseous plasmacytoma)** presents as a single lytic skeletal lesion (most commonly in the ribs, vertebrae or pelvic bones) and accounts for 3%–5% of all plasma cell neoplasms. These patients most frequently present with pain at the tumor site or with a pathologic fracture. Between 1/4 and 3/4 have an M-protein, but these patients do not have clinical features of PCM and their bone marrow does not show plasmacytosis. ***Plasmacytomas contain diffuse sheets of plasma cells with no normal hematopoietic elements.*** Solitary osseous myelomas progress to multiple myeloma in 70% of cases. They may also undergo local extension or recurrence (15%), or extension to a distant skeletal site (15%). Local control with radiation therapy is often the first line of treatment. The median survival is 10 years.
- **Extramedullary (extraosseous) plasmacytomas** are localized plasma cell tumors that occur in tissues other than bone. Most (80%) arise in the upper respiratory tract, including nasal sinuses, nasopharynx and tonsils. The rest affect other soft tissue sites, such as lungs, breast and lymph nodes. Given their anatomic distribution, they must be distinguished from B-cell lymphoma with plasma cell differentiation such as MALT lymphomas. Extramedullary plasmacytoma can be definitively treated by surgery or local irradiation in most cases. Local recurrences occur in 1/4 of cases, and 15% progress to PCM.
- **Primary amyloidosis** is a complication of plasma cell tumors (or B-cell lymphomas with plasma cell differentiation) that secrete light-chain–type amyloid protein (AL amyloid; see Chapter 15). It is a disease of older adults with a median age of 65. Of patients with amyloidosis, 20% have PCM, but most only meet criteria for MGUS. Clinical presentations reflect organ sites where amyloid deposits are, resulting in organomegaly or organ dysfunction (e.g., congestive heart failure, nephrotic syndrome, malabsorption). Purpura, bone pain, peripheral neuropathy and carpal tunnel syndrome may be early signs of disease. An M-protein is seen in greater than 90% of cases, and most have λ light chains. Tissues infiltrated by amyloid have a dense lardaceous appearance. Median survival of patients with primary amyloidosis is 2 years from the time of diagnosis. Patients with PCM and amyloidosis fare worse than those with either alone. Amyloid-related cardiac disease is the most common cause of death.

Peripheral T-Cell and NK-Cell Lymphomas Originate in Postthymic T Cells

These are a heterogeneous group of mature lymphoid tumors that arise in lymphoid tissues outside of the thymus, such as lymph nodes, spleen, gut and skin (Fig. 26-48). They are relatively rare compared to B-cell lymphomas and generally have a poorer prognosis.

EPIDEMIOLOGY: Mature T-cell neoplasms account for 12% of non-Hodgkin lymphomas worldwide. They are more common in Asia than in the Western world. Major risk factors for T-cell neoplasia include the prevalence of human T-cell leukemia virus type 1 (HTLV-1) and EBV, plus genetic predispositions to those viruses (see Chapter 5). HTLV-1 is endemic in southwestern Japan: 8%–10% of the population is seropositive, and lifetime risk for adult T-cell leukemia/lymphoma (ATLL) is 5%. EBV-associated T-cell lymphomas are more common in Asians than in other racial groups.

PATHOLOGY: Peripheral T-cell and NK-cell neoplasms show variable morphologic features. Involved lymph nodes and other tissues are usually diffusely effaced by a heterogeneous population of malignant lymphoid cells. These vary from small to large, and from relatively bland or overtly anaplastic in appearance. Eosinophils and benign macrophages often comingle with the neoplastic T cells, probably recruited to the site of involvement by cytokines the lymphoma cells secrete. Some of these tumors show prominent vascularity.

Immunophenotypically, mature T-cell lymphomas express surface CD3, as well as a variable number of other pan T-cell antigens such as CD2, CD5 and CD7; CD4 or CD8; and either α–β or γ–δ T-cell receptor subunits. ***Because α–β T cells are more common, most peripheral T-cell lymphomas are of the α–β type***. γ–δ T cells make up less than 5% of the T-cell repertoire and congregate at epithelial surfaces and in the splenic red pulp. γ–δ T cells do not express CD4, CD5 or CD8.

Some mature T-cell lymphomas have a **cytotoxic** phenotype and are positive for the granule-associated proteins perforin, granzyme B and T-cell intracellular antigen (TIA-1). Unlike immature T-cell neoplasms (such as T-cell lymphoblastic lymphoma), mature T-cell neoplasms lack TdT.

Natural killer cells lack surface CD3, but they do express the CD3 ε-subunit, which is intracellular. They also express other T-cell–associated markers including CD2, CD7, CD8, CD16 and CD56.

CLINICAL FEATURES: Peripheral T-cell and NK-cell tumors are grouped clinically into **leukemic, nodal, extranodal** and **cutaneous** forms. ***They are usually widely disseminated at presentation (high stage) and hence are generally more aggressive than are B-cell neoplasms.*** Systemic manifestations such as fever, pruritus, eosinophilia, fever and weight loss are common. T- and NK-cell lymphomas are treated similarly to other aggressive lymphomas, with multiagent chemotherapy; however, most T-cell neoplasms respond poorly. Overall 5-year survival is 20%–30%.

Adult T-Cell Leukemia/Lymphoma

ATLL is caused by the human retrovirus **HTLV-1**. The normal counterparts of ATLL cells are mature, activated, $CD4^+$ T cells.

EPIDEMIOLOGY: In addition to southwestern Japan, ATLL is endemic in the Caribbean basin and parts of Central Africa. Worldwide, it accounts for 10% of mature T-cell neoplasms. Most cases are in people from endemic areas, but sporadic cases also occur elsewhere. The disease has a long latency period. Exposure to HTLV-1 occurs early in life in people who live in endemic regions. Still, ATLL only occurs in adults, with a mean age of 58. The virus may be transmitted in breast milk and via blood and blood products.

PATHOLOGY: ATLL is usually widespread at presentation, often involving lymph nodes, spleen, bone marrow, peripheral blood and skin. The latter is the most common extralymphatic site of disease, and is affected in over 50% of cases. The neoplastic lymphoid cells vary widely in appearance (Fig. 26-69). They commonly have prominent nuclear convolutions and lobations, sometimes likened to flowers (flower cells). They express T-cell–associated antigens including CD2, CD3 and CD5, but usually lack CD7. Nearly all cases strongly express CD25, and most express CD4. ***The tumor cells show clonal T-cell receptor gene rearrangements and have clonally integrated HTLV-1.*** A viral protein, p40 (Tax), directs transcriptional activation of several genes in infected lymphocytes. While ATLL reflects infection with HTLV-1, infection alone is not sufficient for neoplastic transformation. Other genetic lesions are required to progress from lymphocyte infection to malignancy.

CLINICAL FEATURES: ATLL is a systemic disease with multiorgan manifestations and peripheral leukocytosis. Acute, smoldering and chronic variants occur. Hypercalcemia, with or without lytic bone lesions, is typical. The skin is the most important extranodal site of involvement. Acute ATLL has a poor prognosis: most patients survive less than 1 year, despite aggressive systemic chemotherapy. Death frequently occurs from infectious complications, like those seen in HIV-infected patients. Chronic and smoldering forms have a somewhat better prognosis.

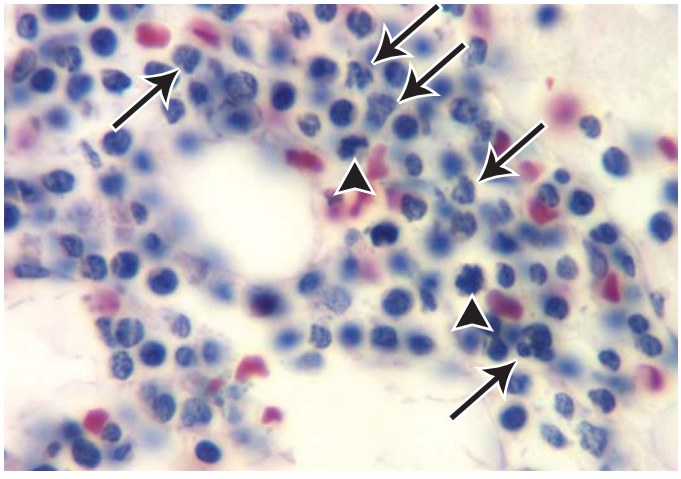

FIGURE 26-69. Adult T-cell leukemia/lymphoma (ATLL). This disease is characterized by proliferation of malignant T lymphocytes (here, in the bone marrow) with extremely irregular, knobby nuclei (*arrows*). The mitotic rate among the malignant cells is characteristically high (*arrowheads*).

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides (MF) is the most common form of primary cutaneous T-cell lymphoma (CTCL). It is characterized by infiltration of the epidermis by malignant $CD4^+$ (helper-type) T cells with marked nuclear folding. Sézary syndrome is a variant of MF, defined by a triad of erythroderma, generalized lymphadenopathy and circulating lymphoma cells in the blood (Sézary cells).

EPIDEMIOLOGY: Mycosis fungoides occurs mainly in adults and the elderly. It affects men twice as often as women.

CLINICAL FEATURES: MF is an indolent lymphoma that progresses slowly over years (and sometimes decades) from patches to plaques to mass lesions.

- The **premycotic or eczematous stage** lasts years and is difficult to distinguish from many benign chronic dermatoses. Skin biopsies may not be diagnostic of lymphoma, showing instead nonspecific perivascular and periadnexal lymphocytic infiltration with accompanying eosinophils and plasma cells.
- The **plaque stage** follows, with well-demarcated, raised cutaneous plaques. It is usually possible to diagnose MF at this stage (see below).
- In the **tumor stage,** there are raised cutaneous tumors, mostly on the face and in body folds. These tumors frequently ulcerate and may become secondarily infected. The name, **mycosis fungoides,** derives from these tumors' raised, fungating, mushroom-like appearance. Extracutaneous involvement is common, particularly of lymph nodes, spleen, liver, bone marrow and lungs.

The clinical stage (i.e., extent of disease) is the most important determinant of prognosis. Patients with limited disease generally have an excellent prognosis: their life expectancies are like those of the general population. Extracutaneous involvement augurs a poor prognosis. The 5-year survival in Sézary syndrome is 10%–20%.

PATHOLOGY: The histologic features of MF vary with the stage of the disease (see Chapter 28). A superficial band-like infiltrate or lichenoid lymphoid infiltrate with early epidermotropism characterizes the initial patch stage.

The diagnostic plaque stage is marked by pronounced infiltration of the epidermis (epidermotropism). A dense band-like infiltrate of variably sized lymphoid cells fills the subepidermal space (Fig. 26-70). These cells have very irregular nuclear contours, reminiscent of the surface of the cerebral cortex (cerebriform nuclei). Such distinctive medium to large lymphoid cells with hyperchromatic cerebriform nuclei are called **mycosis cells,** and are typical. **Pautrier microabscesses** in intraepidermal clear spaces are highly characteristic but are not common.

Diffuse dermal infiltrates composed of small, medium and/or large lymphoma cells and loss of epidermotropism characterize the tumor stage. Identification of MF cells in extracutaneous sites such as lymph nodes may be difficult, and T-cell receptor gene rearrangement studies are necessary as an adjunct to the histologic evaluation.

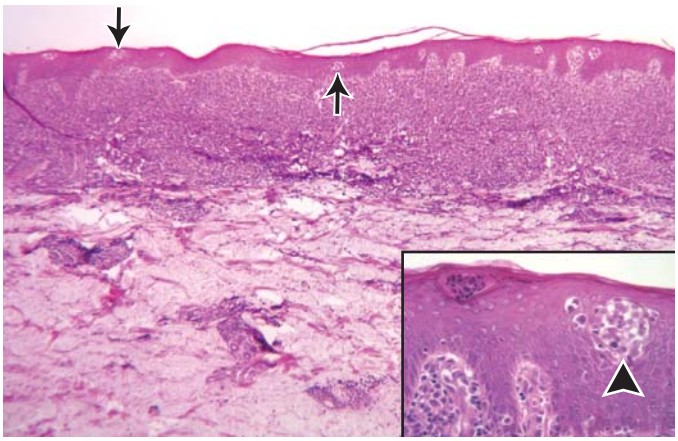

FIGURE 26-70. Mycosis fungoides, plaque phase. A diffuse infiltrate of neoplastic lymphocytes is present in the upper dermis and may occasionally invade the epidermis, as small Pautrier microabscesses (*arrows*). The lower dermis is often spared. A higher magnification of a Pautrier microabscess is shown in the inset (*arrowhead*).

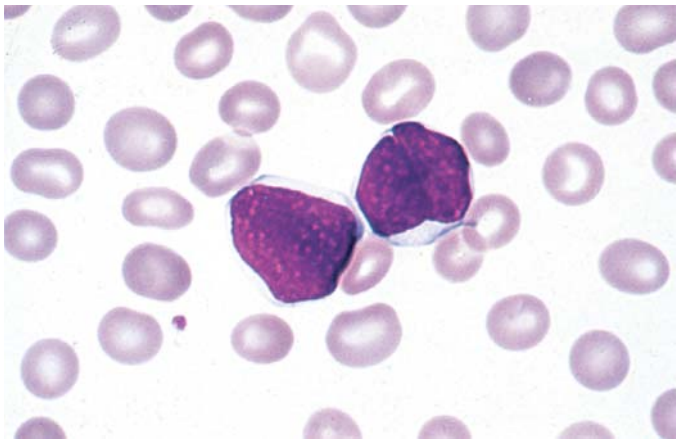

FIGURE 26-71. Sézary cells. Typical cells are medium to large with prominent nuclear convolutions resulting in a cerebriform appearance. This represents the leukemic phase of the cutaneous T-cell lymphoma, mycosis fungoides.

The characteristic cerebriform nuclei of Sézary cells aid in their identification in peripheral blood smears of patients with MF (Fig. 26-71).

The MF cells have a T-helper cell immunophenotype and generally express CD2, CD3, CD5, CD4 and T-cell receptor (TCR)-α,β. As in other mature T-cell lymphomas, CD7, the pan T-cell antigen, is absent. Clonal T-cell receptor gene rearrangements are common, which helps to distinguish subtle cases of MF from inflammatory dermatoses.

Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphomas (ALCLs) are mature T-cell tumors that contain large pleomorphic cells that express the CD30 lymphoid activation marker. These lymphomas often involve both nodal and extranodal sites (frequently skin). This disease has a bimodal age distribution, in which one peak occurs in young people and a second in older people.

MOLECULAR PATHOGENESIS: Some cases show translocations involving the *ALK* gene (Table 26-19) and have a relatively good prognosis. ALK-negative ALCLs tend to be more aggressive. Their prognosis is like that of unspecified types of peripheral T-cell lymphoma.

PATHOLOGY: The histology of ALCL is variable, but all cases have a population of cells with irregularly shaped nuclei (often horseshoe or kidney shaped) and abundant cytoplasm that often has a distinct eosinophilic area near the nucleus (Fig. 26-72). These cells, which are usually large, are diagnostic **hallmark cells** and express CD30. ALCL cells express several pan T-cell antigens

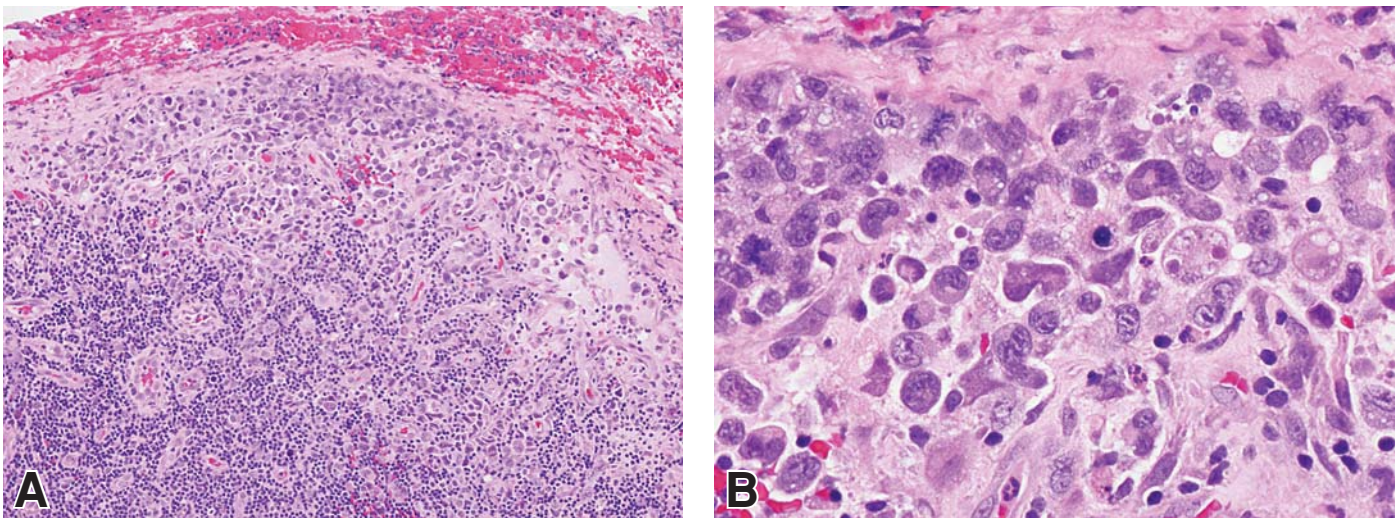

FIGURE 26-72. Anaplastic large cell lymphoma (ALCL). Partially effaced lymph node with accumulation of malignant cells in the subcapsular sinus. This common ALCL pattern may be confused with metastatic carcinoma. **Inset.** The intrasinusoidal lymphoma cells are large and pleomorphic. Cells with kidney-shaped nuclei and an eosinophilic zone near the nucleus are known as hallmark cells and are seen in all variants of ALCL.

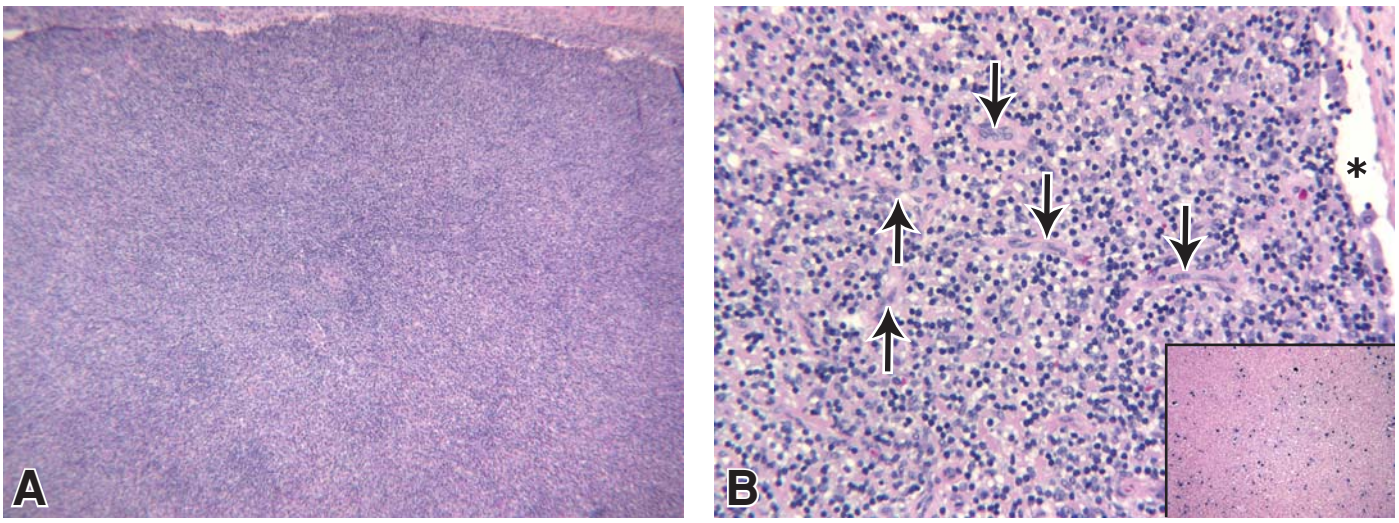

FIGURE 26-73. Angioimmunoblastic T-cell lymphoma. A. Complete effacement of lymph node architecture by an infiltrate that includes a mixture of neoplastic T cells, prominent blood vessels and Ebstein-Barr virus (EBV)-positive B lymphocytes. The lymph node capsule is at the top. **B.** Higher magnification showing the blood vessels (representative vessels are highlighted by *arrows*) and their prominent endothelial cells. The subcapsular sinus is identified (*). **Inset.** In situ hybridization for EBV transcript, demonstrating the scattered EBV-positive B lymphocytes scattered throughout the neoplastic T-cell proliferation.

and cytotoxic T-cell antigens (TIA-1, granzyme B), but most cases are negative for CD3. Over 90% of cases have T-cell receptor rearrangements, even if the tumor cells do not express T-cell antigens. ALK expression (see above) may also be useful in diagnosis.

CLINICAL FEATURES: Most patients have advanced disease (stage III or IV) at presentation. Peripheral and central lymphadenopathy are common, as are extranodal and bone marrow involvement. Patients often have B symptoms, especially fever. Overall 5-year survival with ALK-positive ALCL is 80%. This drops to 48% for patients with ALK-negative tumors.

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AILT) is an aggressive peripheral (mature) T-cell lymphoma. Patients present with generalized adenopathy and symptoms consistent with a systemic disease process. Neoplastic T-cell infiltrates expand the paracortical regions of lymph nodes and are associated with a striking proliferation of high endothelial venules. EBV is present in nearly all cases, but the EBV infects only B cells, not the neoplastic T cells.

CLINICAL FEATURES: AILT occurs in adults and the elderly. At the outset, most patients have high-stage disease, generalized lymphadenopathy, hepatosplenomegaly, bone marrow involvement, hypergammaglobulinemia and body cavity effusions. A pruritic skin rash is also common. Other laboratory findings include cold agglutinins, hemolytic anemia, circulating immune complexes and rheumatoid factor. The tumor renders people with AILT immunodeficient, and the high incidence of EBV-positive B cells in these patients reflects their altered immune function. This is an aggressive lymphoma with a median survival of less than 3 years. Patients often die from infectious complications. Some patients develop a concomitant large B-cell lymphoma.

PATHOLOGY: Lymph nodes involved by AILT show partial or complete architectural effacement by a heterogeneous population of atypical small to medium-sized cells, in a setting of prominent, arborizing high endothelial venules. Some cases contain lymphoma cells with abundant clear cytoplasm and minimal atypia, and others show a population of atypical large lymphoid cells (Fig. 26-73). Tumor T cells express most pan T-cell antigens (CD2, CD3, CD5, CD7), plus CD4 in most cases. They also usually show a phenotype of follicular T-helper cells with expression of CD10, CXCL13 and PD-1. Clonal rearrangement of the T-cell receptor occurs in most AILTs, and a minority of cases also show clonal Ig gene rearrangement (reflecting a clonally expanded EBV-positive B-cell population, *not* T tumor cells).

In Classical Hodgkin Lymphomas an Inflammatory Background Accompanies Hodgkin and Reed-Sternberg Cells

Thomas Hodgkin of Guy's Hospital, London, first recognized and described these lymphomas in 1832, and the first descriptions of the distinctive malignant cell were by Sternberg in 1898 and Reed in 1902 (hence called Reed-Sternberg cells; Fig. 26-74). There are 2 types of HL: **classical Hodgkin lymphoma** and **nodular lymphocyte-predominant Hodgkin lymphoma**. Unlike the non-Hodgkin tumors discussed above, classical HLs usually arise in a single lymph node or lymph node chain and usually spread in a contiguous fashion, occur mostly in younger people and have relatively few neoplastic cells, amid a prominent mixed inflammatory cell background. ***In the vast majority of cases, the neoplastic cells in HL are derivatives of germinal center B cells.***

EPIDEMIOLOGY AND ETIOLOGIC FACTORS: ***HL is the most common malignancy of Americans between the ages of 10 and 30.*** Some 8000 cases occur annually in the United States, an incidence of 3 per 100,000 people. It is

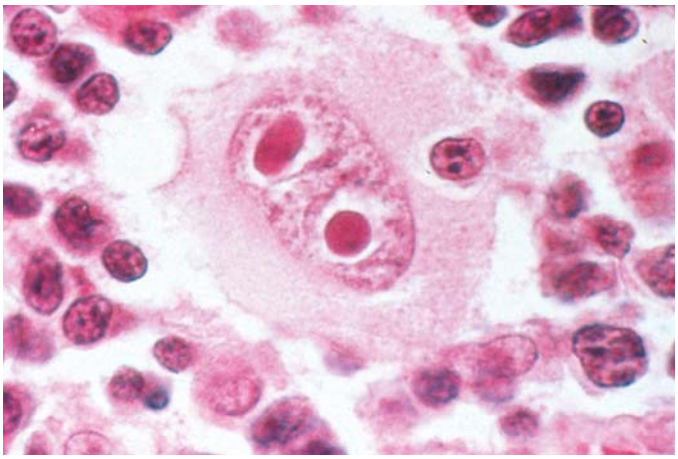

FIGURE 26-74. Classic Reed-Sternberg cell. Mirror-image nuclei contain large eosinophilic nucleoli.

slightly more common in men than in women (4:2.5) and in whites than in blacks (3.5:2).

The geographic variation in HL incidence and some clinicopathologic features that simulate an infectious process suggest a viral etiology. However, proof is lacking. Reports of several self-limited "mini-epidemics" of HL in children suggest possible horizontal transmission (i.e., by interpersonal contact) of an infectious agent. But these clusters are beguiling: such apparent case grouping is predictable on statistical grounds. Broader epidemiologic studies do not support a contagious etiology. A possible link between HL and EBV infection has been suggested. Young adults who have had EBV infectious mononucleosis have a 3-fold higher risk of developing HL, and the EBV genome is frequently identified in Reed-Sternberg cells.

Genetic factors may play a role in HL. Certain HLA subtypes, particularly HLA-B18, are more common in patients with HL. Moreover, siblings of HL patients have a 7-fold increased risk of HL, which rises to 100-fold increased if they are monozygotic twins.

Immune status also seems to be a factor, at least in some cases. HL occurs more often in people with altered immunity or with autoimmune diseases, such as rheumatoid arthritis. Also, HL accounts for 7% of the malignancies seen in people with ataxia-telangiectasia, who develop cancer 100 times more often than the general population.

The fact that Hodgkin/Reed-Sternberg (HRS) cells are often less than 1% of the total cell content of affected tissues in HL has challenged investigators of HL pathogenesis. However, EBV is present in HRS cells in most patients with HL. EBV antigens may be present in HRS cells by immunohistochemistry or in situ hybridization (Fig. 26-75). However, this finding is variable: EBV occurs in 70%–80% of mixed-cellularity HL, but in less than 40% of nodular sclerosis HL.

Classical Hodgkin Lymphoma

This lymphoma, formerly called Hodgkin disease, is a B-cell neoplasm composed (in most cases) of mononuclear Hodgkin cells and multinucleate Reed-Sternberg (Fig. 26-74) cells in a reactive inflammatory cell milieu consisting of small lymphocytes (mostly T cells), plasma cells, bland histiocytes and eosinophils. Fibroblasts are variably prominent, with or without distinct bands of collagen fibrosis (Fig. 26-76). HRS cells are typically scattered and compose only a small fraction of the total cells in involved lymph nodes. Classical Hodgkin lymphomas are divided into 4 histologic subtypes, largely based on the nature of the associated inflammatory and fibroblastic background and the appearance of the HRS cells. These are (1) **nodular sclerosis,** (2) **mixed cellularity,** (3) **lymphocyte rich** and (4) **lymphocyte depleted**. HRS cells in all subtypes share similar immunophenotypes and genetic alterations. Treatment outcomes are about the same for all.

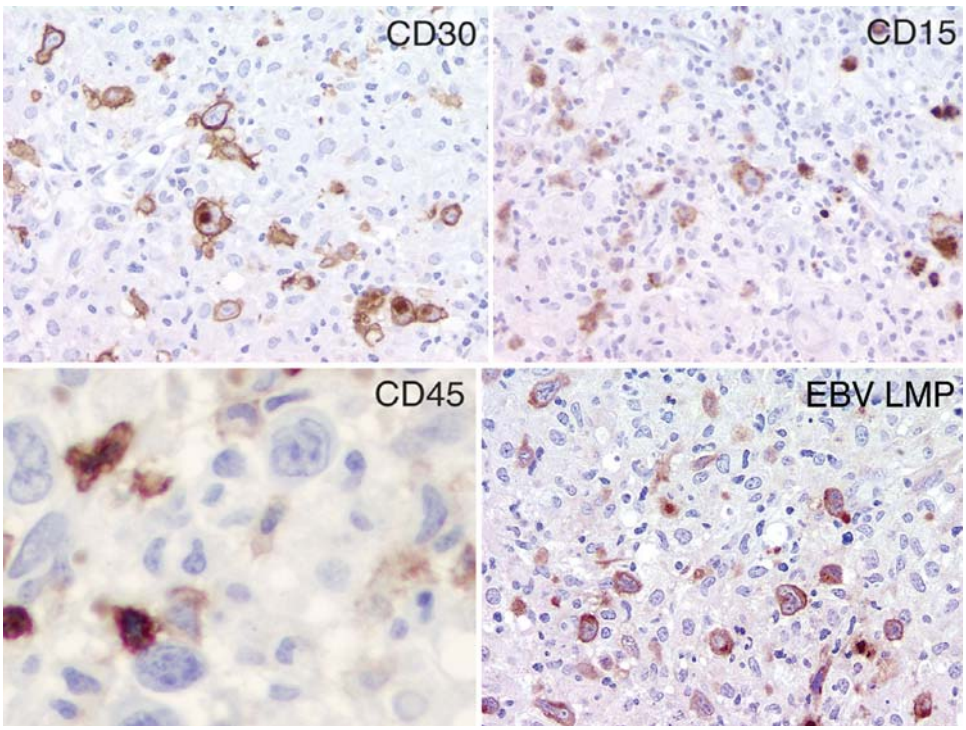

FIGURE 26-75. Reed-Sternberg and Hodgkin cells. The Hodgkin/Reed-Sternberg (HRS) cells are uniformly positive for CD30, CD15 and Epstein-Barr virus latent membrane protein antigen (EBV LMP) (immunohistochemistry; red chromogen). Common leukocyte antigen CD45 is not expressed on HRS cells.

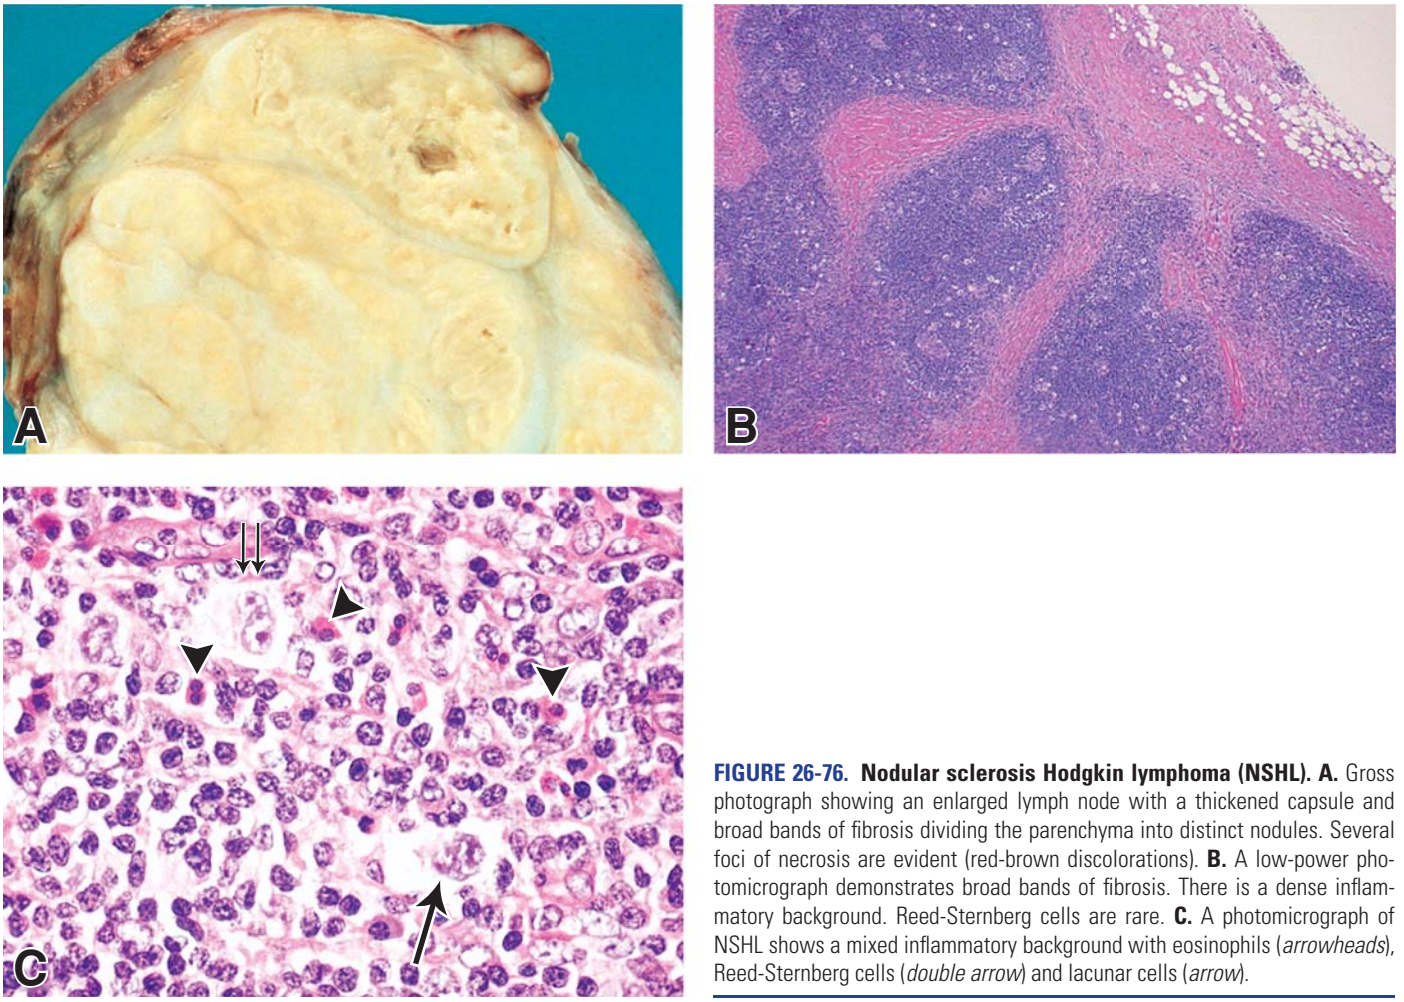

FIGURE 26-76. Nodular sclerosis Hodgkin lymphoma (NSHL). A. Gross photograph showing an enlarged lymph node with a thickened capsule and broad bands of fibrosis dividing the parenchyma into distinct nodules. Several foci of necrosis are evident (red-brown discolorations). **B.** A low-power photomicrograph demonstrates broad bands of fibrosis. There is a dense inflammatory background. Reed-Sternberg cells are rare. **C.** A photomicrograph of NSHL shows a mixed inflammatory background with eosinophils (*arrowheads*), Reed-Sternberg cells (*double arrow*) and lacunar cells (*arrow*).

EPIDEMIOLOGY: Classical Hodgkin lymphomas represent 95% of HLs. The disease has a bimodal age distribution, with one peak at 15–35 years and another in older adults. People with a history of infectious mononucleosis caused by EBV have a higher incidence of classical HL.

PATHOLOGY: Lymph nodes involved by classical HL show architectural effacement by a variable number of HRS cells in a mixed inflammatory cell background with variable amounts of fibrosis (sclerosis) (Fig. 26-76). Prototypical Reed-Sternberg cells are large with at least two nuclear lobes or nuclei and abundant light blue cytoplasm (Fig. 26-74). Their nuclei have irregular nuclear contours, prominent eosinophilic nucleoli and a perinuclear halo, giving the cells the appearance of "owl's eyes" or viral inclusions. HRS cells may undergo apoptosis, resulting in mummified-appearing cells with condensed cytoplasm and pyknotic nuclei. ***Despite their unique appearance, the HRS cells may hide amid the dense reactive background, and typically account for 1%–3% of the cells in involved tissues.***

HRS cells express the lymphoid activation marker CD30 in nearly all cases (Fig. 26-75). They also express the macrophage/monocyte marker, CD15, in 85% of cases. Unlike B-cell non-Hodgkin lymphomas, HRS cells do not typically express such B-cell antigens as CD20 and CD79a, nor do they have CD45 (leukocyte common antigen).

The peculiar HRS immunophenotype, particularly the absence of definitive B-cell differentiation markers, caused decades of confusion about the origin of HRS cells. It was only with advanced molecular diagnostic techniques in the late 1990s that their relationship to clonal B cells of germinal center cell origin became clear. ***A clonal Ig gene rearrangement occurs in greater than 98% of HRS cells.***

HRS cells produce cytokines that elicit characteristic tissue effects. The combined effects of IL-5 and eotaxin attract eosinophils, and IL-6 recruits plasma cells. TGF-β activates fibroblasts and may account for nodular fibrosis. Other growth factors and cytokines made by HRS cells include IL-2, -7, -9, -10 and -13.

Nodular Sclerosis Hodgkin Lymphoma

Nodular sclerosis Hodgkin lymphoma (NSHL) is characterized by a fibrous capsular thickening of involved lymph nodes, with bands of fibrosis extending from the capsule into the nodal cortex and forming nodules (Fig. 26-76A). **Lacunar cells** are helpful in diagnosis but result from a retraction artifact in formaldehyde-fixed tissue (Fig. 26-76C). The nodules contain the mixed inflammatory cell population described above and variable numbers of classical HRS and lacunar cells. NSHL subtype accounts for 70% of cases of classical HL and most often affects 15- to 30-year-olds. Over 80% of patients have mediastinal involvement, with bulky disease in over half of these. B symptoms (Table 26-22) occur in up to 40% of patients. Bone marrow involvement and association

TABLE 26-22
ANN ARBOR STAGING SYSTEM FOR HODGKIN DISEASE

Stage I A or B[a]	I	Involvement of a single lymph node region
		or
	I_E	A single extralymphatic organ or site
Stage II A or B	II	Involvement of two or more lymph node regions on the same side of the diaphragm
		or
	II_E	With localized contiguous involvement of an extralymphatic organ site
Stage III A or B	III	Involvement of lymph node regions on both sides of the diaphragm
		or
	III_E	With localized contiguous involvement of an extralymphatic organ or site
		or
	III_S	With involvement of spleen
		or
	III_{ES}	Both extralymphatic organ or site and spleen involvement
Stage IV A or B	IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement

[a]A = asymptomatic; B = presence of constitutional symptoms (fever, night sweats and weight loss exceeding 10% of baseline body weight in preceding 6 months).

with EBV are low, relative to other types. NSHL has a better prognosis than the other subtypes.

Mixed Cellularity Hodgkin Lymphoma

In mixed cellularity Hodgkin lymphoma (MCHL), HRS cells are present amid a mixed inflammatory background of eosinophils, neutrophils, macrophages and plasma cells (Fig. 26-77),

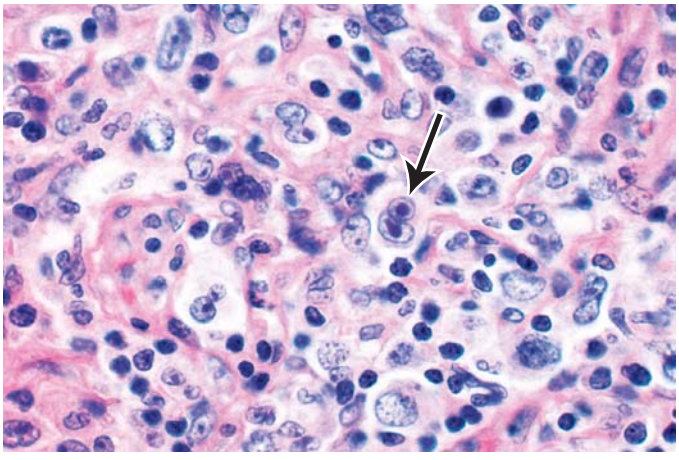

FIGURE 26-77. Mixed cellularity Hodgkin lymphoma. A photomicrograph of a lymph node shows classic, binucleated and mononuclear Reed-Sternberg cells (*arrow*) in a mixed inflammatory background that includes many small lymphocytes (T cells). Note the absence of fibrotic bands, which helps distinguish this subtype from nodular sclerosis Hodgkin lymphoma.

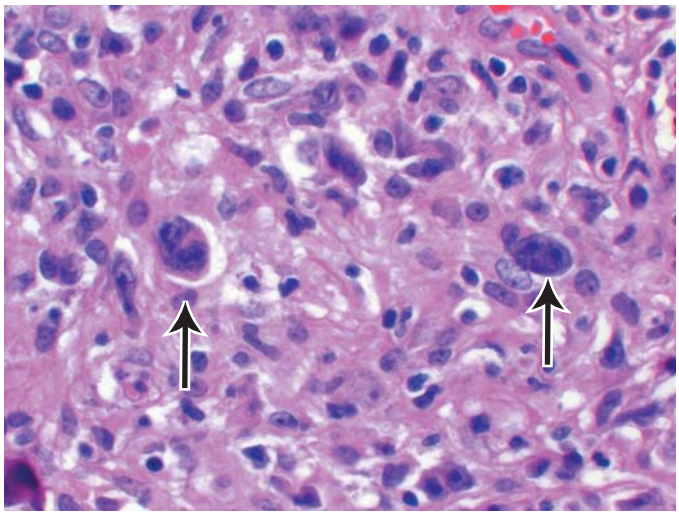

FIGURE 26-78. Lymphocyte-depleted Hodgkin lymphoma. Two Hodgkin/Reed-Sternberg cells are seen (*arrows*). The number of reactive lymphocytes in the fibrotic background is markedly reduced. The differential diagnosis in cases like this includes large cell lymphoma.

but there is a lack of the nodular fibrosis of NSHL. MCHL represents 1/4 of classical HLs. *It is the most frequent subtype in HIV-1–infected patients and shows the highest association with EBV.* MCHL is most common in the 4th and 5th decades. Cervical lymph nodes are the most common initial site of involvement; unlike NSHL, mediastinal involvement is uncommon in MCHL. The prognosis for patients with MCHL is similar to that for patients with NSHL.

Lymphocyte-Rich Hodgkin Lymphoma

In lymphocyte-rich Hodgkin lymphoma (LRHL), classical HRS cells are surrounded by a nodular (or rarely diffuse) lymphoid infiltrate of small B cells. Hallmarks of other forms—eosinophils, neutrophils and sclerosis—are absent. This subtype accounts for only 5% of classical HL and tends to occur in older people. Patients generally present with low-stage disease, without B symptoms. Overall survival for LRHL is better than for all other subtypes of classical HL, and similar to that seen in nodular lymphocyte-predominant HL (see below).

Lymphocyte-Depleted Hodgkin Lymphoma

Lymphocyte-depleted Hodgkin lymphoma (LDHL) is the least common subtype of classical HL, affecting less than 1% of HL patients. In LDHL, HRS cells predominate; background lymphocytes are largely absent (Fig. 26-78). Typical patients with LDHL are 30- to 40-year-old men. This subtype is also often associated with concomitant HIV infection. Involvement of retroperitoneal lymph nodes, which is rare in other subtypes, is not uncommon in LDHL, nor is infiltration of abdominal organs and bone marrow. Patients with associated HIV infection fare worse, but in others the disease course and outcome are like those in the other subtypes. Distinction from non-Hodgkin lymphoma may be more difficult with this subtype of classical HL.

CLINICAL FEATURES: HL usually presents as nontender peripheral adenopathy in a single lymph node or group of nodes. Cervical and mediastinal nodes are involved in over half of cases. The anterior mediastinum is frequently involved, especially in the

FIGURE 26-79. Hodgkin lymphoma involving the spleen. Multiple masses replace the normal splenic parenchyma. Laparotomy and splenectomy are no longer routinely performed for diagnostic and staging purposes.

nodular sclerosis type. Less commonly, axillary, inguinal and retroperitoneal lymph nodes are affected. Peripheral lymph node groups, such as antecubital, popliteal and mesenteric lymph nodes, are usually spared. Initially, HL spreads predictably between contiguous lymph node groups via efferent lymphatics. As it progresses, spread becomes less predictable because of vascular invasion and hematogenous dissemination (Fig. 26-79).

Constitutional ("B") symptoms are present in 40% of HL patients. These include low-grade fever, which may be cyclical (Pel-Ebstein fever); night sweats; and weight loss over 10% of body weight. Pruritus may occur as the disease progresses. For unknown reasons, drinking alcoholic beverages induces pain at involved sites in 10% of patients.

Patients with HL often have deficient T-lymphocyte function. Subtle defects of delayed-type hypersensitivity, which can be detected in most patients even at the time of initial diagnosis, often get worse as the disease progresses. Anergy to skin test antigens occurs early in HL. Such immune dysfunction is in addition to the immunosuppressive side effects of therapy. Absolute lymphocytopenia (<1500 cells/μL) is present in half of cases, most often those with advanced HL. Humoral immunity is usually intact until late in the course of the disease.

HL prognosis depends mainly on the patient's age and anatomic extent (stage) of the disease. Good prognostic factors include (1) younger age, (2) lower clinical stage (localized disease) and (3) absence of B signs and symptoms. The comprehensive Ann Arbor Staging System (Table 26-22) relies on clinical evaluation and radiographic and pathologic findings (including bone marrow biopsy) to assign stage.

Complications of HL include compromise of vital organs by enlarging tumor and secondary infections due to both primary defects in delayed-type hypersensitivity and immunosuppressive effects of therapy. Development of second malignancies after therapy is of special concern, and eventually affects over 15% of patients. AML develops in 5% of patients; aggressive large cell lymphomas occur somewhat less often.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) is different from classical HL discussed above. While classified as an HL, its immunomorphologic, clinical and pathologic features more resemble indolent B-cell non-Hodgkin lymphomas than they do classical HL. In NLPHL, the characteristic cells are Hodgkin variants called **L&H cells** (for lymphocyte and histiocytic cells), or "popcorn" cells, because of their characteristic appearance. As in classical HL, these neoplastic cells are infrequent in tissues with NLPHL.

This is also a tumor of germinal center B-cell origin. Unlike classical HL, lymphoma cells in NLPHL express specific B-cell lineage antigens (CD20, CD79a, surface Ig) and are negative for CD15 and CD30. Clonal Ig gene rearrangement occurs in almost all cases. Rearranged immunoglobulin heavy-chain genes show a high degree of somatic hypermutation in the variable region, which indicates that they most likely derive from germinal center B cells.

NLPHL represents about 5% of HLs. It mainly affects men 30–50 years old. However, NLPHL also occurs in younger people, including children. It is typically localized at the time of diagnosis (i.e., stage I). Cervical, axillary or inguinal lymph nodes are common sites of disease. Unlike classical HL, mediastinal, splenic and bone marrow involvement is rare. Visceral involvement is also uncommon. This form of HL tends to skip anatomic lymph node regions (i.e., noncontiguous spread). Only 20% of cases present with B signs and symptoms. These tumors follow an indolent clinical course and are rarely fatal. The 10-year survival for patients with low-stage disease (stage I or II) is greater than 80%. However, outcomes are worse for patients with more advanced disease. Complications include recurrences, which are common, and progression to diffuse large B-cell lymphoma, which occurs in 3%–5% of cases.

Lymphoproliferative Disorders Are Associated with Immune Deficiencies

While several of the non-Hodgkin and Hodgkin lymphomas occur in patients with immune dysfunction, a specific group of lymphoproliferative diseases associated with immunodeficiency is also recognized. These develop against a background of primary immune defects (e.g., CD40 ligand and CD40 deficiencies, common variable immunodeficiency, Wiskott-Aldrich syndrome, ataxia-telangiectasia, Nijmegen breakage syndrome, X-linked lymphoproliferative disorder), lesions associated with HIV infection, posttransplant lymphoproliferative disorders and immune deficiency–associated lymphoproliferative disorders due to other iatrogenic immunosuppression.

Posttransplant Lymphoproliferative Disorders

Posttransplant lymphoproliferative disorders (PTLDs) occur in people who are treated with immunosuppressive regimens because they have received solid organ, bone marrow or stem cell allografts. PTLDs are either lymphoid or plasmacytic, and range from proliferations resembling infectious mononucleosis to overt large cell lymphomas, which are mostly B-cell type. Occasional PTLDs have T-cell phenotypes, and some resemble Hodgkin lymphomas or plasma cell neoplasms. ***Most of these disorders reflect Epstein-Barr virus infection, and the key risk factor is seronegativity for EBV at the time of transplantation.***

EPIDEMIOLOGY: Several factors increase the risk of developing PTLD. These include patient characteristics, allograft types and immunosuppressive regimens, which may vary from institution to institution. The incidence of PTLD most closely parallels the extent of immunosuppression. Patients with renal allografts have the lowest frequency of PTLD (<1%), while those who receive heart/lung or intestinal allografts have the highest (>5%). Patients with stem cell or bone marrow allografts have a low risk of PTLD (1%). The risk in these individuals reflects the degree of HLA matching: unrelated or HLA-mismatched transplants are linked to higher rates of PTLD. PTLD is more common in children, probably because they are more often EBV naive than are adults.

MOLECULAR PATHOGENESIS: Most cases are caused by EBV, with an average latency period of less than 1 year. However, EBV-negative cases may evolve 5 years or more after transplantation. In solid organ recipients, host lymphocytes become infected with EBV, but in bone marrow or stem cell allograft recipients, PTLD is often caused by infected ***donor*** lymphocytes.

PATHOLOGY: The histology of PTLD is diverse and includes:

- **Early lesions:** These are characterized by plasmacytic hyperplasia or infectious mononucleosis–like changes. They tend to occur in younger patients, particularly those without prior EBV infection. Early lesions involve lymph nodes or tonsils and adenoids more often than true extranodal sites. These lesions usually regress spontaneously, or with a reduction in immunosuppression; however, some infectious mononucleosis–like lesions may occasionally be fatal. Early lesions can evolve into other PTLDs over time.
- **Polymorphic PTLD:** These lesions contain heterogeneous cellular populations, including immunoblasts, plasma cells and small to medium-sized lymphocytes (Fig. 26-80). The atypical lymphoplasmacytic and immunoblastic proliferation tends to efface lymph node architecture and/or form destructive extranodal masses. This type of PTLD is most common in children and frequently follows primary EBV infection. Its clinical presentation is indistinguishable from other types of PTLD. Variable numbers of cases regress with reduction in immunosuppression, but others progress and require cytotoxic chemotherapy for lymphoma. The atypical cells in polymorphic PTLD show clonally rearranged immunoglobulin genes, although detectable clones are less prominent compared to the level seen in monomorphic PTLD (see below).
- **Monomorphic PTLD:** These are proliferations of transformed monoclonal B lymphocytes or plasma cells that qualify as diffuse large B-cell lymphomas, or less commonly Burkitt lymphomas or plasma cell myelomas/plasmacytomas. This type of PTLD presents similarly to other lymphomas or plasma cell neoplasms. Virtually all cases show clonal Ig gene rearrangements; most have clonal EBV genomes. Cytogenetic abnormalities are common. The majority require treatment for lymphoma; this type of PTLD does not typically respond to reduction in immunosuppression like other PTLD types discussed above.
- **Classical Hodgkin lymphoma–type PTLD:** This rare type of PTLD occurs more often in renal transplant patients, is almost always EBV positive and resembles classical HL (see above).

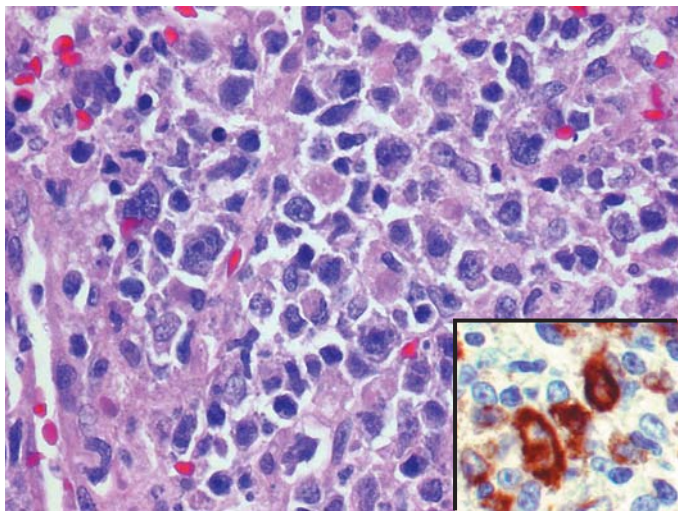

FIGURE 26-80. Posttransplant lymphoproliferative disorder (PTLD). Polymorphic-type PTLD is characterized by a heterogenous population of atypical lymphocytes with clonal immunoglobulin gene rearrangements. **Inset.** Atypical lymphocytes are positive for Ebstein-Barr virus latent membrane protein (EBV LMP) by immunohistochemistry.

CLINICAL FEATURES: Patients with PTLD present with nonspecific symptoms, such as lethargy, malaise, weight loss and fever. Lymphadenopathy and allograft dysfunction are also common. Some patients, mostly children, may have symptoms of airway obstruction because of enlarged tonsils. In addition to lymph nodes and tonsils, PTLDs commonly involve extranodal sites, particularly the gut, lungs and liver. Moreover, PTLDs frequently involve the allograft itself, which may cause diagnostic confusion since allograft rejection can present similarly, both clinically and histologically. The prognosis of PTLD varies and depends largely on the type of lesion. Early lesions (see above) tend to regress with reduction in immunosuppression, without graft loss. Other forms that more closely resemble lymphomas may also regress when immunosuppression is reduced, but many of these require additional cytotoxic therapy, such as anti-CD20 (rituximab), chemotherapy or both. Bone marrow/stem cell allograft recipients tend to show a higher mortality from PTLD than do solid organ allograft recipients. Mortality may be lower in children than in adults. EBV viral load monitoring of seronegative patients is common practice in many transplant centers and has decreased the incidence of disseminated PTLD.

Iatrogenic Immunodeficiency-Associated Lymphoproliferative Disorders

These disorders mostly occur in patients receiving immunosuppressive drugs for autoimmune diseases or other conditions (excluding transplantation). Lymphoid proliferations in this group of patients resemble those in patients with PTLD, and vary from polymorphic disorders to outright diffuse large B-cell lymphoma, peripheral T-cell lymphoma

or classical HLs. Methotrexate, which has long been used to treat rheumatoid arthritis (RA), was the first immunosuppressive agent reported to be associated with lymphoproliferative disorders. Newer agents used to treat RA, such as the TNF-α antagonists, also increase the risk of lymphoma, compared to healthy age-matched people. Like most PTLDs, the iatrogenic lymphoproliferative disorders are often associated with EBV, but EBV is not the only important risk factor. Chronic antigenic stimulation, with consequent lymphocytic proliferation, caused by the underlying inflammatory disease, plus the patient's genetic background, also affects lymphoma development. Close to 50% of cases have an extranodal presentation, with the GI tract, skin, liver, spleen, lung, kidney, thyroid gland, bone marrow and soft tissue commonly involved. The remaining clinical features are like those in lymphomas that occur in immunocompetent patients.

Many of these tumors resemble diffuse large B-cell lymphomas or classical HLs. Like PTLDs, iatrogenic lymphoproliferative disorders often respond, at least partially, to withdrawal of immunosuppressive medication. Most such responses occur in cases with EBV-positive cells. Overall survival of patients with DLBCL in this setting is 50%.

HISTIOCYTIC DISORDERS

Histiocytic Proliferations May Be Neoplastic or Nonneoplastic

Among the nonneoplastic disorders are Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy; see above), storage disorders such as Niemann-Pick disease, Gaucher disease and Tangier disease (see Chapter 6) and hemophagocytic syndromes.

Hemophagocytic Disorders

All hematophagocytic disorders have in common an immunologic defect that results in immune dysregulation, with consequent increases in certain cytokines. The result is inadequately regulated T-cell and macrophage activation. NK cells are normal in number but do not regulate antigen-presenting cells effectively. This leads to uncontrolled activation of $CD8^+$ T cells. Proinflammatory cytokines (see Chapter 4), such as TNF-α, IL-6 and interferon-γ (IFN-γ), are increased.

Hemophagocytic syndromes may be genetic or acquired. Diagnosis requires a combination of clinical and pathologic criteria: (1) fever over 38.5°C, (2) splenomegaly, (3) anemia, (4) thrombocytopenia, (5) hypertriglyceridemia and (6) hypofibrinogenemia, accompanied by hemophagocytosis in bone marrow, spleen or lymph nodes. In these organs, one may find macrophages engulfing normal hematopoietic cells (Fig. 26-81).

Inherited hemophagocytic syndromes commonly involve mutations of the *PFR1* gene and typically present in children. They are associated with activation and proliferation of benign macrophages, hemophagocytosis, systemic symptoms (fever, etc.) and circulating cytopenias affecting one or more hematopoietic series. Cellular immune defects may also accompany these clinical manifestations.

Acquired hemophagocytic syndromes occur in several settings. These include viral infections (primary infections with EBV, CMV, HIV, parvovirus), malaria, *E. coli* and histoplasmosis. Hematologic malignancies such as T-cell and NK-cell lymphomas may underlie hemophagocytic diseases. Autoimmune diseases (juvenile rheumatoid arthritis, systemic lupus erythematosus) are also occasionally implicated.

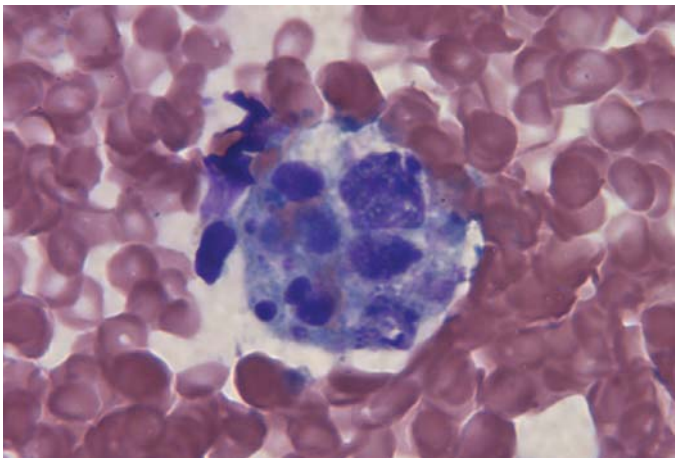

FIGURE 26-81. Hemophagocytic syndrome. This disorder is characterized morphologically by phagocytosis of hematopoietic cells by tissue macrophages. Shown here is a macrophage engulfing bone marrow cells.

Histiocytic Neoplasms Are Rare Tumors Derived from Macrophages, Dendritic Cells or Histiocytes

The true incidence of these tumors is unknown as many were poorly recognized and characterized until recently. Their clinical and pathologic features are broad and vary from indolent to aggressive. This group of neoplasms includes **Langerhans cell histiocytosis (LCH), histocytic sarcoma** and **follicular and interdigitating dendritic cell sarcomas.** Only the former will be discussed.

Langerhans Cell Histiocytosis Is a Neoplastic Proliferation of Langerhans Cells That Occurs Mainly in Children

LCH represents a spectrum of uncommon Langerhans cell proliferations. Disorders arising from these cells span the gamut from asymptomatic involvement at a single site, such as bone or lymph nodes, to aggressive systemic multiorgan disease. Langerhans cells are mononuclear phagocytes derived from precursor cells in the bone marrow. They are present in the epidermis, lymph nodes, spleen, thymus and mucosal tissues, and their role is to ingest, process and present antigens to T cells. In lymph nodes, Langerhans cells are called interdigitating reticulum cells (IDCs).

The etiology and pathogenesis of LCHs are unknown. Langerhans cells in all forms of LCH are clonal, which strongly suggests that these are neoplastic diseases. LCHs mostly affect infants, children and young adults. The extent of disease and rate of progression correlate inversely with age at presentation. There were once eponyms attached to various presentations of LCH, but these terms are now used infrequently.

The least aggressive form is called **eosinophilic granuloma**. It is a localized, usually self-limited, disorder, usually involving one bone or, less often, lymph nodes, skin and

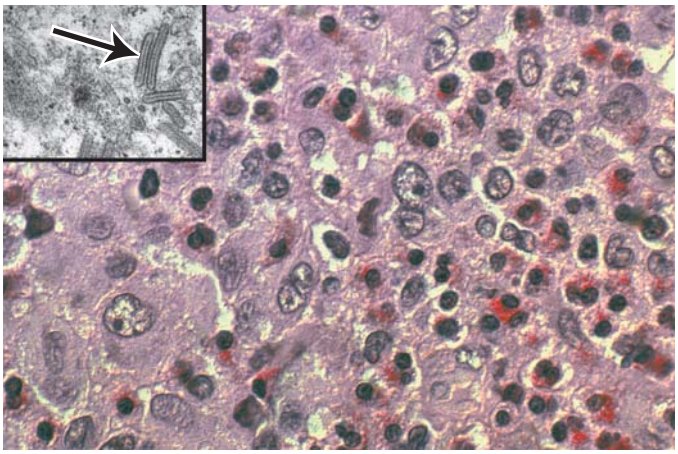

FIGURE 26-82. Eosinophilic granuloma. A section of an affected rib shows proliferated Langerhans cells and numerous eosinophils. **Inset.** Electron micrograph showing a Birbeck granule (*arrow*) in Langerhans histiocytosis.

lungs. This form of LCH affects older children (5–10 years old) and young adults (under 30), mostly males. Eosinophilic granuloma represents 75% of LCH.

In some cases, these lesions present as a multifocal, typically indolent disorder, localized to one organ system, largely bone. Children ages 2–5 generally present with multiple bony lesions that may be associated with soft tissue masses. This was once called **Hand-Schüller-Christian disease**.

The rarest of all forms of these diseases (<10% of cases) is an acute, disseminated variant that usually occurs in infants and children under age 2. There is no sex predominance. Skin lesions, hepatosplenomegaly, lymphadenopathy and bone lesions, along with pancytopenia, are typical. In older literature, this was **Letterer-Siwe** disease.

PATHOLOGY: Despite their clinical heterogeneity, LCHs share common histopathologies (Fig. 26-82). The cells accumulate in an environment with eosinophils, histiocytes and small lymphocytes. Langerhans cells are large (15–25 µm), with grooved nuclei, delicate vesicular chromatin and small nucleoli. These cells contain distinctive rod-shaped or tubular cytoplasmic inclusions with dense cores and a double outer sheath, called Birbeck granules. One end of these granules is bulbous, in which case they resemble tennis rackets. Cell markers are identical to those of epidermal Langerhans cells, and include S-100 protein and CD1a.

CLINICAL FEATURES: Clinical manifestations of LCH reflect the sites involved. Skin involvement, mainly in the Letterer-Siwe variant, resembles seborrheic or eczematoid dermatitis, and is most prominent on the scalp, face and trunk. Otitis media is common. Patients show painless localized or generalized lymphadenopathy and hepatosplenomegaly. Lytic lesions of bone cause pain or tenderness to palpation (see Chapter 30). Proptosis (protrusion of the eyeball) may reflect infiltration of the orbit. Diabetes insipidus occurs if the hypothalamic–pituitary axis is affected. *The classic triad of diabetes insipidus, proptosis and defects in membranous bones occurs in only 15% of cases of Hand-Schüller-Christian disease.*

Prognosis in LCH depends mainly on age at presentation, extent of disease and rate of progression. The disorder is usually self-limited and benign in older people (eosinophilic granuloma), while children under 2 years (Letterer-Siwe disease) tend to do poorly. Rarely, LCH follows an aggressive clinical course like a malignant tumor.

Spleen

ANATOMY AND FUNCTION

The spleen is a lymphoid organ that plays a major role in blood filtration, removing abnormal or senescent cells, immune complexes and opsonized bacteria. A normal spleen weighs 100–170 g and is not palpable on physical examination. The spleen's supporting structure includes a fibrous capsule, radiating fibrous trabeculae and a delicate stromal framework of reticulum fibers (Fig. 26-83). The splenic artery enters at the hilum and branches into trabecular arteries, following the course of the fibrous trabeculae. The organ is subdivided into areas of red and white pulp. This division is useful, since most diseases affect either one or the other.

THE WHITE PULP: The lymphoid tissue of the spleen, the white pulp, contains masses of T and B lymphocytes, ensheathing a central artery. The T-cell domain is in the periarteriolar lymphoid sheath; the B-cell domain has follicles and a perifollicular marginal zone. Arising from the central artery, follicular arteries enter B-cell follicles and end in marginal sinuses at the junction between the white and red pulp. Circulating lymphocytes exit the vascular system from the marginal sinus and travel to their respective B-cell and T-cell domains. Lymphocytes leave the white pulp and enter the red pulp by way of the same marginal sinuses.

As part of the peripheral lymphoid system, effector B and T cells of the white pulp carry out immunologic functions for the circulatory system like the immunologic functions of lymph nodes. The white pulp is (1) the source of protection from blood-borne infection, (2) a major site for synthesis of opsonizing IgM antibody and (3) a source of lymphocyte and plasma cell production.

THE RED PULP: The red pulp contains a network of stromal cords and vascular sinuses. Blood from the penicilliary arteries empties directly into the sinuses (closed circulation), then drains into trabecular veins, and ultimately into the splenic vein. A small fraction (5%–10%) is diverted into splenic cords (open circulation) and slowly percolates through a meshwork studded with phagocytic macrophages. Blood then reenters the sinusoids through narrow slits made of longitudinally oriented, slender endothelial cells and radially oriented ring fibers.

The red pulp is mainly a filter that screens and eliminates defective or foreign cells. In the splenic cords, mononuclear phagocytes scrutinize erythrocytes, which must be deformable enough to traverse the narrow interstices between the lining endothelial cells. The red blood cells must also be able to withstand hypoxia, hypoglycemia and acidosis that characterize the stromal cord microenvironment. Splenic macrophages identify and eliminate senescent and damaged erythrocytes. The spleen normally removes half of aged erythrocytes; the liver, bone marrow and other organs deal with the rest. After phagocytosing and breaking down erythrocytes, macrophages first store the resulting iron as hemosiderin. This pigment then binds to transferrin, leaves the macrophages and travels to the bone marrow to be reused in erythropoiesis.

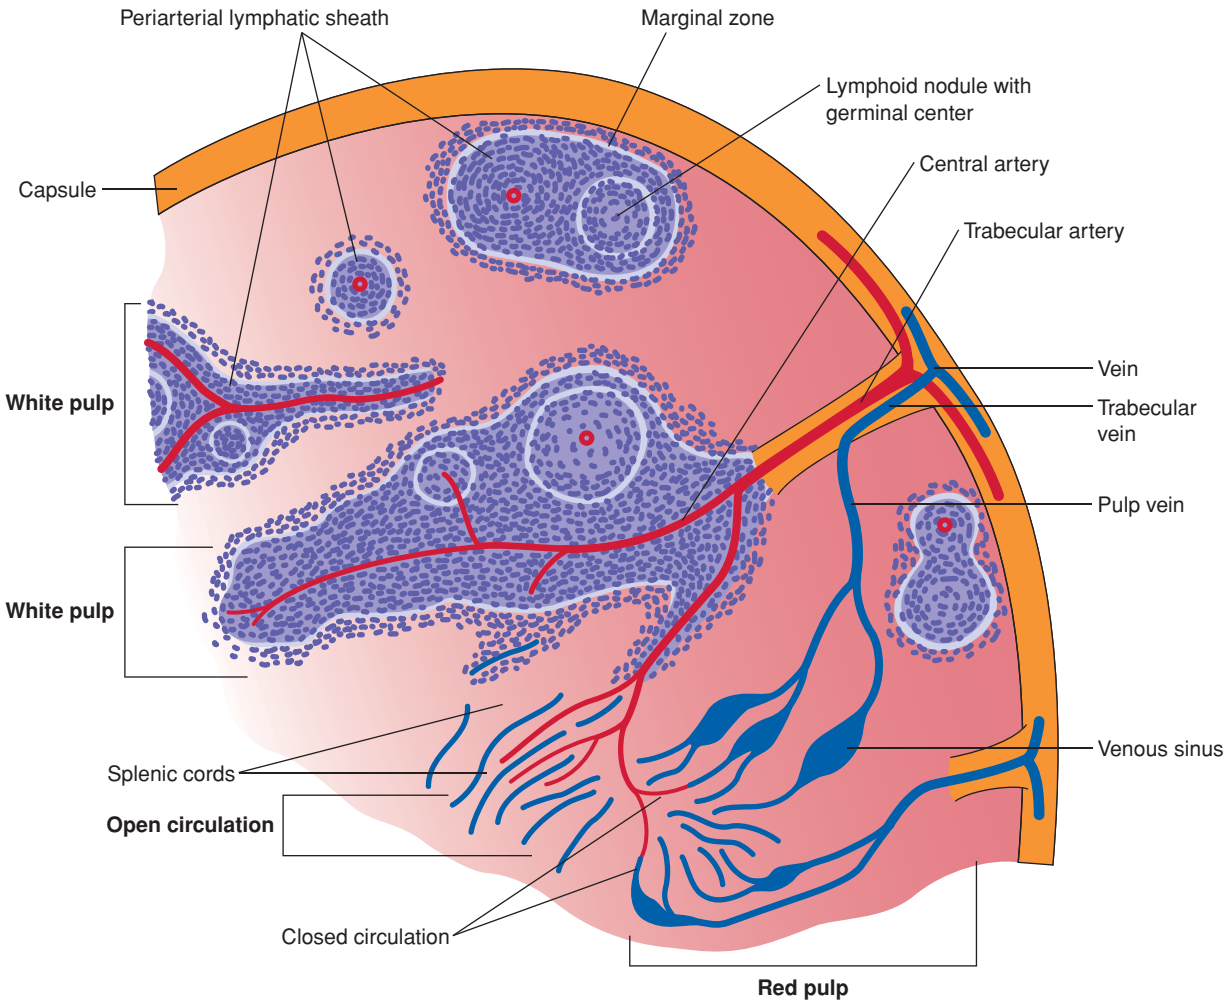

FIGURE 26-83. Structure of the normal spleen.

Splenic macrophages can also identify abnormal erythrocyte inclusions, such as Howell-Jolly bodies (remnants of nuclear DNA), Heinz bodies (denatured hemoglobin) and siderotic granules (iron), and remove them without destroying the erythrocytes.

Some membrane lipids of maturing erythrocytes are removed in the red pulp. Without this function, such as after splenectomy, red blood cell membrane may accumulate, relative to the amount of hemoglobin. This leads to central pooling of hemoglobin and a "target cell" appearance.

Most normal erythrocytes survive, as do granulocytes and platelets. They ultimately enter trabecular veins and leave the hilum via the splenic vein. One third of the blood platelet pool and a small fraction of granulocytes normally reside, undamaged, in the spleen. The spleen does not significantly sequester erythrocytes, however. Splenectomy, then, is followed only by increases in platelet and granulocyte counts.

DISORDERS OF THE SPLEEN

Hypersplenism is a functional disorder, which (see hemolytic anemia, above) features anemia, leukopenia, thrombocytopenia and compensatory bone marrow hyperplasia. In **hyposplenism,** normal splenic functions are impaired by disease or are absent after splenectomy. The spleen's normal filtering function is gone, which increases risk of severe bacteremia and causes mild leukocytosis and thrombocytosis. Nuclear remnants and Howell-Jolly bodies are present in many of circulating erythrocytes.

Asplenia, congenital absence of the spleen, occurs once in 40,000 births, and often accompanies other congenital anomalies. Acquired asplenia occurs in young adults with sickle cell anemia, after a period of hypersplenism. In these patients, multiple infarctions eventually lead to splenic atrophy and hyposplenism. Episodic infarction is often painful because of secondary fibrinous perisplenitis. Without the spleen to sequester erythrocytes and remove redundant materials from them, excess membrane and intracellular debris persist, and many red cells assume target shapes and carry nuclear remnants, Howell-Jolly bodies or even intact nuclei.

Accessory spleens are common congenital anomalies and occur in 1/6 of pediatric splenectomies. They are usually solitary and involve the splenic hilum, the tail of the pancreas or the gastrosplenic ligament. After splenectomy, accessory spleens may enlarge, but they rarely become large enough to replace the functions of a lost spleen. Other congenital anomalies of the spleen include polysplenia with multiple small splenic masses, fusion, hamartomas and cysts.

Reactive Splenomegaly

The spleen is a key member of both lymphopoietic and mononuclear phagocyte systems. Thus, splenomegaly is common in many unrelated benign and malignant diseases (Table 26-23). Acute splenitis occurs in many blood-borne infections: the spleen becomes congested, with red and white pulp infiltrated by neutrophils and plasma cells. In most cases the spleen is moderately enlarged (400 g).

In acute and chronic parasitemias, the red pulp may be engorged with parasites and their breakdown products. The spleen is often massively enlarged in chronic malaria (up to 10 kg). It shows fibrous thickening of the capsule and trabeculae, with slate gray to black coloration of the pulp because of phagocytosed malarial pigment (hematin).

In infectious mononucleosis, half of patients have splenomegaly, which may rarely lead to potentially fatal splenic rupture. Reactive lymphocytes infiltrate the capsular and trabecular systems and blood vessels, weaken the spleen's supporting structure and predispose the spleen to traumatic rupture in infectious mononucleosis. A polymorphic population of T and B immunoblasts, which may include large multinucleated forms, permeates the red pulp cords and sinuses.

In chronic inflammatory disorders, splenomegaly reflects white pulp hyperplasia. Germinal centers are prominent, as in rheumatoid arthritis, and the red pulp has a parallel increase in mononuclear phagocytes, immunoblasts, plasma cells and eosinophils. In systemic lupus erythematosus, fibrinoid necrosis of the capsule and concentric, or "onion skin," thickening of penicilliary arteries and central arterioles of the white pulp occur.

TABLE 26-23
PRINCIPAL CAUSES OF SPLENOMEGALY

Infections
Acute
Subacute
Chronic
Immunologic Inflammatory Disorders
Felty syndrome

Splenic or portal vein thrombosis or stenosis
Right-sided cardiac failure
Primary or Metastatic Neoplasm
Leukemia
Lymphoma
Hodgkin disease
Myeloproliferative syndromes
Sarcoma
Carcinoma
Storage Diseases
Gaucher
Niemann-Pick
Mucopolysaccharidoses

Congestive Splenomegaly

Chronic passive congestion of the spleen causes splenomegaly and hypersplenism. This occurs most often in patients with portal hypertension due to cirrhosis, thrombosis of the portal or splenic veins or right-sided heart failure. Splenic congestion also complicates hereditary hemolytic anemias and hemoglobinopathies. Common inherited causes of hemolytic anemia include hereditary spherocytosis and elliptocytosis, thalassemia and sickle cells anemia. Erythrocytes in these conditions are inflexible, so they become trapped as they attempt to pass through splenic cords.

The Spleen in Sickle Cell Anemia

The spleen is modestly enlarged (300–700 g), with a thickened, fibrotic capsule. Focal accentuation of the capsular fibrosis leads to a "sugar-coated" appearance. The cut surface is firm, and the color varies from pink to deep red, depending on the extent of fibrosis. Venous sinuses are distended with red cells and surrounded by hemosiderin-laden macrophages. Later, because of hypoxia and infarcts, splenic parenchyma becomes fibrotic, and the red pulp is hypocellular. Foci of old hemorrhage persist as Gamna-Gandy bodies, fibrotic nodules containing iron and calcium salts encrusted on collagenous and elastic fibers. The white pulp tends to be atrophic.

Infiltrative Splenomegaly

The spleen may be enlarged owing to increased cellularity or deposition of extracellular material, as in amyloidosis. Splenic macrophages accumulate in chronic infections, hemolytic anemias and a variety of storage diseases (see Chapter 6). Diverse neoplastic and reactive bone marrow diseases lead to extramedullary hematopoiesis and corresponding increases in spleen size. Malignant cells may infiltrate the spleen in hematologic proliferative disorders, such as leukemias and lymphomas, and in virus-associated hemophagocytic syndrome.

Splenomegaly Caused by Cysts and Tumors

Splenic cysts are rare. Most are actually pseudocysts, lined by fibrous walls. These represent the residues of old hemorrhage or infarction. Hydatid, or echinococcal, cysts are the most common cysts worldwide, in areas endemic for *Echinococcus granulosus* (see Chapter 9). They are quite rare in the United States.

Primary splenic neoplasms are also rare. Vascular tumors are the most common nonhematopoietic neoplasms that involve the spleen. They include benign tumors such as hemangiomas and lymphangiomas. The former are usually of the

cavernous variety, with large endothelial-lined spaces. They may vary from minute foci to lesions that occupy most of the spleen. The vascular spaces in hemangiomas contain erythrocytes; in lymphangiomas they have lymph. Other benign tumors include littoral cell angiomas and hemangioendotheliomas.

The most common primary malignant tumor of the spleen is the hemangiosarcoma. Splenic hemangiosarcomas are rare, highly malignant neoplasms of vascular endothelial cells that tend to metastasize to the liver via the portal drainage. Other malignancies, such as malignant lymphomas or HL, usually affect the spleen as part of generalized disease. Despite its large blood supply and filtering function, the spleen is only rarely involved by metastatic solid tumors, and then only in the setting of wildly metastatic cancers.

Thymus

The thymus elaborates many factors (thymic hormones) that play key roles in maturation of the immune system and development of immune tolerance. On this basis, we discuss certain entities associated with thymus abnormalities in this chapter.

ANATOMY AND FUNCTION

The thymus derives embryologically from the 3rd pair of pharyngeal pouches, with an inconstant contribution from the 4th pair. The organ is irregularly pyramidal. Its base is located inferiorly and its two lobes fuse in the midline. Its fibrous capsule extends into the parenchyma, forming septa that delimit lobules. The thymus is largest, relative to total body size and weight at birth, when it averages about 15 g. It continues to grow until puberty, and may then weigh 30–40 g.

Thymic lobules have outer cortices and inner medullas. The former consist of densely packed lymphocytes, which in this location are called thymocytes. Thymocytes mingle with a few epithelial and mesenchymal cells. The medulla has many more epithelial cells and fewer thymocytes. Hassall corpuscles are medullary structures that are focally keratinized, concentric aggregates of epithelial cells characteristic of the thymus.

The thymus is the key site for T-lymphocyte differentiation (see Chapter 4). It also has a small population of neuroendocrine cells, which may explain how neuroendocrine tumors arise in this organ. There is also a complement of myoid cells, which resemble striated muscle cells but are nevertheless regarded as epithelial cells. Their function is uncertain.

Beginning at puberty, the thymus starts to involute and continues to diminish in size into adulthood. Initially, cortical thymocytes are decreased relative to epithelial cells. Eventually, the thymus is little more than islands of epithelial cells depleted of lymphocytes and aggregates of Hassall corpuscles separated by adipose tissue.

AGENESIS AND DYSPLASIA

Alterations in the thymus vary from complete absence (agenesis) or severe hypoplasia to a situation in which the thymus is small but has normal architecture. Some small glands may show thymic dysplasia, in which there are no thymocytes, few if any Hassall corpuscles and only epithelial components. Various developmental anomalies are associated with immune deficiencies (see Chapter 4) and hematologic disorders.

- **Severe combined immunodeficiency (SCID)** represents a group of genetically distinct syndromes all characterized by defects of both T- and B-cell functions and associated with severe thymic dysplasia. Both X-linked and autosomal recessive inheritance may be involved. SCID can be caused by mutations in at least 10 different genes. The most common form is the X-linked type, caused by mutations in *IL-2RG*, a cytokine receptor gene. Common autosomal recessive inherited forms include adenosine deaminase deficiency and IL-7Ra.
- **Chromosome 22q11.2 deletion syndrome** (DiGeorge, velocardiofacial, Shprintzen, conotruncal anomaly face and Cayler syndromes) is a spectrum of overlapping conditions caused by 22q11.2 deletions. It is one of the most common (of 180 at least) genetic syndromes associated with variable clinical manifestations. Patients with DiGeorge syndrome fail to develop their 3rd and 4th branchial pouches, resulting in thymic and parathyroid agenesis or hypoplasia, congenital heart defects, dysmorphic facies and other congenital anomalies. As a result, patients have hypocalcemia and deficient cellular immunity, with a particular susceptibility to *Candida* infections. These patients are also at increased risk for psychotic illnesses. Endocrine abnormalities include hypocalcemia, thyroid dysfunction and short stature. The diagnosis, suspected on clinical grounds, can be readily established by FISH analysis.
- In **Nezelof syndrome,** lymphopenia, hypoplastic lymphoid tissue, abnormal thymus architecture and abnormal T-cell function are the rule. It resembles DiGeorge syndrome, save for the lack of parathyroid and cardiac manifestations.
- **Wiskott-Aldrich syndrome** is an X-linked, recessive immunodeficiency caused by mutations in the *WAS* gene. This syndrome entails a hypoplastic thymus, recurrent infections, eczema and thrombocytopenia (see Chapter 4). Patients are highly susceptible to lymphoid malignancies and autoimmune disorders.
- **Reticular dysgenesis (RD)** is a very rare, severe immune deficiency characterized by a vestigial thymus and developmental failure of bone marrow stem cells. It results in lymphopenia, granulocytopenia and death, either in utero or in the neonatal period. The defect in RD is not known.
- **Swiss-type hypogammaglobulinemia** is an autosomal recessive disorder with severe thymic hypoplasia or dysplasia. Infants with this condition have no lymphocytes or Hassall corpuscles in the thymus and die within a few years from infection. In this disease, thymic anlage in the neck fail to descend into the mediastinum.
- **Ataxia-telangiectasia (A-T)** is an autosomal recessive cerebellar ataxia associated with immunodeficiency, telangiectasia, increased sensitivity to ionizing radiation and frequent occurrence of lymphoma. The involuted thymus lacks epithelial differentiation and Hassall corpuscles. Classic A-T results from two truncating *ATM* gene mutations that cause complete loss of ATM protein kinase (see Chapter 5).

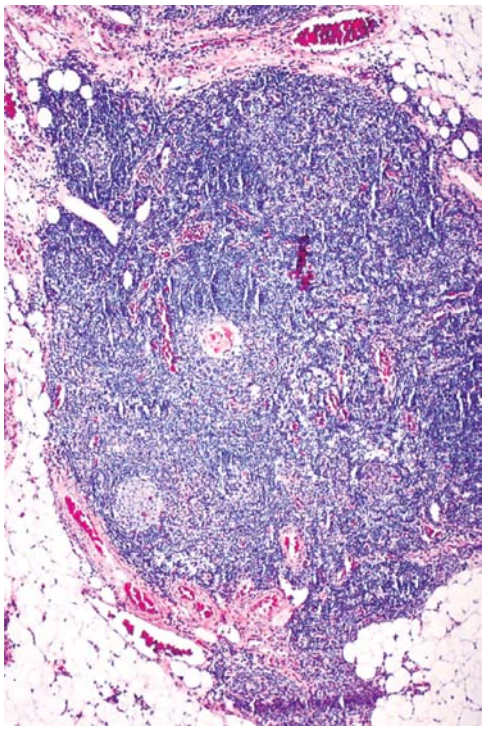

FIGURE 26-84. Thymic hyperplasia. This thymus removed from a patient with myasthenia gravis shows lymphoid follicles with germinal centers.

THYMIC HYPERPLASIA

Thymic hyperplasia is the presence of lymphoid follicles in the thymus, regardless of the size of the gland (Fig. 26-84). The total weight of the thymus is usually in the normal range, but may be slightly increased. The follicles contain germinal centers, composed largely of B lymphocytes that produce IgM and IgD. These follicles tend to occupy and distort the medullary zones.

Thymic hyperplasia occurs in 2/3 of patients with myasthenia gravis (see Chapter 31). Interestingly, thymic epithelial and myoid cells contain nicotinic acetylcholine receptor protein, which may stimulate the development of antibodies against that receptor. Thymic follicular hyperplasia also occurs in other autoimmune diseases, such as Graves disease, Addison disease, systemic lupus erythematosus, scleroderma and rheumatoid arthritis.

THYMOMA

Thymomas are neoplasms of thymic epithelial cells. They almost always occur in adult life and most (80%) are benign.

PATHOLOGY: Most thymomas are in the anterosuperior mediastinum, although a few may occur elsewhere where thymic tissue is present, such as the neck, middle and posterior mediastinum and pulmonary hilus. Benign thymomas are irregularly shaped masses that vary from a few centimeters to 15 cm or more. They are encapsulated, firm and gray to yellow tumors that are divided into lobules by fibrous septa (Fig. 26-85). Large thymomas may have foci of hemorrhage, necrosis and cystic degeneration. Sometimes, the entire thymoma is cystic and

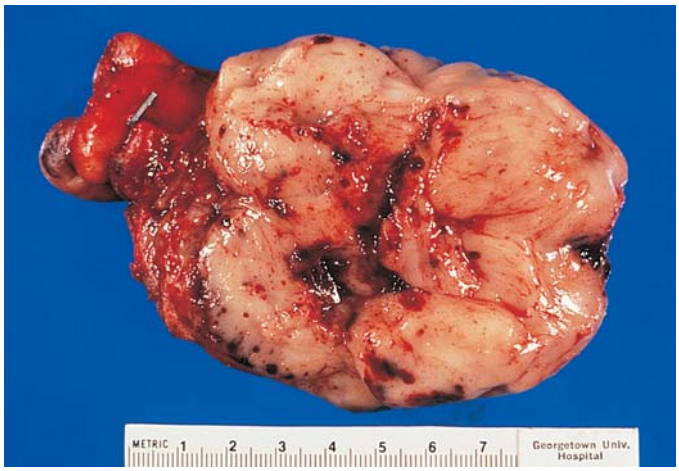

FIGURE 26-85. Thymoma. The tumor in cross-section is whitish and has a bulging surface with areas of hemorrhage. Note the attached portion of normal thymus.

multiple sections are required to identify the true nature of the lesion.

Thymomas contain a mixture of neoplastic epithelial cells and nontumorous lymphocytes (Fig. 26-86). The proportions of these elements vary from case to case, and even among different lobules. The epithelial cells are plump or spindle shaped, with vesicular nuclei. In cases in which epithelial cells predominate, they may show organoid differentiation, including perivascular spaces with lymphocytes and macrophages, tumor cell rosettes and whorls suggesting abortive Hassall corpuscles.

MYASTHENIA GRAVIS: Fifteen percent of patients with myasthenia gravis have thymomas. Conversely, 1/3 to 1/2 of patients with thymomas develop myasthenia gravis. This coincident occurrence of thymomas and myasthenia gravis is more common in men older than age 50.

When thymoma is associated with myasthenic symptoms, the epithelial cells are plump, rather than spindly. Antigens related to the nicotinic acetylcholine receptor also occur in thymomas. Thymic hyperplasia is almost always present in the nontumorous thymic tissue, and lymphoid follicles may even be present in the thymoma itself.

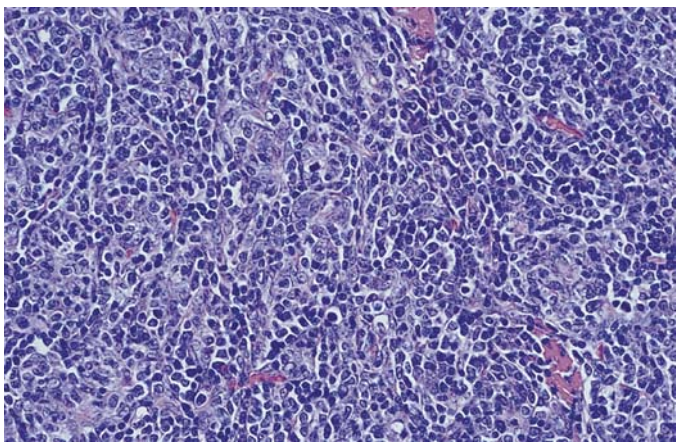

FIGURE 26-86. Microscopic features of thymomas. The tumor consists of a mixture of neoplastic epithelial cells and nontumorous lymphocytes.

OTHER ASSOCIATED DISEASES: Thymomas are associated with many other immune disorders. Over 10% of patients have hypogammaglobulinemia and 5% have erythroid hypoplasia. In these patients, unlike those with myasthenia gravis, the epithelial component of the thymoma is spindle shaped. Other associated diseases include myocarditis, dermatomyositis, rheumatoid arthritis, lupus erythematosus, scleroderma and Sjögren syndrome. Certain malignant tumors may also occur with thymoma, including T-cell leukemia/lymphoma and multiple myeloma.

Malignant Thymomas Invade Locally and May Metastasize

One fourth of thymomas are not encapsulated and show malignant features.

PATHOLOGY: Type I malignant thymoma is the most common cancer of the thymus, and is virtually indistinguishable histologically from encapsulated, benign thymomas. However, it penetrates the capsule, implants on pleural or pericardial surfaces and metastasizes to lymph nodes, lung, liver and bone.

Type II malignant thymoma is a very uncommon invasive tumor, also called thymic carcinoma. Its morphology is highly variable and it resembles squamous carcinomas, lymphoepithelioma-like carcinomas (identical to those in the oropharynx; see Chapter 29), sarcomatoid variants (carcinosarcoma) and other rare patterns. These variants share a distinct epithelial appearance and a mediastinal tumor that lacks this feature is probably not thymic carcinoma.

CLINICAL FEATURES: Malignant thymomas are treated by surgical excision and radiation. Chemotherapy is added in cases with distant metastases. The prognosis for benign thymoma is excellent. The presence or absence of myasthenic symptoms has little prognostic value. For type I malignant thymomas, the prognosis correlates with the extent of disease. Most patients with type II thymomas die within 5 years of diagnosis.

Other Tumors of the Thymus Are Uncommon

NEUROENDOCRINE TUMORS: Several neuroendocrine tumors arise in the thymus. These resemble comparable tumors elsewhere, clinically and pathologically, and include carcinoids (typical and atypical) and carcinomas (small and large cell). Neuroendocrine tumors express cytokeratins (AE1/AE3, CAM5.2) and endocrine markers (synaptophysin, chromogranin, NSE). They may produce ACTH and cause Cushing syndrome. Interestingly, many thymic neuroendocrine tumors lack expression of thyroid transcription factor 1 (TTF-1).

CARCINOID: Thymic carcinoid tumors are malignant. They tend to invade locally and metastasize widely, although they may be cured by local excision if they are well circumscribed. While 1/3 of these patients show Cushing syndrome, carcinoid syndrome is exceedingly rare. Thymic carcinoid tumors occur sporadically, in familial forms, and in the syndromes of multiple endocrine neoplasia (MEN)-1 and -2A. They may also accompany neurofibromatosis type I. Most thymic carcinoids are atypical (intermediate category) with frequent mitoses and/or necrosis.

SMALL CELL CARCINOMA: Small cell carcinomas (SCCs), indistinguishable from those in the lung, may also arise in the thymus. In them, SCC elements may mingle with squamous cell carcinomas.

GERM CELL TUMORS: Thymic germ cell tumors account for 20% of mediastinal tumors. It is felt that they arise from cells left behind when germ cells migrate during embryogenesis. The histologies of mediastinal germ cell tumors are like those in the gonads (see Chapters 23 and 24). Mature cystic teratomas are most common. Seminomas, embryonal carcinomas, endodermal sinus tumors, teratocarcinomas, immature teratomas and choriocarcinomas all occur. Mixed germ cell histologies are common.

Mediastinal germ cell tumors may on occasion show somatic-type malignant components of sarcoma, carcinoma or hematologic malignancies. Save for mature cystic teratoma, which affects both sexes equally, the other tumors occur mostly in males. Thymic seminomas arise only in men. Prognosis is like that for comparable gonadal tumors, although mediastinal nonseminomatous germ cell tumors are more aggressive.

Other lesions include benign and malignant stromal tumors. Thymolipomas are benign, well-circumscribed masses of mature adipose tissue and unremarkable thymic parenchyma. Thymic stromal sarcomas are low-grade malignant mesenchymal tumors with variable morphology, but frequently of a liposarcomatous nature.

Nonneoplastic masses include thymic, mesothelial and enteric-type cysts.

Paraneoplastic Syndromes Involving the Hematopoietic System

Paraneoplastic syndromes are tumor-associated clinical manifestations that occur distant to the tumor and are caused by the secretion of tumor cell products such as hormones, cytokines, growth factors and tumor antigens. They may precede, coexist or follow the diagnosis of underlying malignancy. Occasionally, they may be the first signs of tumor relapse. Rarely, they can even present when patients are in remission. Their clinical manifestations are diverse, depending on the organ/system involved, and early recognition of these syndromes may facilitate a timely diagnosis of malignancy. The most effective management of paraneoplastic syndromes in the setting of hematologic malignancies remains the treatment of the underlying malignancy.

The following are paraneoplastic syndromes commonly associated with hematologic disorders, grouped by organ system in which the manifestations occur.

HEMATOLOGIC MANIFESTATIONS OF NEOPLASIA

Abnormalities in Peripheral Blood Cell Counts Occur in Several Hematologic Malignancies

These may be identified before the diagnosis of malignancy is made, or they may be apparent at the time of diagnosis.

Autoimmune hemolytic anemia presents similar to idiopathic hemolytic anemia, with elevated LDH, unconjugated bilirubin and reticulocyte count and low serum haptoglobin. Direct antiglobulin test (DAT) is positive (IgG). The antibody specificity is against red blood cell antigens, owing to immune dysregulation resulting in the loss of tolerance to self-antigens (in this case, red cell antigens) in the setting of malignancy. CLL is a frequent hematologic malignancy associated with AIHA, but NHLs and HLs can also be the cause.

Immune thrombocytopenia presents with petechiae, bleeding and bruising. The antibody specificity is unknown. Among the most frequent hematologic malignancies, CLL and B-cell lymphomas are on top of the list.

AIHA occurring in combination with ITP is called **Evans syndrome**. If drugs, infections or connective tissue diseases are ruled out, evaluation for a lymphoproliferative disorder needs to be done.

Cancer-related **microangiopathic hemolytic anemia** (CRMAHA) is a Coombs-negative hemolytic anemia with schistocytes and thrombocytopenia. Among lymphomas, CRMAHA was described in Hodgkin lymphoma, diffuse large B-cell lymphoma, intravascular lymphoma, myeloma and rare cases of hairy cell leukemia. Treatment with fresh frozen plasma or plasmapheresis, which is usually effective in TTP and HUS, is rarely effective, but early chemotherapy may be efficacious and prolong survival.

Paraneoplastic leukocytosis with predominant neutrophilia and increased serum levels of G-CSF is attributed to release of cytokines (G-CSF and TNF-α) by tumor cells. Paraneoplastic leukocytosis has been reported in different malignancies of lung, gastrointestinal and genitourinary tract, multiple myeloma, Hodgkin lymphoma and anaplastic large cell lymphoma. Although some studies claimed that the presence of paraneoplastic leukocytosis with malignancies portends a poor prognosis, it is not clear if the association of paraneoplastic leukocytosis and lymphomas has the same impact on prognosis.

Eosinophilia without leukocytosis has been described in Hodgkin lymphoma and T-cell lymphoma.

Paraneoplastic leukocytosis has been described in multiple myeloma, Hodgkin lymphoma and anaplastic large cell lymphoma, and is characterized by neutrophilia in the absence of infection and elevated serum G-CSF levels. It is considered to be the consequence of intratumor G-CSF production.

Deep vein thrombosis can be a paraneoplastic manifestation of lymphomas.

CUTANEOUS MANIFESTATIONS OF HEMATOLOGIC MALIGNANCIES

Paraneoplastic pemphigus (PNP) is a mucocutaneous disease presenting with painful oral and mucosal ulcerations, with concomitant blistering skin lesions. In addition, ocular (conjunctivitis), lung (in the form of bronchiolitis obliterans) and nervous system involvement can occur. Therefore, PNP is considered a severe form of autoimmune multiorgan syndrome. The disease, immunologic in nature, is initiated by an occult or overt neoplasm, which elicits an immune response in the form of autoantibody production. The autoantibodies are directed against cell surface adhesion molecules (mainly plakin family proteins and desmogleins). Hematologic neoplasms or disorders are associated with 84% of the cases: non-Hodgkin lymphomas, chronic lymphocytic leukemia, Castleman disease, dendritic cell tumors (sarcomas) and thymomas. Histopathologic evaluation reveals intraepidermal acantholysis, necrotic keratinocytes and vacuolar interface changes. In PNP, patients' serum contains autoantibodies that recognize proteins in the epithelium. Direct immunofluorescence shows intercellular and basement membrane staining for IgG and complement. Indirect immunofluorescence detects serum antibodies that bind to cell surfaces of stratified squamous epithelia. Response to treatment is generally poor, with high mortality rates.

Sweet syndrome is an acute febrile neutrophilic dermatosis characterized by abrupt onset of papular skin lesions, accompanied by systemic symptoms: fever, arthralgia, malaise, headache and myalgia. Laboratory abnormalities, if present, consist of elevated erythrocyte sedimentation rate and peripheral leukocytosis with neutrophilia. The lesions show dermal edema and dense superficial dermal infiltrate of mature neutrophils, with or without lymphocytes and histiocytes (Fig. 26-87). As a paraneoplastic syndrome preceding or accompanying hematologic malignancies, Sweet syndrome is seen mostly in acute myeloid leukemia and myelodysplastic syndromes. It occurs as well, albeit less commonly, in patients with lymphoid malignancies (hairy cell leukemia, Hodgkin and non-Hodgkin lymphomas).

Pyoderma gangrenosum is an ulcerative skin disease, most frequently associated with inflammatory bowel disease and rheumatoid arthritis. When associated with myelodysplastic syndrome, myeloma or leukemia, the presentation can be atypical, with vesiculobullous lesions and atypical distribution. The mechanism is not known, but numerous cytokines (TNF-α, IFN-γ, G-CSF, IL-6, IL-1β) are elevated.

Vasculitides, which manifest as acute-onset rashes, can be paraneoplastic manifestations of malignancies including myeloid leukemias, lymphomas and hairy cell leukemia. Several pathogenic mechanisms have been proposed: tumor-associated antigens mediate vascular damage, either directly or indirectly through formation of immune

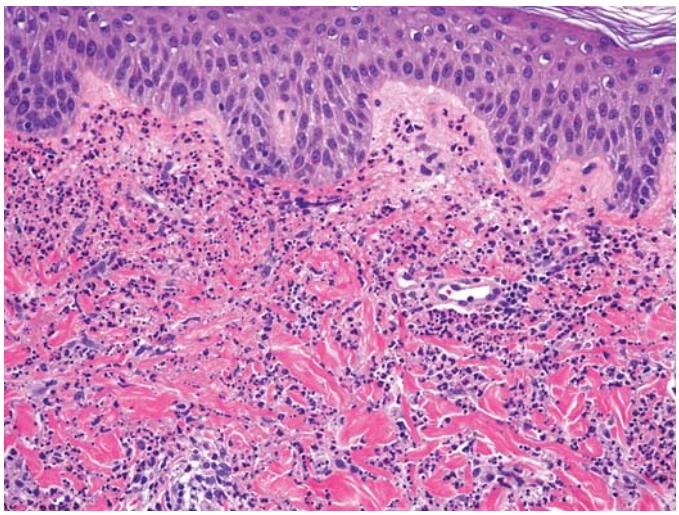

FIGURE 26-87. Sweet syndrome. Skin biopsy in a patient with Sweet syndrome, which developed clinically 4 months before myelodysplastic syndrome became evident. There is a dense neutrophilic infiltrate in the upper and mid-dermis, sparing the epidermis and without evidence of vasculitis.

complexes; direct vascular damage occurs by antibodies formed against leukemic cells. Examples of these include cutaneous leukocytoclastic vasculitis, which is the most common vasculitis associated with hematologic malignancies. Others (polyarteritis nodosa, Churg-Strauss syndrome, microscopic polyangiitis, granulomatous polyangiitis and Henoch-Schönlein purpura) are described in detail in Chapter 17.

Eczema and **erythema nodosum** have also been described in lymphomas.

ENDOCRINE MANIFESTATIONS OF HEMATOLOGIC MALIGNANCIES

Hypercalcemia has been described in patients with Hodgkin lymphoma. The mechanisms are either secretion of parathormone-related peptide by tumor cells or excess calcitriol produced by reactive macrophages infiltrating neoplastic lymph nodes.

Hypoglycemia of nonpancreatic causes including lymphomas (non–insulin-secreting tumors) is the result of hypersecretion of insulin-like growth factors (IGF-I and IGF-II) by tumor cells. Endocrinologic causes for hypoglycemia need to be excluded. Laboratory tests detect low levels of blood glucose and C peptide.

RENAL MANIFESTATIONS OF HEMATOLOGIC MALIGNANCIES

Paraneoplastic glomerular diseases often occur in lymphomas.

Minimal change disease (MCD) presents with heavy proteinuria at the level of nephrotic syndrome, in the absence of glomerular lesions on light microscopy. At the ultrastructural level (electron microscopy), glomerular epithelial cells show alterations of their foot processes, which normally regulate protein permeability. MCD can have multiple etiologies. Among malignancies, Hodgkin lymphoma is the most common. The pathophysiology is incompletely understood but involves dysfunctional podocytes due to cytokine production by infiltrated lymphocytes and macrophages.

Membranoproliferative glomerulonephritis (MPGN) and **membranous glomerulonephritis (MGN)** can be paraneoplastic manifestations of CLL and Hodgkin and non-Hodgkin lymphoma.

Focal segmental glomerulosclerosis (FSGS) presents with proteinuria, nephrotic syndrome, arterial hypertension and progressive renal insufficiency. Glomerular lesions are focal (only some glomeruli are affected) and segmental (portions of the glomeruli are affected), and commonly, tubular atrophy and interstitial fibrosis also occur.

NEUROLOGIC MANIFESTATIONS OF HEMATOLOGIC MALIGNANCIES

Paraneoplastic neurologic syndromes (PNSs) are caused by specific autoimmune responses to antigens produced by tumor cells, which mimic or are identical to antigens normally restricted to neurons. Specific antibodies are present in approximately 60% of patients with paraneoplastic syndromes of the CNS, in both serum and cerebrospinal fluid. If antibodies are not found, the differential diagnosis is extensive, since each of the following disorders can be caused by nonneoplastic conditions such as toxins, infections, vitamin deficiencies and metabolic or autoimmune disorders. Management includes treatment of the tumor and immunosuppression.

Paraneoplastic cerebellar degeneration starts with dizziness, vertigo, ataxia and dysarthria. It is mediated by specific antibodies (anti-Tr, anti-GAD, anti-mGLuR1). Among hematologic malignancies, Hodgkin lymphomas have a higher prevalence.

Limbic encephalitis presents with short-term memory loss, seizures, confusion, sleeping problems, psychiatric symptoms, irritability or depression. Although this condition is more common in nonhematopoietic tumors (non–small cell lung cancer), it may also be seen in lymphomas, both Hodgkin (associated with anti-Tr antibodies) and non-Hodgkin (serum anti-Ma2 antibodies).

Paraneoplastic encephalomyelitis is an immune-mediated inflammatory disorder that presents as a subacute sensory neuronopathy. Specific antibodies described are anti-Hu.

Paraneoplastic involvement of the peripheral nervous system, although rare, can occur in lymphomas. Careful differential diagnosis is important since neuropathies due to direct root infiltration by tumor, amyloid deposition or chemotherapy-induced neuropathy are not infrequent. Clinical manifestations include **chronic inflammatory demyelinating polyradiculopathy (CIDP), sensory-motor neuropathy, Guillain-Barré syndrome, myotonia and inclusion body myositis.**

RHEUMATIC MANIFESTATIONS OF HEMATOLOGIC MALIGNANCIES

Malignant neoplasms are associated with a large variety of paraneoplastic rheumatologic syndromes, and the most common malignancies are carcinomas of the lung, GI tract and prostate. Lymphomas and leukemias are rare players. As with other paraneoplastic disorders, a direct anatomic relationship between the malignant tumor and the sites of manifestation needs to be excluded.

Paraneoplastic polyarthritis, presenting as acute or chronic forms affecting both large and small joints, was described in several cases of B-cell lymphoma and acute leukemias of both lymphoid and myeloid lineage. In most cases, treatment of the underlying malignancy is followed by remission of the rheumatologic disorder.

Dermatomyositis (DM) and **polymyositis (PM)** may constitute paraneoplastic myopathies. They manifest with severe muscle weakness, skin manifestation, respiratory muscle weakness and dysphagia, and their clinical course parallels the course of malignancy. The risk of malignancy associated with DM is very high, while the risk of cancer associated with PM is smaller. DM is more commonly associated with solid tumors (adenocarcinomas of the lung, ovary, uterine cervix, stomach, colon, pancreas) and rarely with lymphoma. Paraneoplastic PM is associated with lymphoma.

Systemic lupus erythematosus is often idiopathic, but can be associated with malignancies. Patients present with fatigue, myalgia, rash and arthritis. Laboratory tests show antibodies including antinuclear antibody (ANA), Sm and double-stranded DNA (dsDNA).

Sjögren syndrome, which clinically presents with keratoconjunctivitis sicca and xerostomia (dryness of eyes and mouth), can be a paraneoplastic manifestation of non-Hodgkin lymphoma or chronic lymphocytic leukemia. In these cases, in addition to serum autoantibodies such as ANA, Ro/SSA and La/SSB, flow cytometry or molecular studies will detect abnormal, clonal B-cell populations.

GENERAL SYMPTOMATOLOGIC MANIFESTATIONS OF HEMATOLOGIC MALIGNANCIES

Paraneoplastic pruritus, defined as itch lasting more than 6 weeks, occurs early during the clinical evidence of malignancy or precedes clinical signs of malignancy by weeks or months. According to some studies, generalized pruritus is caused by malignancy in less than 10% of cases. Lymphoma and leukemia are the most common malignancies. The pathophysiologic mechanisms remain poorly understood.

PARANEOPLASTIC SYNDROMES WITH ENDOCRINE FUNCTION

Peptide Hormones

The main function of the endocrine system is communication. Although the nervous and endocrine systems use some of the same soluble mediators and sometimes overlap functionally, the endocrine system is unique in its ability to communicate at a distance using soluble mediators, hormones.

The term **hormone** (from the Greek, *horman,* "set in motion") applies to chemicals secreted by "ductless" (i.e., endocrine) glands into the circulation, which carries it to the target organ. Many hormones, such as thyroid hormone, corticosteroids and pituitary hormones, fit this definition. However, some traditionally recognized hormones, such as

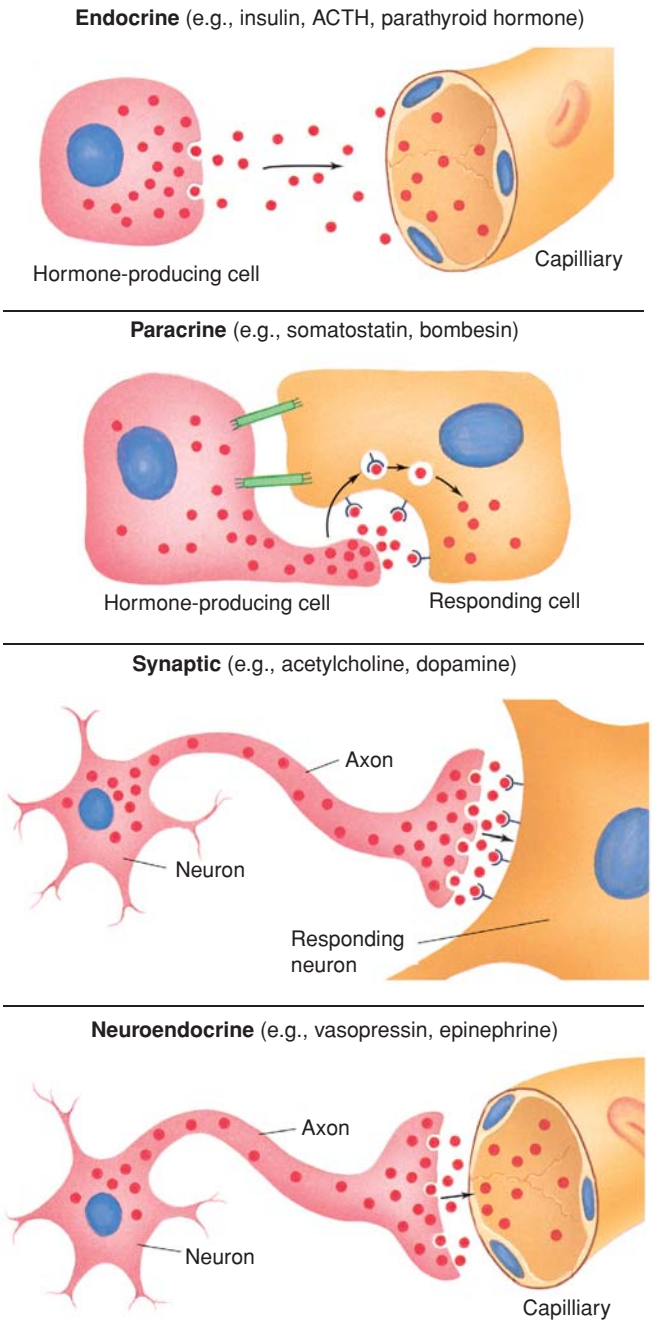

FIGURE 27-1. Mechanisms of chemically mediated cell-to-cell communication. Biological messages may be transmitted by mechanisms other than the classic endocrine pathway via the circulation. These include paracrine, synaptic and neuroendocrine modes of communication.

catecholamines, are produced in multiple sites and may act either locally or through the circulation. Other mediators function only in restricted circulation compartments: hypothalamic hormones only act on the pituitary and reach it via portal tributaries without entering the systemic circulation. Finally, many hormones exert their effects in the very tissues that make them, such as müllerian-inhibiting substance. These diverse chemically mediated cell-to-cell communications are summarized in Fig. 27-1.

To qualify as a hormone, a chemical messenger must bind a receptor, whether on a cell's surface or inside it. Hormones act either on the final effector target or on other glands that in turn produce other hormones. For instance, thyroid-stimulating hormone (TSH) is released by the pituitary and promotes thyroid hormone secretion by the thyroid gland. Thyroid hormone, then, directly affects many types of peripheral cells. Diseases of the endocrine system may entail too little or too much hormone secretion. Target tissue insensitivity may simulate the clinical picture of hormone underproduction.

Pituitary Gland

ANATOMY

The pituitary gland, or the hypophysis, is a small gland that weighs 0.5 g and measures 1.3 × 0.9 × 0.5 cm. It sits at the base of the brain in a bony cavity called the sella turcica, within the sphenoid bone.

Anatomically, it is composed of two lobes. The anterior lobe, or **adenohypophysis,** arises from the ectoderm, makes up 80% of the gland and is populated by epithelial cells. The posterior lobe, or **neurohypophysis,** originates from neuroectoderm as a prolongation of the hypothalamus (Fig. 27-2). The gland is near the optic chiasm and cranial nerves III, IV, V and VI; thus, pituitary enlargement may alter vision or cause palsies by impinging on various cranial nerves.

The anterior lobe develops from **Rathke's pouch,** an endodermal evagination from the developing oral cavity. Along its migration tract, this craniopharyngeal duct may leave intrasphenoidal squamous epithelial rests that may later give rise to tumors known as **craniopharyngiomas**. The neurohypophysis (posterior lobe) begins as a downward projection of the brain and remains connected to the

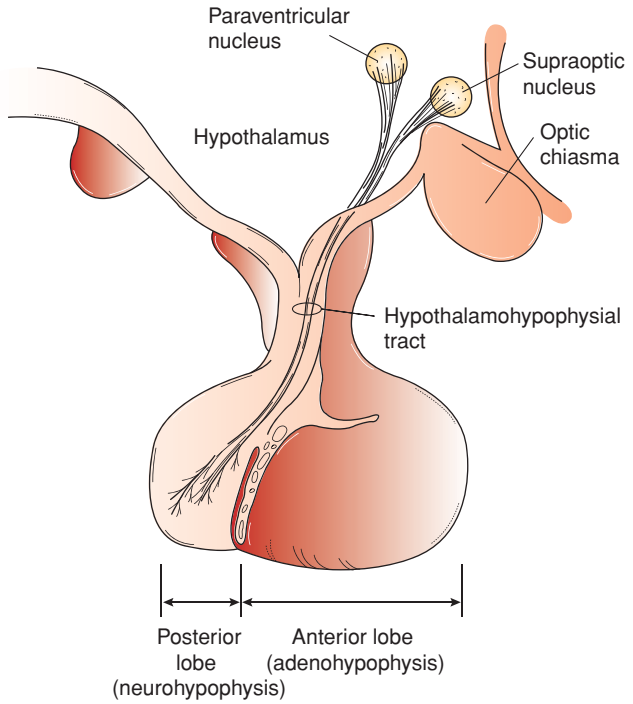

FIGURE 27-2. The pituitary gland.

hypothalamus by the hypophyseal stalk. Flanked on either side by the anterior and posterior lobes is a vestigial intermediate lobe, containing a few cystic cavities lined by cuboidal or columnar epithelium and considered as part of the anterior pituitary in humans.

The pituitary has a dual circulation. It has a complex portal system that originates in the hypothalamus, and a separate arterial and venous blood supply. The hypophysial portal system transports stimulatory and inhibitory hypothalamic-releasing hormones to the anterior pituitary. Venous drainage from the pituitary follows the cavernous sinus to both inferior petrosal sinuses.

Axons and unmyelinated nerve fibers from the hypothalamus proceed along the pituitary stalk to the neurohypophysis and are the nerve supply of the posterior lobe. These nerves regulate secretion of **arginine vasopressin** (**antidiuretic hormone [ADH]**) and **oxytocin,** which are made in the hypothalamus, stored in the posterior lobe and later released into the systemic circulation.

The cells of the anterior pituitary are arranged in cords or nests in a highly vascular stroma. These cells were classically divided into two groups of equal number: stainable and unstainable cells, based on their hematoxylin and eosin (H&E) staining properties. The latter cells are **chromophobes** and have minimal to no hormone content. The cytoplasmic granules of stainable cells appeared acidophilic (eosinophilic) (40%), which contain polypeptide hormones, and basophilic (10%), which contain glycoprotein hormones. However, granules' tinctorial properties do not reflect their functions, so this histologic classification has been superseded by a system that identifies cells by the hormones they secrete, as identified by immunochemical staining (Fig. 27-3). The hormone-producing cells in the anterior pituitary are:

- **Corticotrophs:** These basophilic cells secrete **proopiomelanocortin (POMC)** and its derivatives including **adrenocorticotropic hormone (ACTH, corticotropin)**, which controls adrenal secretion of **corticosteroids, melanocyte-stimulating hormone (MSH), lipotropic hormone (LPH)** and **endorphins**. In cases of glucocorticoid excess, corticotrophs may undergo an alteration called Crooke's hyaline change. Basophilic corticotrophs of the **pars intermedia** may cluster and spread deep into the posterior lobe, a phenomenon called "basophil invasion."
- **Lactotrophs:** These acidophilic cells secrete **prolactin,** which is essential for lactation and other metabolic activities.
- **Somatotrophs:** These acidophilic cells produce and secrete growth hormone and constitute half of the hormone-producing cells of the adenohypophysis.
- **Thyrotrophs:** TSH is produced by pale basophilic or amphophilic cells, which make up only 5% of the cells of the anterior lobe.
- **Gonadotrophs: Follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** are secreted by the same basophilic cell. FSH stimulates Graafian follicle formation in the ovary. LH induces ovulation and formation of corpora lutea.

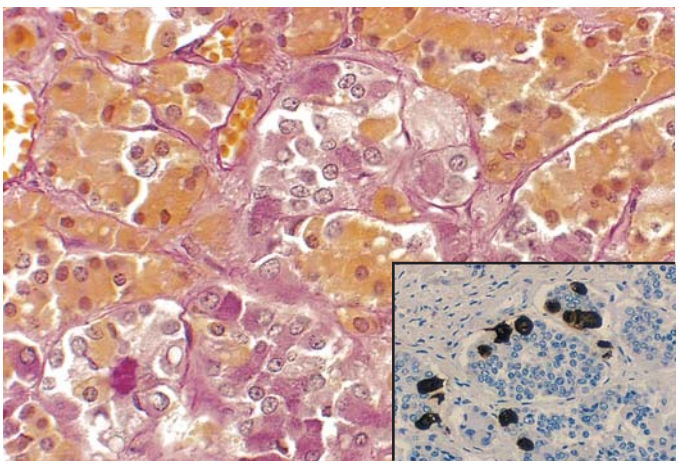

FIGURE 27-3. Normal anterior lobe of pituitary. In a periodic acid–Schiff (PAS)–orange G stain, the cytoplasm of somatotropic and prolactin-secreting cells takes up the orange G stain. Most of the cells with a lavender cytoplasm produce adrenocorticotropic hormone (ACTH) (corticotropes). An immunohistochemical stain (*inset*) demonstrates cells that synthesize growth hormone (somatotropes).

The posterior lobe of the pituitary contains **pituicytes,** modified glial cells with no secretory function, axon terminals and unmyelinated nerve fibers containing ADH and oxytocin. Both of these hormones are formed in neurons in the hypothalamus and transported along axons to the neurohypophysis. A rich network of capillaries surrounds the axon terminals and facilitates hormone release into the vasculature. ADH promotes water resorption from distal renal tubules; oxytocin stimulates contraction of the pregnant uterus at term and also of cells around lactiferous ducts in the breasts.

HYPOPITUITARISM

Hypopituitarism is a rare disorder in which the pituitary secretes insufficient amounts of one or more hormones. It has many causes and various clinical presentations. Most often, only one or a few pituitary hormones are deficient. Occasionally **panhypopituitarism** occurs, in which the gland fails totally. The effects of hypopituitarism vary with the extent of the loss, specific hormones involved and age of the patient. In general, symptoms relate to deficient function of the thyroid and adrenal glands and the reproductive system. In children, growth retardation and delayed puberty are additional problems.

PITUITARY TUMORS: Over half of hypopituitarism in adults is caused by pituitary tumors, usually adenomas. The tumor itself may be functional, but symptoms of hypopituitarism often result because the tumor compresses adjacent tissue.

SHEEHAN SYNDROME: In this condition, ischemic necrosis of the pituitary causes panhypopituitarism. It is often caused by severe hypotension from postpartum hemorrhage or, rarely, without massive bleeding or after normal delivery. The pituitary is particularly vulnerable during pregnancy, because of reduced blood flow associated with its enlargement at this time. The result of the damage to the gland is permanent underproduction of essential pituitary hormones (hypopituitarism). Agalactia, amenorrhea, hypothyroidism and adrenocortical insufficiency are important consequences (Fig. 27-4). Treatment of Sheehan syndrome is hormone replacement therapy. This syndrome has become rare in developed countries.

PITUITARY APOPLEXY: Hemorrhage and/or infarction can occur in a normal pituitary, but at least half of cases occur

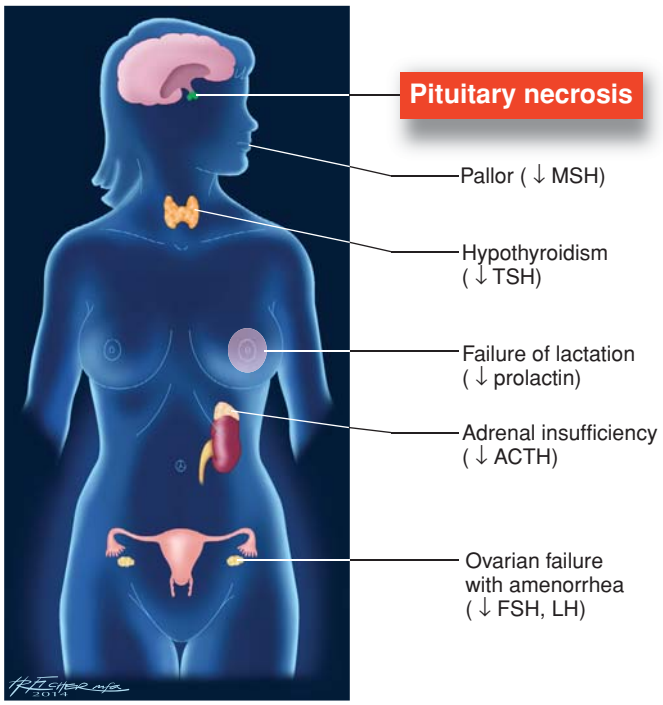

FIGURE 27-4. Major clinical manifestations of panhypopituitarism. *ACTH* = adrenocorticotropic hormone; *FSH* = follicle-stimulating hormone; *LH* = luteinizing hormone; *MSH* = melanocyte-stimulating hormone; *TSH* = thyroid-stimulating hormone.

in association with endocrinologically inactive adenomas. On occasion, pituitary apoplexy leads to hypopituitarism. The initial symptoms include headaches and associated visual problems.

IATROGENIC HYPOPITUITARISM: Radiation damage to the hypothalamic–pituitary axis or neurosurgical procedures may cause neuroendocrine abnormalities, including hypopituitarism.

TRAUMA: Traumatic brain injury entails significant risk to the pituitary gland, with potential development of diabetes, hypopituitarism and other endocrinopathies.

INFILTRATIVE DISEASES: Bacterial and viral infections may lead to inflammation, which can damage the gland. The process can be primary if only the gland is involved or secondary if it is associated with an underlying systemic condition such as fungal or tuberculous infection. Involvement of the hypothalamic–pituitary axis in Langerhans cell histiocytosis (see Chapter 26) causes endocrine abnormalities including diabetes insipidus in 5%–50% of patients and panhypopituitarism in 5%–20%. Panhypopituitarism may occur in hemochromatosis (see Chapter 20), owing to iron deposition in the pituitary.

GENETIC ABNORMALITIES OF PITUITARY DEVELOPMENT: Congenital growth hormone deficiency constitutes a unique group of disorders. It may occur in isolation, in **isolated growth hormone deficiency** (IGHD), or together with other pituitary hormone deficiencies. There are 4 types of familial and sporadic IGHD, differentiated by the severity of the condition, inheritance pattern and causative gene. Inheritance can be autosomal recessive (AR), autosomal dominant (AD) or X-linked recessive. Inherited IGHD is linked to mutations, including deletions, amino acid substitutions and splice site mutations, in the genes for **human growth hormone** (GH) or growth hormone–releasing hormone (GHRH) receptor. This syndrome is caused by mutations in one of at least three genes. Isolated growth hormone deficiency types IA and II are caused by mutations in the *GH1* gene. Type IB is caused by mutations in either the *GH1* or *GHRHR* gene. Type III is caused by mutations in the *BTK* gene. When no gene is identified as a cause of the disease, it is called idiopathic. Recombinant GH is the treatment of choice for children with this disorder.

There are several mutations targeting transcription factors during embryogenesis:

- **Pit-1:** Pit-1 is a POU homeodomain transcription factor important for **pituitary** development and expression of somatotrophs, lactotrophs and thyrotrophs. It is encoded by the *POU1F1* gene on human chromosome 3p11. Mutations in this gene appear to cause combined pituitary hormone deficiency (CPHD) with low levels or absence of GH, prolactin (PRL) and TSH.
- **PROP1 (5q):** Prop 1 is a pituitary specific paired-like homeo-domain transcription factor. Mutations of *PROP1* inactivate LH, FSH, GH, PRL and TSH. This trait is inherited as an autosomal recessive condition.
- **HESX1 (3p21):** This gene is a member of the paired-like class of homeobox genes important for optic nerve and pituitary development. Its expression begins before that of other developmental genes. Mutations of the *HESX1* gene occur in patients with septo-optic dysplasia, a rare congenital anomaly with midline forebrain abnormalities, optic nerve hypoplasia and hypopituitarism. Endocrinopathies are characterized by growth hormone deficiency followed by TSH and ACTH deficiency. This mutation is also associated with **Pickardt syndrome,** an uncommon form of tertiary hypothyroidism caused by abnormalities in the portal veins connecting the pituitary with the hypothalamus.
- **PITX2:** This gene is expressed in the fetal pituitary and in most cells of the adult gland. Mutations are associated with **Rieger syndrome,** an autosomal dominant condition with variable phenotypic expression including pituitary abnormalities.
- **LX3/LX4:** These genes belong to the LIM family of homeobox genes that are expressed early in the Rathke pouch. *LHX3* is on chromosome 9q. Its mutations are associated with GH, TSH, LH, FSH and PRL deficiencies. Rarely, mutation of the *LX4* gene may present as GH, TSH and ACTH deficiency.

GROWTH HORMONE INSENSITIVITY (LARON SYNDROME): *Laron dwarfism is a rare,* autosomal recessive disorder characterized *by short stature due to extreme resistance to GH because of abnormalities in growth hormone receptor* (GHR). These dwarfs tend to be obese and have high serum GH levels, but low concentrations of insulin-like growth factor-I (IGF-I). Laron syndrome occurs mainly in people of Mediterranean origin, such as Sephardic Jews. The same lesion is responsible for dwarfism in African pygmies.

Laron syndrome is caused by more than 30 *GHR* mutations, all of which involve the receptor's extracellular domain. Clinical presentations are heterogeneous, and most cases are unique to particular families or geographic areas. Since GH exerts its effects by promoting IGF-I secretion, IGF-I is effective replacement therapy for Laron syndrome, mimicking most effects ascribed to GH itself. It is believed

that patients with this syndrome may have lower incidences of cancer and diabetes (see Chapters 5 and 13).

ISOLATED GONADOTROPIN DEFICIENCY (KALLMANN SYNDROME): *Kallmann syndrome is characterized by hypogonadotropic hypogonadism (due to gonadotropin-releasing hormone [GnRH] deficiency) and anosmia (absent sense of smell).* Cleft lip/palate and other anomalies may also be present. Kallmann syndrome is usually diagnosed at puberty because of a delay in the appearance of secondary sex characteristics. It is likely to occur 3–5 times more often in males than females (1:8000). Most cases are sporadic, but there are familial forms, some of which are X-linked, while others are autosomal dominant or recessive. X-linked Kallmann syndrome (KAL1) involves mutations of the *KAL1* gene (Xp23.3), which encodes an extracellular matrix component with putative antiprotease activity and cell adhesion function. As a result, neurons destined to secrete GnRH fail to migrate from their origin in the olfactory anlage to their normal hypothalamic location. The autosomal dominant form of the disease (KAL2) is associated with mutations of the gene encoding fibroblast growth factor receptor 1 (FGFR1, at 8p11). A third form of Kallmann syndrome (KAL3) appears to be autosomal recessive, but the affected gene is unknown.

EMPTY SELLA SYNDROME: This is primarily a radiologic term for an enlarged sella containing a thin, flattened pituitary at the base (Fig. 27-5). It is due to a congenitally defective or absent diaphragma sella, which permits transmission of cerebrospinal fluid pressure into the sella. Empty sella syndrome can cause various degrees of pituitary dysfunction and endocrine abnormalities. It has been linked to both pituitary and nonpituitary causes and can result from pituitary gland regression after an injury, surgery or radiation therapy. Endocrine disturbances include hyperprolactinemia, oligomenorrhea or amenorrhea, frank hypopituitarism, acromegaly, diabetes insipidus and Cushing syndrome.

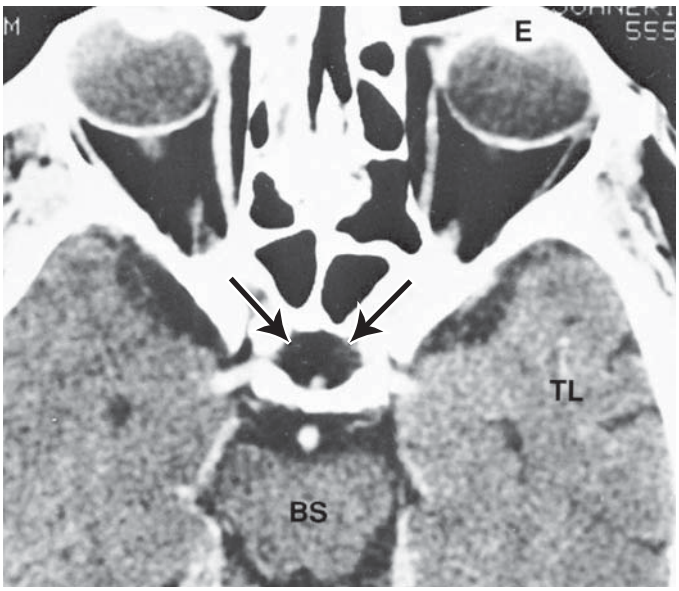

FIGURE 27-5. Empty sella syndrome. A computed tomography (CT) scan of the cranium in an axial section demonstrates an empty sella turcica (*arrows*). *BS* = brainstem; *E* = eye; *TL* = temporal lobe.

TABLE 27-1
FREQUENCY OF ADENOMAS OF THE ANTERIOR PITUITARY

Cell Type	Hormone	Frequency (%)
Lactotrope	Prolactin	26
Null cell	None	17
Corticotrope	ACTH (corticotropin)	15
Somatotrope	Growth hormone	14
Plurihormonal	Multiple	13
Gonadotrope	FSH, LH	8
Oncocytoma	None	6
Thyrotrope	TSH	1

ACTH = adrenocorticotropic hormone; FSH = follicle-stimulating hormone; LH = luteinizing hormone; TSH = thyroid-stimulating hormone.

PITUITARY ADENOMAS

Pituitary adenomas are benign tumors of the anterior lobe of the pituitary. They often cause excess secretion of one or more pituitary hormones and corresponding endocrine hyperfunction (Table 27-1). Pituitary adenomas occur in both sexes. They are more common in adults and rare in children. **PRL-producing adenomas** are the most common hormone-secreting tumors of adults and children. **Gonadotroph adenomas** are more frequent in the elderly. Small, apparently **nonfunctioning pituitary adenomas** are found incidentally in as many as 27% of adult autopsies.

ETIOLOGY AND MOLECULAR PATHOGENESIS: The etiology of pituitary adenomas is obscure, but it is clear that hormonal, environmental and genetic factors are involved. Rarely, they occur in the context of multiple endocrine neoplasia (MEN) type 1, a hereditary syndrome in which patients develop pituitary adenomas, parathyroid hyperplasia or adenoma and islet cell adenomas of the pancreas (see Chapter 21). There is no evidence that *MEN1* mutations are involved in sporadic pituitary tumorigenesis.

Acquired activating mutations in the stimulatory subunit of the G_s protein that activates adenylyl cyclase have been reported in 40% of growth hormone–secreting pituitary adenomas. More specifically, elevation of intracellular cyclic adenosine 3′,5′-monophosphate (cAMP) levels is thought to stimulate hypersecretion of GH and cell proliferation. Some human pituitary tumors express a kinase-containing variant of fibroblast growth factor/receptor (FGFR4), which causes pituitary tumor formation in transgenic mice. Mutations or overexpression of a number of regulatory genes have been described in a number of pituitary adenomas, including *cyclin* D_1, *CREB*, *ras* and *pituitary tumor transforming* gene.

Patients with **Carney syndrome** can develop GH- and prolactin-producing pituitary tumors. Other syndromes associated with pituitary tumors include **McCune-Albright** and **familial acromegaly**.

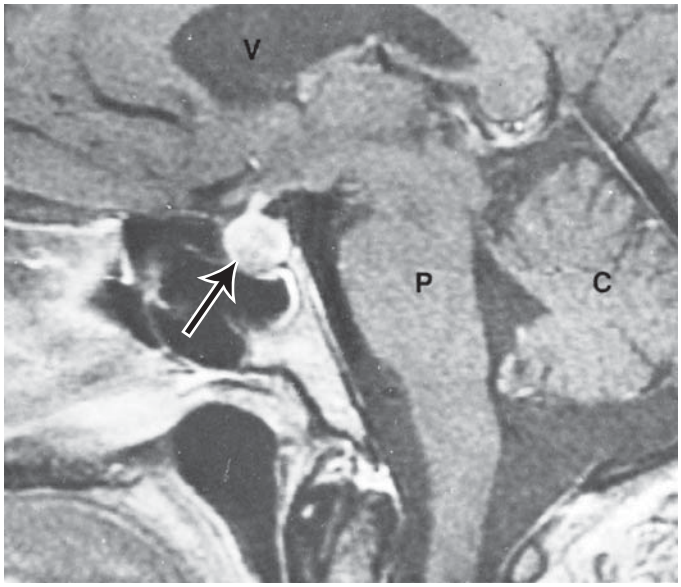

FIGURE 27-6. Pituitary adenoma. A magnetic resonance sagittal view of the brain shows a distinct pituitary tumor (*arrow*). *C* = cerebellum; *P* = pons; *V* = lateral ventricle.

PATHOLOGY: Pituitary adenomas were traditionally classified as either acidophil, basophil or chromophobe adenomas depending on how constituent cells stained. Acidophil adenomas were associated with overproduction of GH, basophil adenomas with ACTH and chromophobe adenomas with no endocrine hyperfunction. Since H&E staining properties of the tumor cells do not correlate with the type of hormone secreted, pituitary adenomas are now classified by the hormone(s) they produce. The 2004 World Health Organization (WHO) classification of pituitary lesions accounts for histologic, histochemical, immunohistochemical and electron microscopic features.

Pituitary adenomas range from small lesions that do not enlarge the gland to expansive tumors that erode the sella turcica and impinge on adjacent cranial structures (Fig. 27-6). In general, adenomas less than 10 mm are called microadenomas; larger tumors are macroadenomas. Microadenomas are not symptomatic until they secrete hormones. Macroadenomas tend to cause local compression, by virtue of their size, and systemic manifestations, owing to overproduction of hormones.

CLINICAL FEATURES: In general, symptoms reflect the hormone produced. Pituitary macroadenomas may compress the optic chiasm, causing severe headaches, bitemporal hemianopsia and loss of central vision. Oculomotor palsies occur when a tumor invades the cavernous sinuses. Large adenomas may invade the hypothalamus, interfere with normal hypothalamic input to the pituitary and lead to loss of temperature regulation, hyperphagia and hormonal syndromes. Symptoms of hypopituitarism may be present but difficult to recognize.

Hyperprolactinemia Is the Most Common Endocrinopathy Caused by Pituitary Adenomas

Almost half of pituitary microadenomas contain PRL, but many fewer actually secrete this hormone. PRL-producing tumors are most often symptomatic in young women, but more than half of macroadenomas that secrete PRL are in men. This difference in sex distribution is related to the more frequent occurrence of endocrine symptoms in women. The true incidence in unselected autopsies is similar in both sexes. In general, larger adenomas secrete more PRL. These are the most common pituitary adenomas, comprising 1/4 of the gland's benign tumors. They are mostly in the lateral or posterior parts of the pituitary gland.

PATHOLOGY: Lactotroph adenomas tend to be chromophobic and contain spheroid nuclei with prominent nucleoli. They are sparsely granulated and may show diffuse or papillary growth patterns. Endocrine amyloid (see Chapter 15) and psammoma bodies (calcospherites) occur but are not pathognomonic. Lactotroph adenomas stain for PRL in a dot-like "Golgi pattern" by immunohistochemistry.

CLINICAL FEATURES: In women, functional lactotroph adenomas lead to amenorrhea, galactorrhea and infertility. The consistently elevated blood PRL levels inhibit the surge of pituitary LH necessary for ovulation. Men tend to suffer from decreased libido and impotence. Functional lactotroph microadenomas are successfully treated with dopamine agonists (bromocriptine) to inhibit PRL secretion, but macroadenomas may require surgery or radiation therapy. Excess PRL secretion may be caused by factors other than pituitary adenomas, including pregnancy, lactation, administration of certain drugs or pressure on the hypothalamus by other tumors. They can occur in children and adolescents, in whom symptoms depend on the patient's age. Radiologically, they are mostly microadenomas and are frequently part of MEN1. The prognosis of these patients is good.

Somatotrope Adenomas Secrete Growth Hormone

Dramatic changes result from excess GH secretion. A somatotroph adenoma arising before epiphyses close in a child or adolescent causes **gigantism**. After long bone epiphyses have fused and adult height has been attained, however, the same tumor produces **acromegaly**. Most tumors are macroadenomas and cause mass effects and tumor-induced adenohypophyseal hypofunction. Most GH-producing adenomas are sporadic, but some arise as part of MEN1 and Carney syndrome.

PATHOLOGY: Of patients with acromegaly, 75% have a somatotroph macroadenoma within the gland. Most of the rest have microadenomas. Variants of isolated GH-producing tumors include the densely granulated and sparsely granulated somatotroph adenomas. Densely granulated somatotroph adenomas are composed of acidophilic cells with granular cytoplasm and a diffuse growth pattern (Fig. 27-7). They show strong, diffuse immunohistochemical reactivity for GH and low proliferative indices. Acidophilic somatotroph adenomas usually grow slowly and remain within the sella. Sparsely granulated adenomas have small chromophobe cells with characteristic spheroid cytoplasmic inclusions, called "fibrous bodies," that contain keratin intermediate filaments, especially keratin 8. The chromophobic variant tends

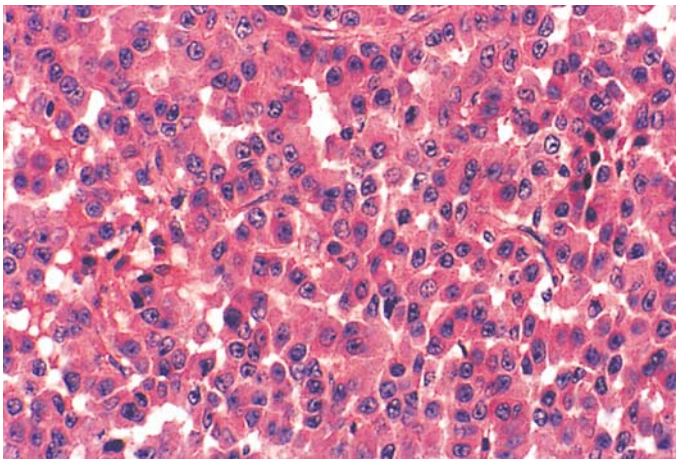

FIGURE 27-7. Pituitary somatotrope adenoma from a man with acromegaly. The tumor cells are arranged in thin cords and ribbons.

to grow faster and to invade. It also shows cellular and nuclear pleomorphism.

In mixed somatotroph–lactotroph adenomas (rare), the two cell types elaborate GH and PRL, respectively. Mammosomatotroph adenomas are monomorphous with a single cell type expressing both GH and PRL. **Acidophil stem cell adenomas** are monomorphous, slightly acidophilic tumors with nuclear pleomorphism and large cytoplasmic vacuoles. Key features include giant mitochondria, keratin 8–positive fibrous bodies and misplaced exocytosis. This subtype is clinically more aggressive.

CLINICAL FEATURES: Acromegaly is uncommon, with an annual incidence of 3 cases per million. Over many years, patients with acromegaly gradually develop coarse facial features (Fig. 27-8), with overgrowth of the mandible (prognathism) and maxilla, increased space between upper incisor teeth and a thickened nose. Their hands, feet and heads often become enlarged.

Acromegaly has serious complications. Cardiovascular, cerebrovascular and respiratory deaths are increased. Most acromegalics have neurologic and musculoskeletal symptoms, including headaches, paresthesias, arthralgias and muscle weakness. One third have hypertension, and even half of normotensive acromegalics have increased left ventricular mass and are at risk for congestive heart failure. Visceral hypertrophy is common. Diabetes occurs in up to 20%, and hypercalciuria and renal stones develop in another 20%. Half of acromegalics have hyperprolactinemia severe enough to be symptomatic (see above).

Treatment for somatotroph adenomas is usually transsphenoidal hypophysectomy, after which circulating GH levels may decline to normal levels within hours. Radiation therapy is an alternative if surgery is contraindicated. A long-acting analog of somatostatin, an antagonist of GH, is a useful therapeutic adjunct. Most of these tumors are associated with good prognosis.

Corticotrope Adenomas Produce ACTH

ACTH excess induces adrenal cortical hypersecretion, causing **Cushing disease** (see below). In most cases, these

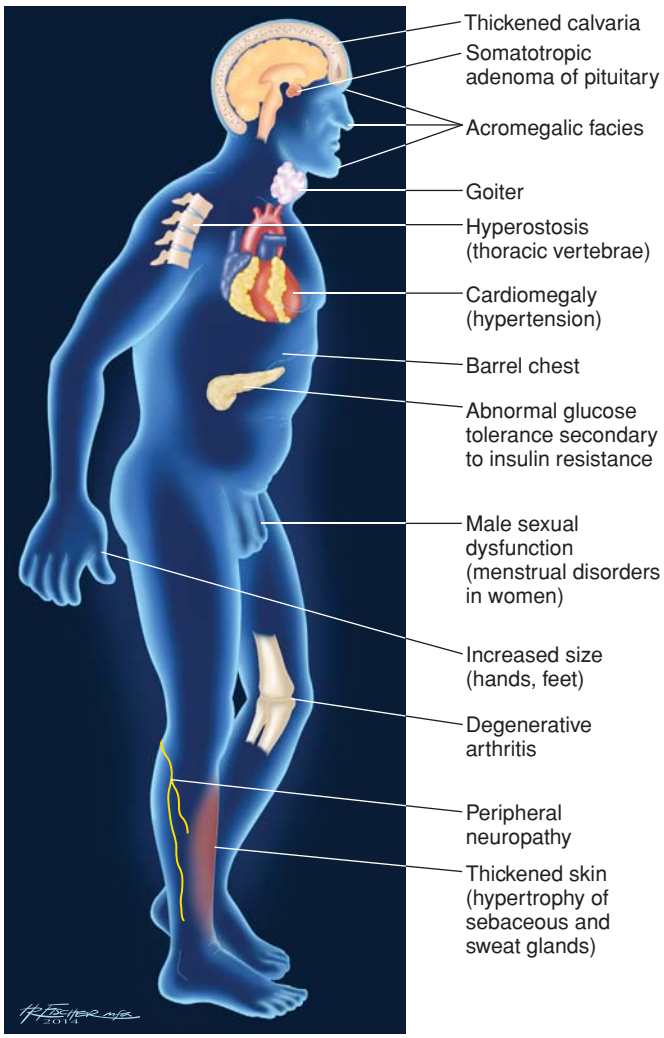

FIGURE 27-8. Clinical manifestations of acromegaly.

tumors are intrasellar microadenomas that are intensely basophilic and periodic acid–Schiff (PAS) positive. Immunohistochemistry shows ACTH and related peptides, such as endorphins and lipotropin. A few functional corticotroph adenomas are chromophobic and more aggressive than their basophilic counterparts and may show pleomorphic features and apoptosis. The proliferative index can be variable.

By electron microscopy, basophilic adenomas contain many secretory granules and perinuclear bundles of fine, keratin-positive, intermediate filaments (type I filaments). These filaments may be abundant enough to be visible by light microscopy as **Crooke hyalinization,** which reflects suppression of ACTH secretion by high levels of circulating cortisol. **Crooke adenomas** represent ACTH-producing tumors with massive cell hyaline deposition.

The prognosis of these patients depends on the severity of the symptoms.

Gonadotrope Adenomas Secrete LH and FSH

Most of these tumors are hormonally inactive macroadenomas and are detected either incidentally or because of local compressive effects due to suprasellar extension. Clinical

presentations include headache, visual disturbance and hypopituitarism.

In general, gonadotrope adenomas are chromophobic and PAS negative and grow in a diffuse pattern. They proliferate slowly. Tumor cells are strongly immunopositive for FSH, LH or both. Treatment is surgical resection. Prognosis depends on the results of the surgery.

Thyrotrope Adenomas Produce TSH

These are the rarest of pituitary adenomas. They come to medical attention when there are symptoms of hyperthyroidism, goiter or a pituitary mass lesion. Circulating TSH and thyroid hormone levels are usually elevated, which is unique to this tumor. Thyrotroph adenomas are predominantly macroadenomas and can be invasive and fibrotic. They are chromophobic, with polyhedral or columnar cells that form collars around blood vessels. They stain for α- and β-TSH and tend to have high proliferative indices. By electron microscopy, secretory granules are often arranged in a single row just subjacent to the plasma membrane.

Patients with long-standing hypothyroidism may develop hyperplasia of pituitary thyrotrophs (thyroid deficiency cells), presumably due to inadequate feedback inhibition by thyroid hormones.

Nonfunctional Pituitary Adenomas Do Not Cause Endocrinopathies

One quarter of pituitary tumors removed surgically do not secrete excess hormones. They are slowly growing macroadenomas that occur in older people and come to medical attention because of their mass effect.

Null cell adenomas are usually chromophobic and arise in the adenohypophysis, are PAS negative and grow in a pseudopapillary pattern. Tumor cells are negative or sparsely positive for all anterior pituitary hormones. They are typically immunopositive for chromogranin A and synaptophysin.

Oncocytomas are variants of nonfunctional null cell adenoma, containing enlarged, eosinophilic and often granular cells. They are typically large at presentation and may extend outside the sella. Visual impairment and symptoms of hypopituitarism are common. The neoplastic cells of oncocytomas are packed with mitochondria but are otherwise similar to other null cell adenomas.

Silent adenomas differ from other nonfunctional pituitary adenomas in appearing well differentiated ultrastructurally. They are often immunoreactive for ACTH and other hormones.

PLURIHORMONAL ADENOMAS: These unusual adenomas produce a variety of pituitary hormones. The most frequent combinations include GH, PRL and one or more glycoprotein hormone subunits. The aggressive subtype 3 has a unique ultrastructural profile and expresses PRL and TSH staining.

PITUITARY CARCINOMAS: It is not possible to distinguish between pituitary adenomas and carcinomas on morphologic grounds. Pituitary carcinomas spread to cerebrospinal and/or extracranial sites. When functional, they primarily secrete PRL or ACTH.

Imaging reveals a tumor extending beyond the sella turcica. The tumors are very rare and their prognosis is poor.

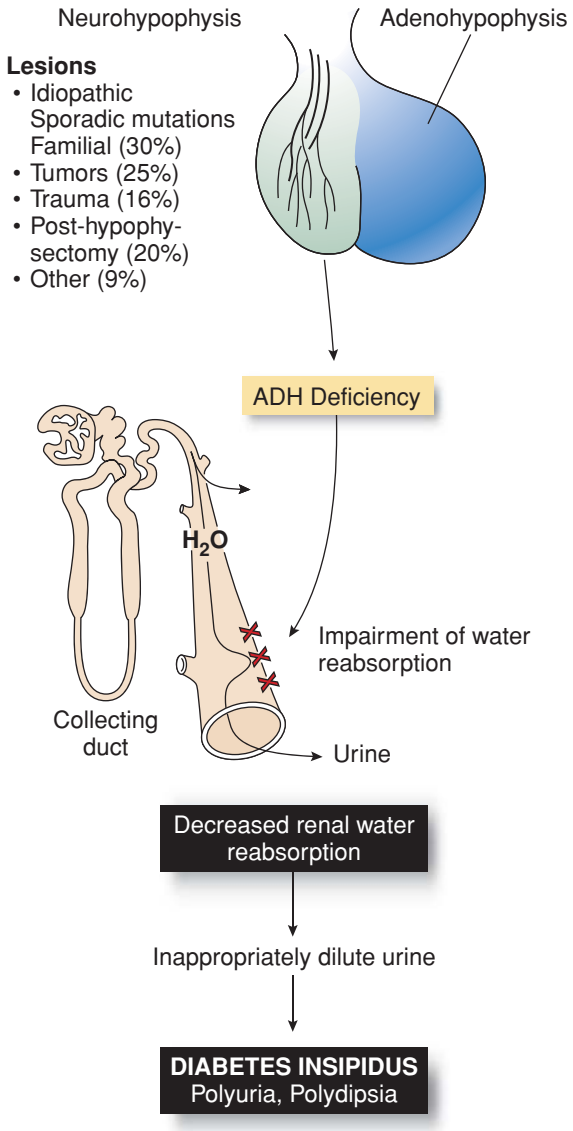

FIGURE 27-9. Mechanism of diabetes insipidus.

POSTERIOR PITUITARY

Central diabetes insipidus (Fig. 27-9) is the only significant disease associated with the posterior pituitary. Affected patients cannot concentrate their urine and so have chronic water diuresis (polyuria), thirst and polydipsia because they lack sufficient ADH (vasopressin). ADH is secreted by the posterior pituitary under the influence of the hypothalamus. One third of cases of central diabetes insipidus are of unknown etiology or can be attributed to sporadic or familial mutations in the vasopressin–neurophysin II gene. Currently, there are over 35 mutations known in familial neurohypophysial diabetes insipidus. Mutations or deletions in the vasopressin V2 receptor (Xq28) and the vasopressin-sensitive aquaporin-2 water channel genes may cause **nephrogenic diabetes insipidus**.

One fourth of cases of central diabetes insipidus are associated with brain tumors, particularly **craniopharyngiomas** (Fig. 27-10; see Chapter 32). These tumors arise above the sella turcica from remnants of the Rathke pouch and invade

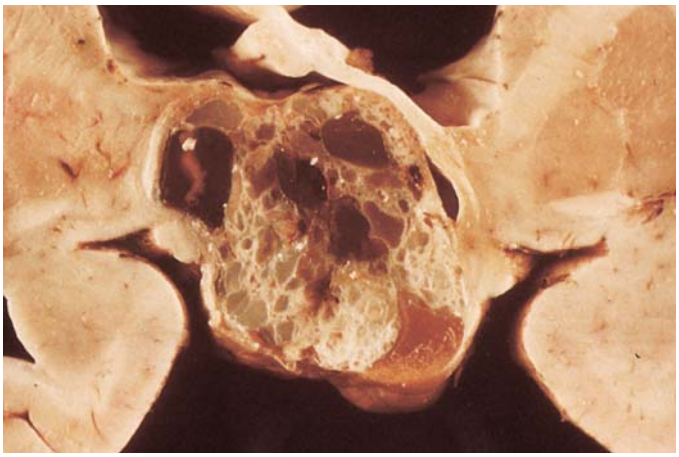

FIGURE 27-10. Craniopharyngioma. Coronal section of the brain shows a large, cystic tumor mass replacing the midline structures in the region of the hypothalamus.

and compress adjacent tissues. Trauma and hypophysectomy for anterior pituitary tumors account for most remaining cases of diabetes insipidus. Less often, localized hemorrhage or infarction, Langerhans cell histiocytosis (see Chapter 26) or granulomatous infiltrates involve the posterior pituitary stalk or body. Polyuria may be controlled by powdered posterior pituitary or vasopressin given as snuff. A syndrome of inappropriate ADH secretion (SIADH) may be caused by paraneoplastic secretion of ADH by tumors (see below).

HYPOTHALAMIC–PITUITARY AXIS

The hypothalamus, pituitary stalk and pituitary gland constitute an anatomically and functionally integrated "neuroendocrine system." Hypothalamic neurons secrete factors that stimulate the anterior pituitary (Table 27-2). Secretion of these hypothalamic factors is, in turn, antagonized by hormones made in peripheral target organs, thus completing a feedback loop. There are also specific hypothalamic inhibitory hormones. For example, dopamine inhibits pituitary PRL secretion.

The hypothalamus may be damaged by primary and metastatic tumors, viral infections and granulomatous inflammations, as well as degenerative and hereditary disorders. Hypothalamic dysfunction may also occur without an identifiable anatomic abnormality. Diverse conditions result from disturbances of hypothalamic function and include, among others, hypogonadism, precocious puberty, amenorrhea and eating disorders (obesity or anorexia). Some pituitary disorders characterized by increased or decreased hormone secretion have their origin in hypothalamic dysfunction.

TABLE 27-2
HORMONES OF THE HYPOTHALAMIC–PITUITARY–TARGET GLAND AXIS

Hypothalamus	Pituitary	Target Gland	Peripheral Inhibitory Hormone
CRH	ACTH	Adrenal	Corticosteroids
TRH	TSH	Thyroid	T_3, T_4
GHRH	Growth hormone	Varied	IGF-I
Somatostatin	Growth hormone	Varied	IGF-I
LHRH	LH	Gonads	Estradiol, testosterone
	FSH	Gonads	Inhibin, estradiol, testosterone
Dopamine	Prolactin	Breast	Unknown

ACTH = adrenocorticotropic hormone; CRH = corticotropin (ACTH)-releasing hormone; GHRH = growth hormone–releasing hormone; IGF-I = insulin-like growth factor-I; LHRH = luteinizing hormone–releasing hormone; T_3 = triiodothyronine; T_4 = tetraiodothyronine (thyroxine); TRH = thyrotropin-releasing hormone.

Thyroid Gland

ANATOMY

The thyroid is one of the largest endocrine organs. It appears as early as 24 days of fetal development. The primitive thyroid descends to its eventual location in the lower anterior neck by elongation of its tubular attachment to the tongue, the thyroglossal duct, which then atrophies around the 7th week of life. The adult thyroid has two lobes connected by an isthmus and is below the thyroid cartilage anterior to the trachea. Each lobe is about 4 cm in greatest dimension. The gland weighs 25–35 g. Its cut surface has a glistening, light brown, lobulated appearance. In its early development, the gland contains cords of cells that will become the follicles or acini that make up the functional units of the thyroid gland. Follicles average 200 μm and are formed by a single row of cuboidal cells surrounded by a delicate basement membrane. A thyroid lobule contains 20–40 follicles. These are supplied by a lobular artery and sustained by a diffuse mesh of fibrous stroma, lymphatics and connective tissue. Follicles eventually become filled by an eosinophilic, proteinaceous **colloid**. This substance represents secreted thyroglobulin, from which active thyroid hormones are released.

Immunohistochemical staining for thyroglobulin has become a powerful marker to identify follicular cells. Thyroid transcription factor-1 (TTF1) is another marker utilized to identify follicular epithelium.

In addition to follicular epithelial cells, the thyroid also contains **parafollicular** or **C cells** in the lateral aspects of the upper portion of both thyroid lobes, close to the follicles. These cells probably derive from neural crest and are more prominent in children. They produce **calcitonin,** a calcium-lowering hormone, and can also secrete smaller amounts of other peptides such as serotonin and somatostatin. C cells are difficult to identify using routine stains but are readily seen by immunostaining for calcitonin or neuroendocrine markers such as chromogranin and synaptophysin.

THYROID FUNCTION

The main function of the **follicular cells** in the thyroid gland is to make the thyroid hormones **triiodothyronine** (T_3) and tetraiodothyronine (**thyroxine,** T_4). T_4 is principally a prohormone; the major effector of thyroid function is T_3. These

molecules are formed by iodination of tyrosines in thyroglobulin by follicular cells. Iodinated thyroglobulin is then secreted into the follicle lumen. Alone among endocrine glands, the thyroid can store a large amount of preformed hormone.

On demand, follicular cells reabsorb thyroglobulin, liberate T_4 and T_3 by proteolytic cleavage and release them into the blood. Most secreted hormone is T_4, which is deiodinated in peripheral tissues to its more active form, T_3. Thyroid hormones in the blood are both free and bound to thyronine-binding globulin (TBG). Peripheral cells take up only free hormone, which binds to nuclear receptors and initiates specific protein synthesis.

Thyroid hormone affects almost all organs. It stimulates basal metabolic rate and metabolism of carbohydrates, lipids and proteins. It increases body heat and hepatic glucose production by increasing gluconeogenesis and glycogenolysis. It promotes synthesis of many structural proteins, enzymes and other hormones. Glucose use, fatty acid synthesis in the liver and adipose tissue lipolysis all increase. In general, thyroid hormone upregulates overall metabolic activities, both anabolic and catabolic.

Thyroid structure and function are mainly governed by pituitary TSH. In turn, thyroid hormone suppresses TSH secretion, to complete a feedback loop. Normal thyroid hormone production requires an adequate dietary supply of iodine.

CONGENITAL ANOMALIES

THYROID AGENESIS: Complete absence of thyroid tissue (athyrosis) is a rare congenital abnormality, usually not discovered until several weeks after birth because maternal thyroid hormone supplies the fetus through the placenta.

ECTOPIC THYROID: Thyroid tissue may occur outside the thyroid gland in several locations, as a result of abnormal migration during development. Such ectopic thyroid tissues are functionally normal and can produce thyroid hormone. Malignant tumors may develop in them.

LATERAL ABERRANT THYROID: This term describes the presence of thyroid tissue located lateral to the jugular veins, but not in lymph nodes. Ectopic thyroid tissue may occur in lymph nodes and soft tissue adjacent to the normal gland. The origin of lateral aberrant thyroid is controversial. Some hold that all of these cases actually represent well-differentiated metastases from occult thyroid cancers; others see them as embryonal rests lateral to the thyroid. If the aberrant thyroid tissue is histologically malignant (see below), then the lesion should be considered a metastasis.

LINGUAL THYROID: If the thyroid fails to descend during embryogenesis, it stays at its origin, as a nodule at the base of the tongue. This happens more in females and usually is found because of difficulty in swallowing, speaking or breathing. Removal may lead to total hypothyroidism. These tissues resemble normal thyroid histologically.

HETEROTOPIC THYROID TISSUE: Nests of thyroid tissue may be found anywhere along the gland's pathway of descent into the lower neck. Thyroid tissue may also occur in the pericardium or mediastinum.

THYROGLOSSAL DUCT CYST: Failure of a thyroglossal duct to involute completely can result in a cystic, fluid-filled remnant anywhere along the duct's route. This condition affects patients in all age groups. It presents as cystic masses of variable size (1–4 cm) often in the middle of the neck and attached to the hyoid bone or soft tissues. The cysts can be lined by squamous or respiratory-type epithelium and contain variable amounts of thyroid tissue. Malignancies can develop in these cysts, usually papillary carcinomas. Surgical excision is curative, and portions of the hyoid bone should be removed to avoid recurrences.

NONTOXIC GOITER

Goiter is thyroid gland enlargement, either nodular or diffuse. It is classified according to its function.

Nontoxic goiter *(from the Latin,* guttur, *"throat"), also called simple, colloid or multinodular goiter or nodular hyperplasia, is thyroid enlargement without functional, inflammatory or neoplastic changes.* Thus, patients with nontoxic goiter are euthyroid and do not have thyroiditis (see below). The disease is far more common in women than in men (8:1). Diffuse goiter is frequent in adolescence and during pregnancy, while the multinodular type usually occurs in people older than 50 years.

In nontoxic goiter, the capacity of the thyroid to produce thyroid leads to enlargement of the gland, which maintains the euthyroid state.

PATHOPHYSIOLOGY: The cause of the decrease in thyroid hormone production is unknown. However, in some endemic cases decreased hormone production is caused by low iodine content in drinking water. The thyroid gland can enlarge during pregnancy and during the course of inflammatory conditions. Goiters can develop in patients receiving a variety of medications such as sulfonamides or having an excess of iodine intake.

MOLECULAR PATHOGENESIS: Simple nodular thyroid enlargement tends to be familial, suggesting a genetic factor in the disorder. Indeed, mutations in the thyroglobulin gene occur in a number of families who have simple goiter. Linkage analysis studies identified two chromosomal regions (MNG-1 in chromosome 14q, and Xp22) as possible loci for multinodular goiter. These nodules may be either monoclonal or polyclonal. Recently, thyroid-stimulating hormone receptor (*TSHR*) gene D727E has been related to the development of nodular goiter.

PATHOLOGY: Nontoxic goiters range from double the size of a normal gland (40 g) to massive thyroid weighing hundreds of grams (Fig. 27-11).

Diffuse nontoxic goiter characterizes the early stages of the disease. The gland is diffusely enlarged, with hypertrophy and hyperplasia of follicular epithelial cells. On occasion, the epithelium is papillary. At this stage, follicles contain decreased colloid.

Multinodular nontoxic goiter reflects more chronic disease. The enlarged gland becomes increasingly nodular, and the cut surface typically shows many irregular nodules. When these nodules contain large amounts of colloid, the thyroid tends to be soft, glistening and reddish. These

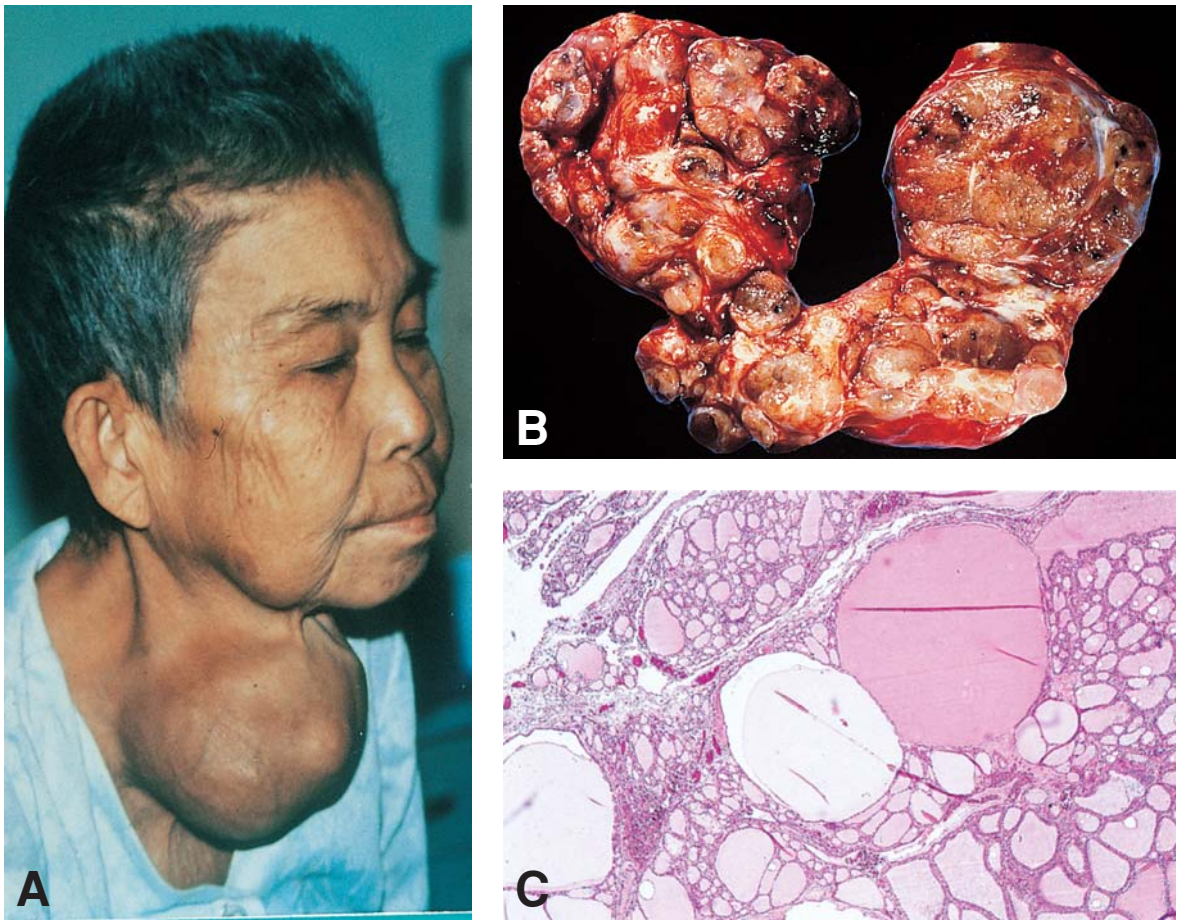

FIGURE 27-11. Nontoxic goiter. A. In a middle-aged woman with nontoxic goiter, the thyroid has enlarged to produce a conspicuous neck mass. **B.** Coronal section of the enlarged thyroid gland shows numerous irregular nodules, some with cystic and old hemorrhage. **C.** Microscopic view of one of the macroscopic nodules shows marked variation in the size of the follicles.

nodules vary considerably in size and shape. Some are distended with colloid; others are collapsed. Large colloid-containing follicles may fuse to form even larger "colloid cysts." Lining epithelial cells are flat to cuboidal and are occasionally arrayed as papillae that project into the follicular lumen. Hemosiderin deposition and cholesterol granulomas are evidence of old hemorrhage. Individual follicles or groups of follicles are separated by dense fibrosis and dystrophic calcifications. Hemorrhage and chronic inflammation are common.

CLINICAL FEATURES: Patients with nontoxic goiter are typically asymptomatic and come to medical attention because of a mass in the neck. Large goiters may compress structures in the neck. Thus, they may cause dysphagia (esophagus), inspiratory stridor (trachea), venous congestion of the head and face (neck veins) or hoarseness (recurrent laryngeal nerve). Hemorrhage into a nodule or cyst leads to local pain. Patients are euthyroid: blood T_4, T_3 and (usually) TSH are normal.

Nontoxic goiters are most commonly treated with thyroid hormone to reduce TSH levels and, thus, the stimulus to thyroid growth. Older patients often have low TSH levels, so further suppression by exogenous thyroid hormone may be ineffective. In them, radioactive iodine therapy is indicated. Surgery is ordinarily contraindicated but may be necessary if local obstructive symptoms become troublesome. Many patients with nontoxic goiter eventually develop hyperthyroidism, in which case the term **toxic multinodular goiter** is applied (see below).

HYPOTHYROIDISM

Hypothyroidism is the clinical manifestations of thyroid hormone deficiency. It can be the consequence of three general processes:

- **Defective thyroid hormone synthesis,** with compensatory goitrogenesis (goitrous hypothyroidism)
- **Inadequate thyroid parenchyma function,** usually due to thyroiditis, surgical resection of the gland or therapeutic radioiodine administration
- **Inadequate secretion of TSH** by the pituitary or of thyroid-releasing hormone (TRH) by the hypothalamus

Other causes include pregnancy (postpartum thyroiditis), congenital conditions and certain medications such as lithium.

MOLECULAR PATHOGENESIS: Defects in thyroidal H_2O_2 generation have been identified in some patients with congenital hypothyroidism.

These include loss-of-function mutations in *DUOX2* and *DUOXA2* genes. Also, cloning of the *NIS* gene has allowed examination of the molecular basis of congenital hypothyroidism due to iodide transport defect (ITD). Inactivation of Kif3a leads to altered G-protein–coupled receptor expression, which may also cause hypothyroidism.

CLINICAL FEATURES: Symptoms of hypothyroidism reflect decreased circulating thyroid hormone (Fig. 27-12). They develop insidiously. Often the first manifestations are tiredness, lethargy, sensitivity to cold and inability to concentrate. Many organ systems are affected, but all are hypofunctional. Hypothyroidism is treated effectively with thyroid hormone.

SKIN: Cutaneous signs are almost universal in patients with clinical hypothyroidism. Proteoglycans accumulate in the extracellular matrix and bind water, resulting in a peculiar form of edema called **myxedema**. Myxedematous patients have boggy facies, puffy eyelids, edema of the hands and feet and enlarged tongues. Thickening of laryngeal mucous membranes causes patients to be hoarse. A pale, cool skin reflects cutaneous vasoconstriction. The skin is also dry and coarse, because sebaceous and sweat gland secretions are inadequate. Ecchymoses are common because of increased capillary fragility. Skin wounds heal slowly.

NERVOUS SYSTEM: Hypothyroidism in pregnancy has grave neurologic consequences for the fetus, expressed after birth as cretinism (see below). Hypothyroid adults are lethargic and somnolent and show memory loss and slowed mental processes. Psychiatric symptoms are common, including paranoid ideation and depression. Severe agitation, **myxedema madness,** may develop. Sensory defects, including deafness and night blindness, occur. Cerebellar ataxia may appear and tendon reflexes are slow. The brain shows mucinous accumulations in nerve fibers and in the cerebellum.

HEART: In early hypothyroidism, heart rate and stroke volume are reduced, resulting in decreased cardiac output.

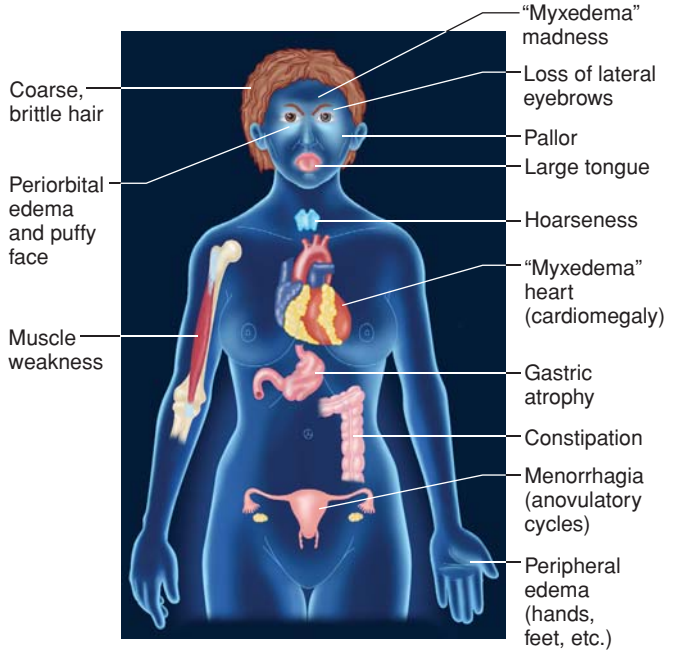

FIGURE 27-12. Dominant clinical manifestations of hypothyroidism.

In untreated hypothyroidism, so-called **myxedema heart** develops, with cardiac dilatation and pericardial effusion. Such hearts are flabby and show interstitial edema and myocyte swelling. Coronary atherosclerosis is common.

GASTROINTESTINAL (GI) TRACT: Constipation, due to decreased peristalsis, is common and may be severe enough to lead to fecal impaction **(myxedema megacolon)**.

REPRODUCTIVE SYSTEM: Women with hypothyroidism suffer ovulatory failure, progesterone deficiency and irregular and excessive menstrual bleeding. In men, erectile dysfunction and oligospermia are common.

Primary (Idiopathic) Hypothyroidism Is Often Autoimmune

Primary hypothyroidism is most common in the 5th and 6th decades. Like most thyroid disorders, it is more common in women than in men. Circulating antibodies to thyroid antigens are present in 75% of patients, suggesting that these cases represent an end stage of autoimmune thyroiditis (see below). Nongoitrous hypothyroidism may also result from antibodies that block TSH or TSH receptor without activating the thyroid. Some cases of primary hypothyroidism are part of the **multiglandular autoimmune syndrome,** including insulin-dependent diabetes, pernicious anemia, hypoparathyroidism, adrenal atrophy and hypogonadism (see below).

Goitrous Hypothyroidism Reflects Inadequate Secretion of Thyroid Hormone

There are a number of conditions in which thyroid enlargement (goiter) accompanies hypothyroidism. The etiology of goitrous hypothyroidism includes iodine deficiency, antithyroid agents (drugs or dietary goitrogens), long-term iodide intake and various hereditary defects in thyroid hormone synthesis. *The evolution of the pathology of goitrous hypothyroidism is like that described above for nontoxic goiter.*

Endemic Goiter

Endemic goiter is goitrous hypothyroidism due to dietary iodine deficiency in areas with a high prevalence of the disease. Salt water and seafood are rich sources of iodides. Thus, goiters are (or were) common far inland—for example, the Great Lakes area of the United States, alpine Europe, central Africa, parts of China and the Himalayas. The availability of iodized salt has eliminated endemic goiter in many areas. Still, over 200 million people worldwide have endemic goiters.

Pathologic evolution of endemic goiter is like that of nontoxic goiter (see above). However, unlike the latter, endemic goiter rarely causes hyperthyroidism. Iodine treatment may reverse the early, diffuse stage of endemic goiter but has little effect on a fully developed multinodular goiter. Replacement therapy with thyroid hormone is indicated. Local symptoms may necessitate surgical resection.

Goiter Induced by Antithyroid Agents

A number of drugs and naturally occurring chemicals in foods suppress thyroid hormone synthesis and so are goitrogenic. Such goiters may or may not be associated with hypothyroidism. Common goitrogenic drugs include **lithium,**

which is used to manage manic depressive states; phenylbutazone; and *p*-aminosalicylic acid. Certain cruciferous vegetables (turnips, rutabaga, cassava) contain goitrogens and can potentiate an iodine-deficient diet to produce goitrous hypothyroidism.

Iodide-Induced Goiter

Goiter and/or hypothyroidism may occur in people who consume large amounts of iodide, either as a medicinal component (potassium iodide–containing expectorants) or in foods rich in it (e.g., seaweed in Japan). In most cases, iodide-induced goiter develops in the context of preexisting thyroid disease, such as thyroiditis. Women given large doses of iodine during pregnancy may deliver goitrous infants.

Congenital Hypothyroidism Is Also Called Cretinism

Cretinism may be endemic, sporadic or familial and occurs twice as often in girls as boys. In nonendemic regions, 90% of cases result from developmental defects of the thyroid **(thyroid dysgenesis)**. The remainder mainly reflect inherited metabolic defects, including mutations in genes for TRH and its receptor, TSH and its receptor, sodium–iodide symporter, thyroglobulin and thyroid oxidase.

CLINICAL FEATURES: Symptoms of congenital hypothyroidism start in the early weeks of life. Infants are apathetic and sluggish. Their abdomens are large and often show umbilical hernias. Body temperatures are often below 35°C (95°F), and the skin is pale and cold. Refractory anemia and dilated hearts are common. By 6 months, the clinical syndrome of congenital hypothyroidism is well developed. Mental retardation, stunted growth (due to defective osseous maturation) and characteristic facies are evident. Serum T_4 and T_3 are low and TSH levels are high (unless the problem involves defective TSH secretion).

Prompt thyroid hormone replacement therapy is needed to prevent mental retardation and stunted growth. Although treatment may prevent dwarfism, its effects on mental development are more variable. Children in whom hypothyroidism is detected early with neonatal screening respond well to thyroid hormone treatment and are apparently normal mentally. Delayed treatment leads to irreversible brain damage.

Endemic cretinism *is congenital hypothyroidism in areas of endemic goiter.* Both parents are usually goitrous. The disease encompasses two overlapping clinical presentations, a neurologic syndrome and a predominantly hypothyroid one.

- **Neurologic cretinism** features mental retardation, ataxia, spasticity and deaf-mutism. In the pure form of neurologic cretinism, children may be of normal stature and virtually euthyroid. Iodine deficiency in the first trimester of pregnancy may damage a developing nervous system (see Chapter 12) independently of its effect on thyroid hormone production.
- **Hypothyroid cretinism** is thought to arise from iodine deficiency in late fetal life and in the neonatal period. The clinical course in these children is similar to that of other forms of congenital hypothyroidism.

Treatment is aimed at replacing the lacking thyroid hormone. Levothyroxine is the most common medication used.

HYPERTHYROIDISM

Hyperthyroidism is the clinical syndrome of excessive circulating thyroid hormone. In general, signs and symptoms of hyperthyroidism reflect a hypermetabolic state of target tissues. Prolonged hypersecretion of thyroid hormone can result from abnormal thyroid stimulator (Graves disease), intrinsic thyroid disease (toxic multinodular goiter or functional adenoma) and excess TSH production by a pituitary adenoma (rare).

Graves Disease Is the Most Common Cause of Hyperthyroidism in Young Adults

Also known as diffuse toxic goiter and **Basedow disease** in continental Europe, Graves disease is an autoimmune disease characterized by diffuse goiter, hyperthyroidism, exophthalmos (Fig. 27-13), tachycardia, weight loss and dermopathy. It is the most prevalent autoimmune disease in the United States, affecting 0.5%–1% of the population under age 40. Graves disease can also affect children.

PATHOPHYSIOLOGY: The cause of Graves disease is not fully understood and seems to involve an interplay between immune mechanisms, heredity, sex and possibly emotional factors.

IMMUNE MECHANISMS: Patients have immunoglobulin G (IgG) antibodies that bind to specific domains of the plasma membrane TSH receptor (Fig. 27-14). These antibodies act as agonists; that is, they stimulate the TSH receptor and activate adenylyl cyclase, increasing thyroid hormone secretion. Under such continued stimulation, the thyroid becomes diffusely hyperplastic and highly vascular.

Elaboration of thyroid-stimulating antibodies requires thyroid-specific helper ($CD4^+$) T cells that recognize multiple

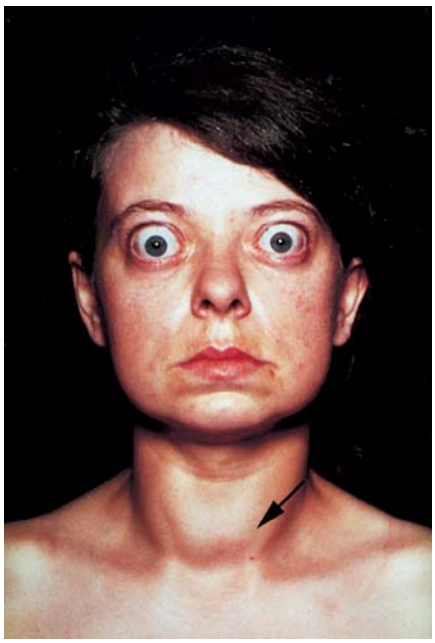

FIGURE 27-13. Graves disease. A young woman with hyperthyroidism displays a mass in the neck and exophthalmos.

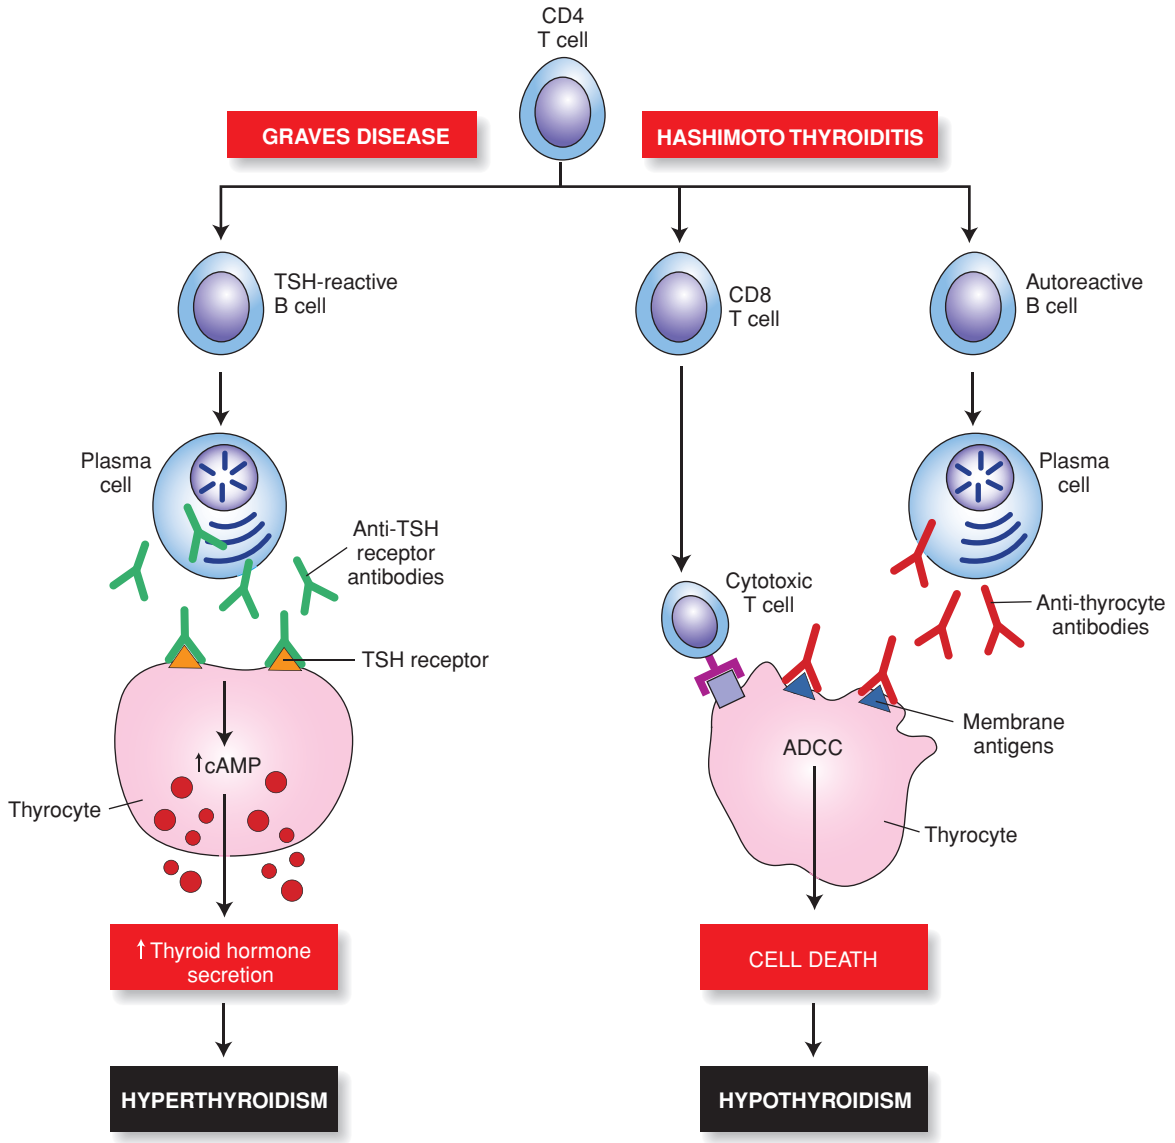

FIGURE 27-14. Immune mechanisms of Graves disease and Hashimoto thyroiditis. $CD4^+$ T cells stimulate antibody production by autoreactive B cells. Anti–thyroid-stimulating hormone (TSH) receptor antibodies stimulate thyroid hormone synthesis in Graves disease. Antibodies induce thyrocyte cell death in Hashimoto thyroiditis by complement-dependent cytotoxicity and antibody-dependent cell-mediated cytotoxicity (ADCC). Thyrocyte death also results from attack by $CD8^+$ (cytotoxic) T cells. *cAMP* = cyclic adenosine 3′,5′-monophosphate.

TSH receptor epitopes and stimulate autoreactive B cells. These then produce thyroid-stimulating immunoglobulins.

Graves autoantibodies are heterogeneous, and those that stimulate thyroid hormone secretion are only one component. Other antibodies seem to be cytotoxic and may cause the thyroid failure that often follows long-standing Graves disease. These include antibodies against thyroglobulin, thyroid peroxidase and the sodium–iodide symporter, all of which may also play roles in the pathogenesis of chronic lymphocytic thyroiditis (Hashimoto disease; see below). Patients with Graves disease have decreased levels of suppressor $CD8^+$ cells, which may play a role in the lack of immune tolerance.

SEX: Like other autoimmune diseases, Graves disease is far more common (7–10-fold) in women than in men. It tends to arise during periods of hormonal imbalance, including puberty, pregnancy and menopause. Men with Graves disease are usually older, and although the degree of thyroid hyperfunction is often greater in men than in women, symptoms tend to be less severe in men.

EMOTIONAL INFLUENCES: Endocrinologists have long observed that onset of Graves disease often follows a period of emotional stress, such as separation anxiety, death of a loved one or injury in an accident. Quantitative data are lacking.

SMOKING: Smoking increases risk of Graves disease, and particularly the severity of the eye disease in patients who develop ophthalmopathy.

OPHTHALMOPATHY: Exophthalmos (protrusion of eyeballs) is a common feature of Graves disease (Fig. 27-13),

but its occurrence and severity correlate poorly with levels of thyroid hormone. A combination of humoral and cell-mediated immune mechanisms is probably involved. T lymphocytes sensitized to antigens shared by thyroid follicular cells and orbital fibroblasts (possibly TSH receptor) accumulate around the eye, where they secrete cytokines that activate fibroblasts. There is also evidence for systemic or local production of antibodies that stimulate orbital fibroblasts to proliferate and produce collagen and glycosaminoglycans.

MOLECULAR PATHOGENESIS: The strongest risk factor for Graves disease is a positive family history. No single gene is responsible or is necessary for Graves disease: the concordance rate in monozygotic twins is only 30%–50%, while in dizygotic twins it is merely 5%. Thus, both genetic and environmental factors are probably involved. With respect to the genetic contribution, human leukocyte antigen (HLA) class II molecules exposed on thyrocytes (e.g., HLA-DR3, HLA-DQA1) have been established as susceptibility loci, with a number of loci carrying a relative risk of Graves disease of up to 4. Graves disease is also associated with polymorphism of cytotoxic T-lymphocyte antigen-4 (CTLA-4) on chromosome 2q33, which indicates the importance of autoreactive T cells. Patients with Graves disease and their relatives have a much higher incidence of other autoimmune diseases (e.g., pernicious anemia and Hashimoto thyroiditis). Asymptomatic, first-degree relatives of these patients may also show increased ^{131}I uptake. White patients with Graves disease more often express HLA-B8 and HLA-DR3, while Chinese patients are more likely to be positive for HLA-Bw46, and Japanese ones for HLA-Bw35.

A new polymorphic gene family is called the major histocompatibility complex class I chain-related gene A (MICA). The genotype MICA A5 may be regarded as a risk factor for Graves disease. The genotype MICA A6/A9 may prevent the disease.

A cluster of single nucleotide polymorphism (SNPs) occurring at Xq21.1 suggest the possibility of an X-linked risk locus for Graves disease.

PATHOLOGY: The thyroid is symmetrically enlarged, usually 35–100 g. Cut surfaces are firm and dark red. The tan translucence of normal thyroid, which is due to stored colloid, is notably absent. There are diffuse follicular hyperplasia and increased vascularity. Thyroid epithelial cells are tall and columnar and array themselves on papillae that project into the lumens of the follicles but lack fibrovascular cores. This papillary proliferation may be misdiagnosed as papillary carcinoma. However, the nucleus is hyperchromatic—and not clear as it is in cancer (see below). Thyroid colloid tends to be depleted and appears pale, scalloped or "moth-eaten" where it abuts the epithelial cells (Fig. 27-15). Scattered B and T lymphocytes and plasma cells infiltrate the interstitial tissue, and B cells may even form germinal follicles. T cells predominate, however. Hyperplastic follicles may occur outside the gland's capsule and in adjacent muscle.

Therapy with antithyroid medication (e.g., methimazole or propylthiouracil) commonly results in increased thyroid hyperplasia and complete lack of colloid.

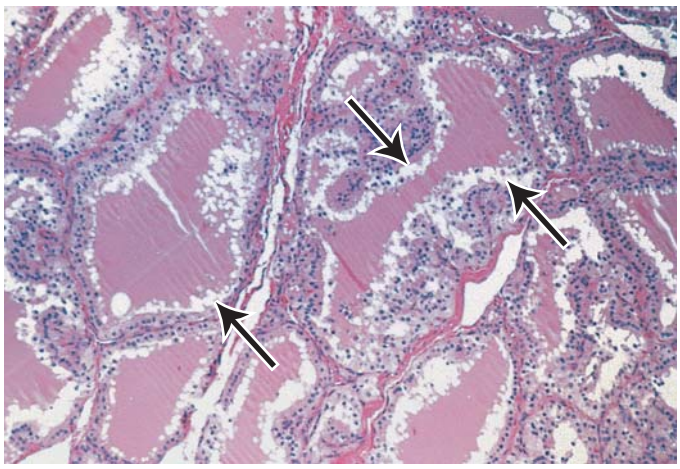

FIGURE 27-15. Graves disease. The follicles are lined by hyperplastic, tall columnar cells. Colloid is pink and scalloped at the periphery adjacent to the follicular cells.

Exophthalmos is caused by enlargement of orbital extraocular muscles. These muscles themselves are normal but are swollen by mucinous edema, accumulation of fibroblasts and lymphocyte infiltration. The increased orbital contents displace the eye forward **(proptosis)**.

The skin shows deposition of acid mucopolysaccharides in the dermis.

CLINICAL FEATURES: Patients with Graves disease note gradual onset of nonspecific symptoms, such as nervousness, emotional lability, tremor, weakness and weight loss (Fig. 27-16). They tolerate heat poorly, seek cooler environments, tend to sweat profusely and may report palpitations. Excess thyroid hormone reduces systemic vascular resistance, enhances cardiac contractility and increases heart rate. In patients with preexisting heart disease, congestive heart failure may ensue.

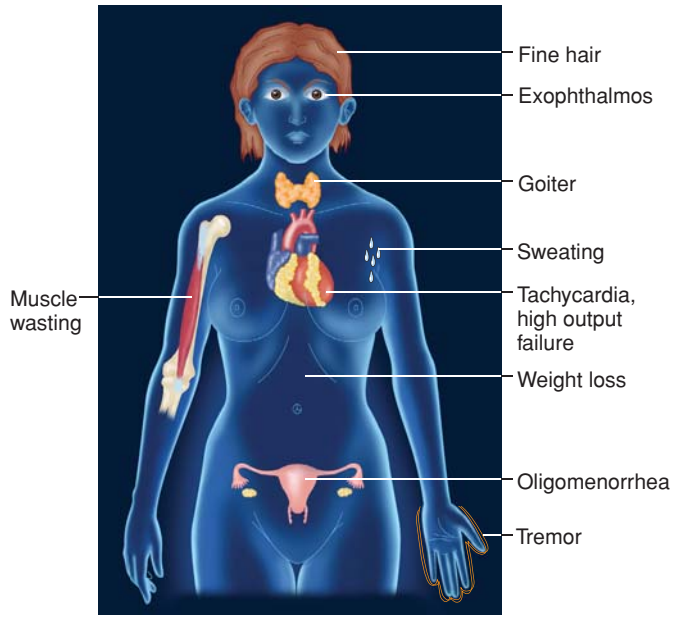

FIGURE 27-16. Major clinical manifestations of Graves disease.

Women develop oligomenorrhea, which may progress to amenorrhea.

They have symmetrically enlarged thyroids, often with an audible bruit and a palpable thrill. Proptosis and retraction of the eyelids expose the sclera above the superior margin of the limbus. The skin is warm and moist. Some patients show **Graves dermopathy,** a peculiar pretibial edema caused by accumulation of fluid and glycosaminoglycans. The diagnosis is confirmed by increased thyroid radioactive iodine uptake and elevated serum of T_4 and T_3. Serum TSH is very low.

The clinical course is characterized by exacerbations and remissions. Untreated, hyperthyroidism may eventually lead to progressive thyroid failure and hypothyroidism. Treatment depends on many individual factors and includes antithyroid medication such as thioisocyanate, destruction of thyroid tissue with radioactive iodine and adjunctive therapy with corticosteroids and adrenergic antagonists. Surgical ablation is uncommon. Unfortunately, even if hyperthyroidism is relieved, exophthalmos often persists and may even worsen.

Toxic Multinodular Goiter Results from Functionally Autonomous Thyroid Nodules

Many patients with nontoxic multinodular goiter, usually over the age of 50, eventually develop a toxic form of the disease. Toxic goiter is more common in women (10:1).

PATHOPHYSIOLOGY AND PATHOLOGY: The mechanisms by which nontoxic multinodular goiter assumes functional autonomy are not clear, but there are two patterns. In some patients, iodine uptake is diffuse and not affected by administration of thyroid hormone. In them, the thyroid shows groups of small hyperplastic follicles mixed with other nodules of varying size that appear to be inactive. In the second pattern, radiolabeled iodine accumulates focally in one or more nodules. These hyperfunctional nodules suppress the rest of the gland. Exogenous thyroid hormone produces no further suppression of iodine uptake, although previously inactive areas respond to TSH by sequestering iodine. The functional nodules show large hyperplastic follicles resembling adenomas and clearly distinct from the inactive areas. The functional nodules are not neoplastic, but the clinical picture is like that of a normal thyroid with a single hyperfunctioning adenoma.

CLINICAL FEATURES: Patients with toxic multinodular goiter often have less severe symptoms of hyperthyroidism than those with Graves disease, and they do not develop exophthalmos. Since patients with toxic goiter tend to be older, cardiac complications, including atrial fibrillation and congestive heart failure, may dominate the clinical presentation. Serum T_4 and T_3 levels are only minimally high, and radiolabeled iodine uptake may be normal or only slightly elevated. Radiolabeled iodine after a course of antithyroid therapy is the most common therapy.

Toxic Adenoma Is a Functional Neoplasm

Toxic adenoma is a solitary, hyperfunctioning, benign follicular tumor in an otherwise normal thyroid. It is an uncommon cause of hyperthyroidism. Such tumors display autonomous function independent of TSH and are not suppressed by exogenous thyroid hormone. A toxic adenoma eventually suppresses the rest of the thyroid, which then atrophies. ^{131}I scintiscans show a solitary focus of iodine uptake ("hot nodule") in a background of minimal uptake. Many, but not all, toxic adenomas have a variety of somatic activating mutations of the TSH receptor gene, leading to constitutive upregulation of the cAMP cascade and less commonly the inositol phosphate–diacylglycerol system.

CLINICAL FEATURES: Toxic thyroid adenoma is most common in the 4th and 5th decades. Symptoms of hyperthyroidism usually begin when the adenoma is about 3 cm. Spontaneous necrosis and hemorrhage within an adenoma may relieve the hyperthyroidism. In that event, the rest of the gland resumes its normal function and the adenoma becomes a "cold" nodule simulating thyroid cancer in a scintigram.

Since the normal thyroid tissue is suppressed, toxic adenomas are treated effectively with radiolabeled iodine. Large nodules may be excised surgically, especially in young patients to minimize risk of thyroid cancer that may occur many years after radiolabeled iodine administration.

THYROIDITIS

Thyroiditis is a heterogeneous group of inflammatory disorders of the thyroid gland, including those caused by autoimmune mechanisms and infectious agents.

Acute Thyroiditis Is Caused by Bacterial or Fungal Infections

The disease usually develops during a systemic infection that reaches the thyroid by hematogenous spread. It occurs in patients of all ages, but children, the elderly or immunocompromised patients are most commonly affected.

Patients present with fever, chills, malaise and a painful, swollen neck. Infection may involve one lobe or the entire gland. There is diffuse acute and chronic inflammation with focal microabscess formation. Rarely, the infection may spread into the trachea, mediastinum and esophagus. The prognosis is excellent when the infection is promptly treated with antibiotics.

ETIOLOGIC FACTORS: The most common causative organisms are streptococcus, staphylococcus and pneumococcus. Other causes include fungi and cytomegalovirus (CMV). Tuberculous thyroiditis is rare but can occur in immunosuppressed patients.

Chronic Autoimmune Thyroiditis (Hashimoto Thyroiditis) Is the Most Common Cause of Goitrous Hypothyroidism in the United States

Hashimoto thyroiditis (HT) is usually part of the spectrum of autoimmune diseases. It can affect several family

members who often also suffer other autoimmune conditions such as lupus, Graves disease, arteritis and scleroderma (see Chapter 11).

MOLECULAR PATHOGENESIS: The pathogenesis of HT involves cellular and humoral immunity. The autoimmune process in HT arises from activation of CD4 (helper) T lymphocytes sensitized to thyroid antigens (Fig. 27-14). Helper T-cell activation may be initiated by viral or bacterial infection.

In turn, these $CD4^+$ cells stimulate proliferation of autoreactive cytotoxic ($CD8^+$) T cells, which attack thyrocytes. The activated lymphocytes secrete interferon-γ, causing thyrocytes to express MHC class II molecules (HLA-DR, -DP, -DQ), thus expanding the autoreactive T-cell population. These effects account for the striking accumulation of lymphocytes in the glands of patients with autoimmune thyroiditis.

Activated CD4 cells also recruit autoreactive B cells to produce antibodies against thyroid antigens. These include antibodies against thyroid microsomal peroxidase (95%), thyroglobulin (60%) and TSH receptor. Cytotoxic antibodies that fix complement have been described in some patients, and antibody-dependent cell-mediated cytotoxicity (ADCC) may contribute to thyroid injury. Unlike the anti-TSH receptor antibodies in Graves disease, which stimulate thyroid function, antibodies in HT block TSH action. Such blocking antibodies have been described in 10% of patients with goitrous autoimmune thyroiditis and in 20% of those with end-stage atrophy of the gland. Half of all first-degree relatives of patients with this condition have antithyroid antibodies, which are apparently transmitted as a dominant trait. Moreover, both Graves disease and chronic autoimmune thyroiditis are described in these family members. A familial tendency for HT is further suggested by the higher prevalence of other autoimmune diseases in patients and their relatives, including MEN syndrome type 2, insulin-dependent diabetes, pernicious anemia, Addison disease and myasthenia gravis. The high incidence of autoimmunity and thyroiditis in people with Down syndrome and familial Alzheimer disease has attracted attention to genes on chromosome 21, but none have yet been identified as causes of these disorders. Interestingly, half of adult patients with Turner syndrome, especially those with an X isochromosome, exhibit antithyroid antibodies, and a third develop hypothyroidism. Only association with HLA and CTLA-4 genes has been seen consistently, but how these contribute to autoimmune thyroiditis remains obscure. The *HLA-DR5* gene has been implicated in families with thyroid disorders.

HT is most common where **iodine intake** is greatest, for example, Japan and the United States. In iodine-deficient areas, iodine supplementation significantly increases the prevalence of chronic inflammation of the thyroid and the presence of thyroid autoantibodies.

PATHOLOGY: The gland in patients with HT is diffusely enlarged and firm, weighing 60–200 g. The cut surface is pale tan and fleshy with a vaguely nodular pattern (Fig. 27-17). The capsule is intact; perithyroid tissues are not involved. The thyroid shows a conspicuous infiltrate of lymphocytes and plasma cells, with destruction and atrophy of follicles and oxyphilic metaplasia of follicular epithelial cells **(Hürthle** or **Askanazy cells)**. Lymphoid follicles, often with germinal centers, are present. The Askanazy cells are filled with mitochondria and often show nuclear atypia, which may be mistaken for cancer. Interstitial fibrosis is variable and is conspicuous in 10% of cases (fibrous variant). The thyroid eventually undergoes atrophy in some patients, who are left with a small, fibrotic gland infiltrated by lymphocytes. Thyroid lymphoma is a rare complication of HT.

CLINICAL FEATURES: HT mainly affects women between 30 and 50 years old, but no age group is spared. Patients may present with nonspecific symptoms such as fatigue, depression and fibromyalgia. Clinically they may have diffuse thyroid enlargement and either mild hyperthyroidism or hypothyroidism. Most patients note gradual onset of a goiter, although sometimes the gland enlarges rapidly. Eventually, 1/3 to 1/2 of patients progress to an overt hypothyroid state, the risk of which is much greater among men than women. Rarely, hyperthyroidism may occur

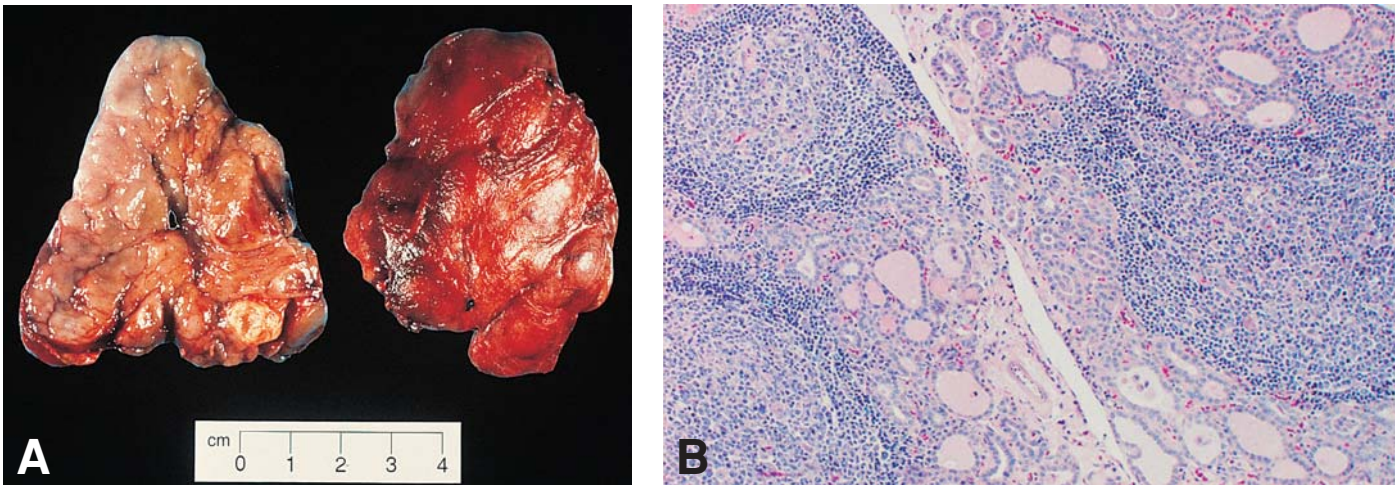

FIGURE 27-17. Chronic autoimmune (Hashimoto) thyroiditis. The thyroid gland is symmetrically enlarged and coarsely nodular. **A.** A coronal section of the right lobe shows irregular nodules and an intact capsule. **B.** A microscopic section of the thyroid reveals a conspicuous chronic inflammatory infiltrate and many atrophic thyroid follicles. The inflammatory cells form prominent lymphoid follicles with germinal centers.

(hashitoxicosis). The diagnosis of HT is now made by identifying circulating antithyroid antibodies (which occur in 95% of patients), **antithyroid peroxidase antibodies (anti-TPO)** and **antimicrosomal, antithyroglobulin** and cell membrane antibodies. Such patients show low levels of T_4, elevated serum thyrotropin and thyroxine index and elevated TSH. HT may frequently coexist with papillary cancer

Many patients need no therapy. Thyroid hormone is given to treat hypothyroidism and decrease the size of the gland. Surgery is reserved for patients who do not respond to suppressive hormone therapy or with troublesome pressure symptoms.

Subacute Thyroiditis (de Quervain, Granulomatous or Giant Cell Thyroiditis) Is Caused by a Viral Infection

Subacute thyroiditis, also known as granulomatous, de Quervain or nonsuppurative thyroiditis, is an uncommon, self-limited disorder characterized by granulomatous inflammation. It typically occurs after upper respiratory viral infections, such as with influenza virus, adenovirus, echovirus or coxsackievirus. Mumps virus has also been incriminated in some cases. de Quervain thyroiditis principally affects women 30–50 years old. The true incidence of subacute thyroiditis is unknown since many infectious thyroiditides have been reported under this name.

PATHOLOGY: The thyroid is enlarged to 40–60 g. Its cut surface is firm and pale. Acute inflammation, often with microabscesses, is followed by a patchy infiltrate of lymphocytes, plasma cells and macrophages throughout the thyroid. Destruction of follicles releases colloid, which elicits a conspicuous granulomatous reaction (Fig. 27-18). Abundant foreign body–type multinucleated giant cells, often containing colloid, are present. Fibrosis may follow resolution of the inflammatory reaction, but normal thyroid architecture is usually restored.

CLINICAL FEATURES: Patients with subacute thyroiditis typically notice pain in the anterior neck, sometimes with fever, malaise, fatigue and pain in the neck or radiating to the jaw. Other patients follow a mild course with only minimal symptoms. The disorder is often mistaken for pharyngitis, as it follows respiratory infections and patients complain of hoarseness and dysphagia. On examination, the thyroid is moderately enlarged and exquisitely tender. Subacute thyroiditis generally resolves within a few months without any clinical sequelae. Iodine uptake is usually suppressed in the early stages of the disease.

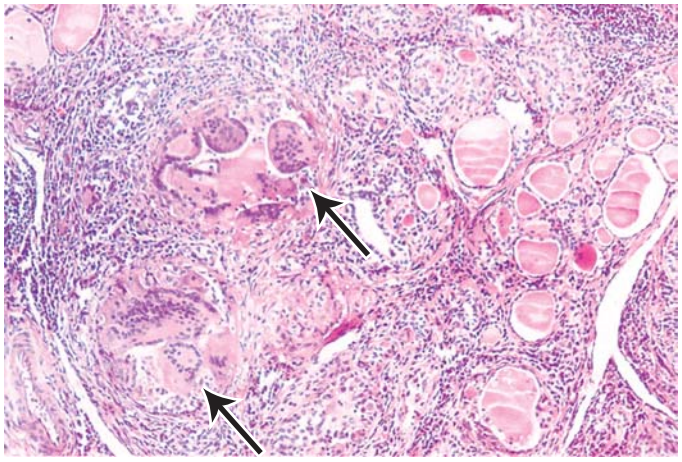

FIGURE 27-18. Subacute thyroiditis. The release of colloid into the interstitial tissue has elicited a prominent granulomatous reaction, with numerous foreign body giant cells (*arrows*).

Release of preformed thyroid hormone by destruction of the follicles often raises serum T_4 and T_3, which may be high enough to cause transient clinical hyperthyroidism. The consequent suppression of TSH leads to decreased radiolabeled iodine uptake. This phase is followed by decreased serum T_4 and T_3 levels, but as inflammation resolves, a euthyroid state returns. There may be low levels of antithyroid antibodies.

Silent Thyroiditis Causes Transient Hyperthyroidism

In silent thyroiditis, also called **painless subacute thyroiditis** or **lymphocytic thyroiditis,** patients experience painless thyroid enlargement, self-limited hyperthyroidism and destruction of gland parenchyma with lymphocytic infiltration. Thus, it resembles subacute thyroiditis clinically but is closer to HT pathologically. *Silent thyroiditis differs from the latter by the lack of antithyroid antibodies or other evidence of autoimmune thyroiditis.* However, association with HLA-DR3 has been reported. As in subacute thyroiditis, the hyperthyroid state reflects release of preformed thyroid hormone from the injured gland.

Silent thyroiditis mainly affects women, often in the postpartum period, causing hyperthyroidism that usually persists for 2–4 months. Treatment is symptomatic, and most patients become euthyroid.

Riedel Thyroiditis Causes Fibrosis of the Thyroid

The "thyroiditis" in Riedel thyroiditis is something of a misnomer, as this rare disease also involves extrathyroidal soft tissues of the neck and often progressive fibrosis in other locations, including the retroperitoneum, mediastinum and orbit. Riedel thyroiditis is mainly a disease of middle age. The female-to-male ratio is 3:1. Riedel thyroiditis is considered to be a manifestation of IgG4-related systemic disease.

PATHOLOGY: Part or all of the thyroid is stony hard and "woody." The process is usually asymmetric and often affects only one lobe. The fibrous infiltrate extends into the thyroid gland and other tissues of the neck, including skeletal muscle and nerves. It may also surround and infiltrate lymph nodes and parathyroid glands. The surgeon may have extreme difficulty identifying a tissue plane. Dense, hyalinized fibrous tissue and chronic inflammation are present throughout involved portions of the thyroid (Fig. 27-19). Eosinophils may be also present. Follicles are normal in unaffected parts of the gland. Fibrosis surrounds and infiltrates other tissues, including skeletal muscle, nerves, fat, blood vessels and, sometimes, the parathyroids.

CLINICAL FEATURES: Patients with Riedel thyroiditis notice gradual onset of painless goiter and present with a hard thyroid mass. They may also have fibrosing lesions at other sites, such as the retroperitoneum, mediastinum and retro-orbital tissues. Immunophenotyping shows mostly T cells with few B cells. Symptoms

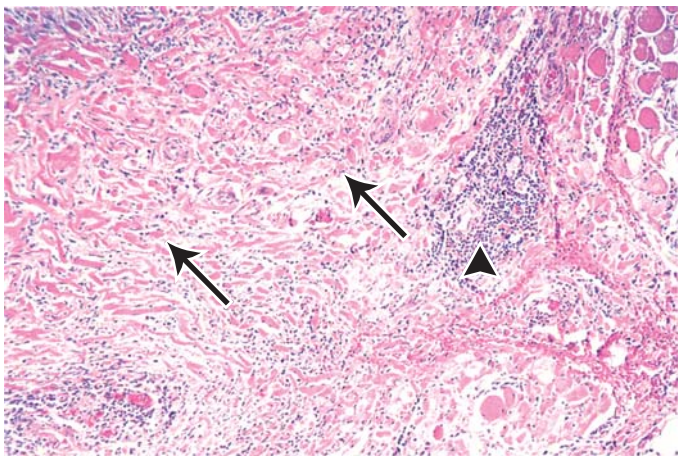

FIGURE 27-19. Riedel thyroiditis. The thyroid parenchyma is largely replaced by dense, hyalinized fibrous tissue (*arrows*) and a chronic inflammatory infiltrate (*arrowhead*).

may be due to compression of neck organs: the trachea (stridor), esophagus (dysphagia) and recurrent laryngeal nerve (hoarseness). Unusual cases may involve the entire thyroid and cause hypothyroidism. Treatment is primarily surgical to relieve symptomatic compression of local structures.

FOLLICULAR ADENOMA OF THE THYROID

Follicular adenomas are benign neoplasms with follicular differentiation. They are the most common thyroid tumors and typically present in euthyroid people as solitary "cold" nodules (i.e., that do not take up radioiodine). Follicular adenomas occur frequently in iodine-deficient areas. They can also occur in irradiated glands and as part of Cowden syndrome (see Chapter 5). Adenomas are solitary encapsulated neoplasms in which cells are arranged in follicles that resemble normal adult thyroid tissue or mimic stages in the gland's embryonic development. Multiple adenomas may occur. Up to 90% of palpable, solitary follicular lesions are actually the dominant nodule in a multinodular goiter. Thus, follicular adenomas are correspondingly uncommon. These are most common in the 4th and 5th decades, with a female-to-male ratio of 7:1. The clonal origin of follicular adenomas has been established.

PATHOLOGY: Follicular adenomas are solitary, circumscribed, 1–3-cm nodules that protrude from the surface of the thyroid. They are completely enclosed by a thin fibrous capsule. The tumor cut surface is soft and paler than the surrounding gland. Hemorrhage, fibrosis and cystic change are common. There are several distinctive histologic patterns (Fig. 27-20). These variants are of no particular clinical or prognostic significance, but it is

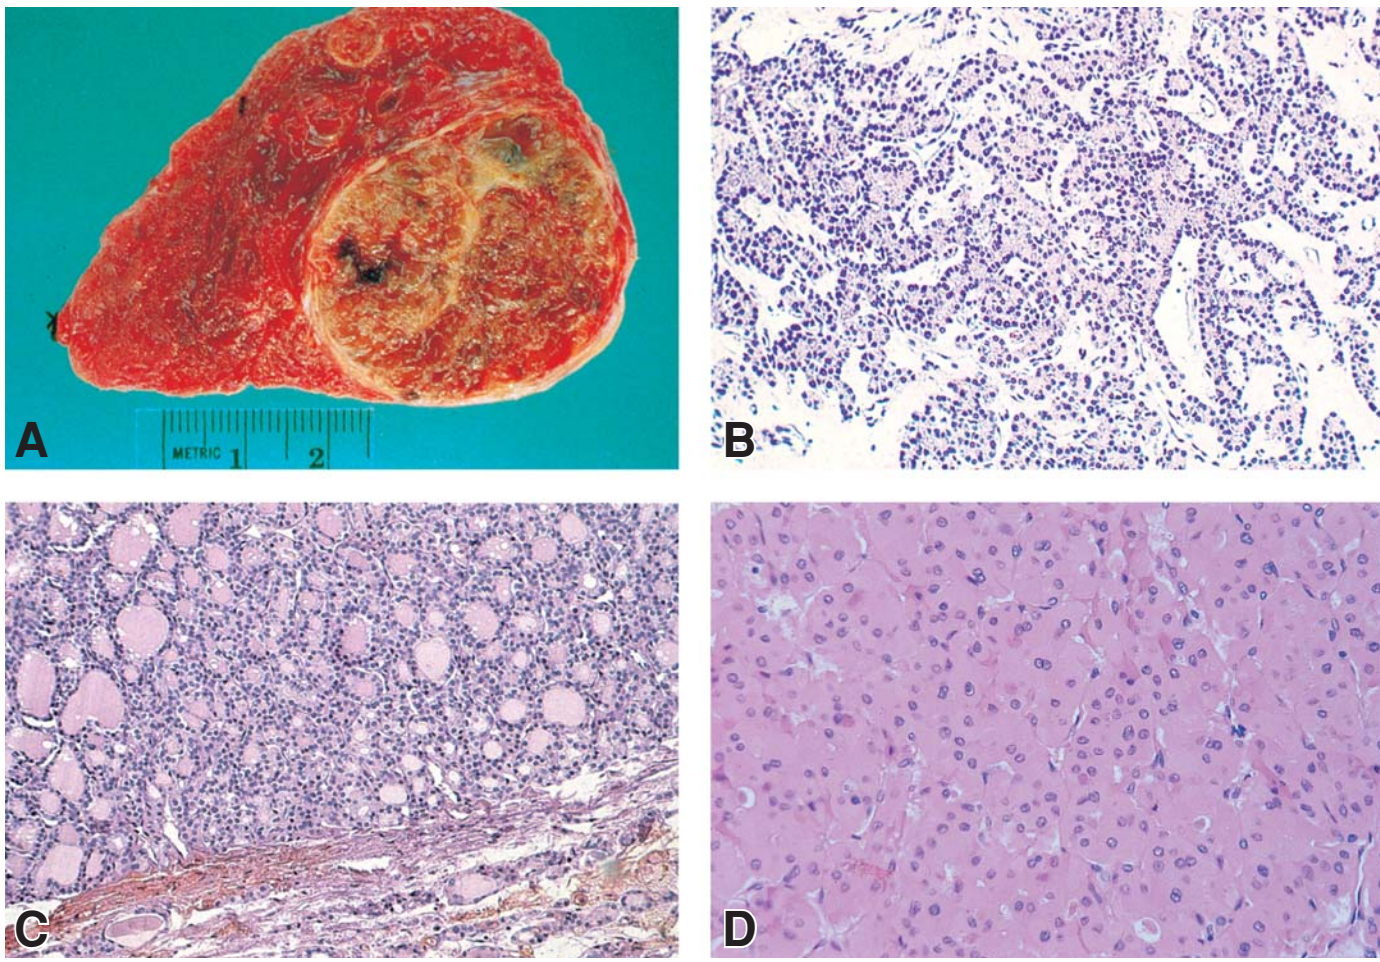

FIGURE 27-20. Follicular adenoma. A. Colloid adenoma. The cut surface of an encapsulated mass reveals hemorrhage, fibrosis and cystic change. **B.** Embryonal adenoma. The tumor features a trabecular pattern with poorly formed follicles that contain little if any colloid. **C.** Fetal adenoma. A regular pattern of small follicles is noted. **D.** Hürthle cell adenoma. The tumor is composed of cells with small, regular nuclei and abundant eosinophilic cytoplasm.

helpful to recognize them so as not to confuse them with thyroid malignancies.

- **Embryonal adenomas** have trabecular patterns, in which poorly formed follicles contain little or no colloid (Fig. 27-20B).
- **Fetal adenomas** contain cells like those of embryonal adenomas, but arranged in microfollicles with little colloid (Fig. 27-20C).
- **Simple adenomas** contain mature follicles with a normal amount of colloid.
- **Colloid adenomas** resemble simple adenomas except with larger follicles that contain more abundant colloid (Fig. 27-20A).
- **Hürthle (oncocytic) cell adenomas** are solid tumors characterized by oxyphil cells, small follicles and scanty colloid (Fig. 27-20D). These lesions frequently undergo infarction after fine-needle aspiration procedures.
- **Atypical adenomas** are follicular tumors with mitoses, excessive cellularity, nuclear atypism or equivocal capsular invasion, but for which a diagnosis of carcinoma cannot be established with certainty.

Differentiation between follicular adenoma and adenomatoid nodules may be difficult. However, adenomatoid nodules lack the fibrous delicate capsule seen in adenomas. Follicular adenomas stain negative for CK19, which can be useful to distinguish them from other papillary tumors.

These benign lesions should be differentiated from follicular carcinomas, which usually have thicker capsules. Careful evaluation of the capsule for capsular or vascular invasion is mandatory to make this distinction. *Malignancies can develop in association with or within benign nodules.* Surgical lobectomy to remove the lesion is curative.

MOLECULAR PATHOGENESIS: Adenomas are clonal in over 60% of cases. Other molecular alterations include trisomy 7; translocations in 19q13; deletions in chromosomes 3p, 10 and 13; and sometimes **mutations in the RAS oncogene**. The oncocytic variant may have alterations in mitochondrial DNA.

Papillary Hyperplastic Nodules

Papillary hyperplastic nodules occur mainly in children and young women. They are solitary, well circumscribed and well encapsulated, and contain papillae of different sizes. Stalks of papillae may contain small follicles. The papillae themselves are lined by cuboidal cells with characteristic follicular nuclei (i.e., dense with dispersed chromatin). The center of nodules is often cystic and can contain colloid-like material. These lesions are often misdiagnosed as papillary cancer.

THYROID CANCER

Thyroid malignancies account for 0.4% of cancer deaths in the United States, with 10,000 new cases diagnosed each year. Mortality from thyroid cancer exceeds that from malignant tumors of all other endocrine organs.

The difficulty of distinguishing clinically between nonneoplastic lesions, benign tumors and thyroid cancer is a major clinical and pathologic concern. Thyroid nodules occur in 1%–10% of the population, but thyroid cancers represent only 1% of all cancers. A single nodule has up to a 12% probability of being malignant, and those odds decrease significantly (3%) if a nodule is palpable.

Most cases of thyroid carcinoma occur between the 3rd and 7th decades, but they do not spare children. These tumors occur in women 2.5-fold more often than in men. However, thyroid cancer is more aggressive in older males.

Fine-needle aspiration biopsy of thyroid nodules makes a diagnosis in most cases. Prognosis is a function of the tumor morphology, and clinical courses may range from virtually benign to rapidly fatal. Fortunately, the latter is uncommon.

Thyroid radioscintigraphy is helpful, since hyperfunctioning nodules are usually benign. "Cold" or nonfunctioning nodules, although more often malignant, may also be benign.

Papillary Thyroid Carcinoma Is the Most Common Thyroid Cancer

Papillary thyroid carcinoma (PTC) accounts for up to 90% of sporadic thyroid cancers in the United States. It occurs most often between the ages of 20 and 50, with a female-to-male ratio of 3:1. However, it may arise at any age, even in children: it is the most common thyroid tumor type in children and young adolescents. Elderly men have a worse prognosis with PTC.

ETIOLOGIC FACTORS AND MOLECULAR PATHOGENESIS: The etiology of PTC is uncertain, but there are several potentially important connections.

- **Iodine excess:** PTC has been produced in animals by administering excess iodine. In endemic goiter regions, addition of iodine to the diet increased the proportion of thyroid cancers showing papillary, as compared with follicular, morphology.
- **Radiation:** External radiation to the neck of children and adults increases the incidence of later PTC. Survivors of atomic bomb explosions in Japan suffered more papillary cancers than would otherwise be expected. Children living in contaminated areas surrounding Chernobyl, the site in Ukraine of a nuclear reactor catastrophe in 1986, had substantially (almost 100-fold) higher rates of PTC, especially if they were under 15 at the time of the incident. The younger the children, the higher the risk, because younger children have a higher uptake of radioactive iodine. It is known that radiation produces DNA double-strand breaks (see Chapters 5 and 8), leading to mutations and translocations including RET rearrangements. On the other hand, treatment with radiolabeled iodine does not increase the risk of this tumor.
- **Genetic factors:** First-degree relatives of PTC patients have a 4–10-fold greater risk for PTC than the general population. Concordance for PTC has been described in monozygotic twins. A familial form of PTC accounts for some 5% of all cases, but the genes responsible have not been identified. Familial thyroid cancers may be more aggressive tumors, with increased frequency of lymph node metastases. PTC also occurs in association with familial polyposis syndrome (*APC* gene; see Chapter 5).
- **Somatic mutations:** Somatic rearrangements of *RET* proto-oncogene on chromosome 10 (10q11.2) are common in PTC, and 60% of such tumors in children exposed to

radiation from the Chernobyl accident showed this mutation. The same mutation occurs after external radiation to the thyroid. These rearrangements cause the tyrosine kinase domain of *RET* to fuse to various other genes, creating *RET/PTC* fusion oncogenes. The frequency of *RET/PTC* rearrangements in PTC varies geographically, from none in Korea to 2% in Saudi Arabia and 60% in the United States and Great Britain. The incidence of *RET/PTC* rearrangements also varies with age, being higher in children and young adults. Many types of RET/PTC are known, the most common of which is RET/PTC3. RET/PTC2 occurs less often and accounts for less than 5% of such rearrangements. RET/PTC3 is common in the tall cell variant of PTC, which is considered an aggressive PTC subtype.

- **Illegitimate recombination** involving the *NTRK1* gene on chromosome 1 with another gene (*TPM3*) on the same chromosome also occurs in some PTCs. *NTRK1* encodes a tyrosine kinase that is a high-affinity nerve growth factor receptor (*NGFR*). TRK rearrangements occur in 10% of PTCs.
- ***BRAF* mutations:** Point mutations of the *BRAF* gene are present in up to 70% of papillary thyroid cancers. This mutation is linked to specific characteristics of PTC that predict tumor behavior and progression. This *BRAF* mutation occurs particularly in PTC and PTC-derived anaplastic thyroid cancer. Differences between *BRAF*-positive and *BRAF*-negative PTC are distinct, suggesting that *BRAF* mutations can be used as a molecular prognostic factor. The BRAFV600E mutation occurs in some types of microcarcinomas.
- ***RAS* mutations:** *RAS* proto-oncogene mutations are present in 10% of PTCs. However, the number of PTCs with *RAS* mutations may be increasing, and approaching 25%.

PATHOLOGY: PTCs vary from microscopic lesions to tumors larger than a normal gland. Serial sections of ostensibly normal thyroids obtained at autopsy have revealed a high proportion of papillary cancers that measure less than 1 mm across, but lymph node metastases in such cases are distinctly uncommon. Papillary cancers may occur in either lobe or the isthmus. They are firm, solid and white-yellowish, with irregular and infiltrative borders. Lesions may be multiple and are occasionally encapsulated (Fig. 27-21A).

Branching papillae contain a central fibrovascular core and a single or stratified lining of cuboidal to columnar cells (Fig. 27-21B). There are usually irregularly shaped or tubular neoplastic follicles, but relative proportions of papillary and follicular elements vary greatly. Nuclear atypia is an important diagnostic feature and includes clear **(ground-glass** or **Orphan Annie)** nuclei, eosinophilic pseudoinclusions (which are invaginations of cytoplasm into the nucleus) and nuclear grooves. Many papillary cancers show dense fibrosis. Calcospherites ***(psammoma bodies)*** are virtually diagnostic of papillary carcinoma: they are rare in other conditions and are present in half of PTCs. The stroma may be infiltrated by lymphocytes and Langerhans cells. In over 3/4 of cases of PTC, careful sectioning of a resected thyroid reveals multiple microscopic foci of tumor. It is not clear, though, whether these reflect multifocal origin of the tumor or lymphatic spread from a solitary primary. Vascular invasion is uncommon.

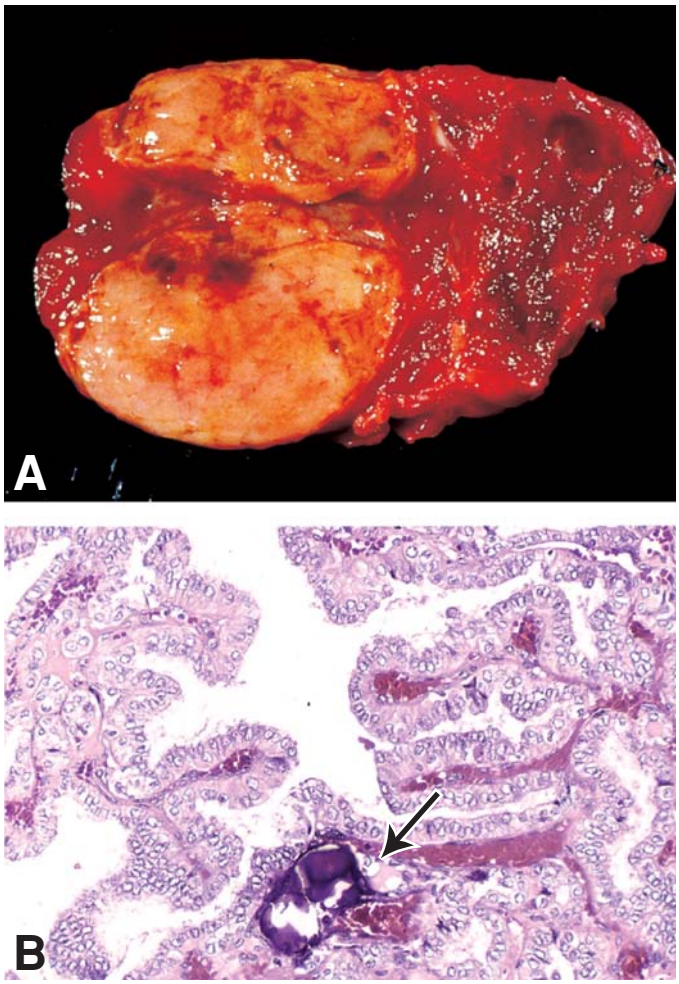

FIGURE 27-21. Papillary carcinoma of the thyroid. A. The cut surface of a surgically resected thyroid displays a circumscribed pale tan mass with foci of cystic change. **B.** Branching papillae are lined by neoplastic columnar epithelium with clear nuclei. A calcospherite, or psammoma body, is evident.

Several morphologic types of papillary carcinoma are known, some associated with good prognosis such as **microcarcinoma** (≤1 cm, not requiring further treatment), **follicular variant** of papillary cancer, **encapsulated** and the **papillary** or most common type. The **diffuse sclerosis, tall cell** and **columnar** variants have worse prognoses.

PTC typically invades lymphatics and spreads to regional cervical lymph nodes. Lymph node metastases vary from tiny foci in otherwise normal lymph nodes to large masses that dwarf the primary lesion. Direct extension of PTC into soft tissues of the neck occurs in 1/4 of cases. Hematogenous metastases are less common than in other types of thyroid cancer, but they do happen occasionally, mostly to the lungs.

CLINICAL FEATURES: PTC generally presents as (1) a painless, palpable nodule in an otherwise normal gland; (2) a nodule with enlarged cervical lymph nodes; or (3) cervical lymphadenopathy without a palpable thyroid nodule. Tumors over 0.5 cm are usually cold areas in thyroid scintiscans.

In general, the prognosis of PTC is excellent, and life expectancy for these patients differs little from that of the general population. The prognosis is more serious in men

over 50 years, but in children, the outlook is good even if there are lung metastases. PTC tends to be more aggressive in men than in women.

As a rule, larger primary tumors are more aggressive, and direct extension into adjacent soft tissues portends a poorer prognosis. The relative proportions of papillary and follicular elements do not affect prognosis, but less differentiated tumors behave worse. The presence of metastases to cervical nodes at the time of surgery does not change the prognosis, as less than 10% of such patients die of the tumor. In fatal cases of PTC, death is caused principally by metastases to the lungs or brain or by obstruction of the trachea or esophagus.

Therapies include surgery (lobectomy or total thyroidectomy) with or without neck dissection, followed by administration of radioiodine.

Follicular Thyroid Carcinoma Is Rarely Fatal

Follicular thyroid carcinoma (FTC) is a purely follicular malignant tumor with no papillary or other elements. It makes up 15%–20% of thyroid tumors. Most patients are older than 40 and female (3:1). FTC is extremely rare in children. However, in areas where iodine is added to salt, as in the United States, FTC is uncommon, representing as few as 5% of thyroid cancers.

ETIOLOGY: Incidence of follicular carcinoma is higher in endemic goiter areas among people who do not receive iodine supplements. Irradiation to the gland may precede FTC in some cases. Genetically, follicular tumors may occur in patients with Cowden and Carney syndromes (see Chapter 5).

MOLECULAR PATHOGENESIS: Molecular changes associated with follicular thyroid carcinoma are point mutations in oncogenes of the *RAS* family (*NRAS, KRAS, HRAS*), which occur in 20%–45% of the tumors, and *PAX8/PPARγ* (paired box 8/peroxisome proliferator-activated receptor γ) rearrangement with a t(2;3)(q13;p25) translocation, affecting 20%–40% of patients. The latter seems to be more common in low-grade FTC with vascular invasion. However, the prevalence of PAX8-PPARγ may be lower than previously noted, and correlation with invasiveness and influence on prognosis are unclear. Mutations of *TP53* tumor suppressor and *PTEN* do occur and may play a role in tumor progression. Cytogenetic studies have shown imbalances in several chromosomes including 3p, 7q, 11, 10q and others.

Follicular tumors with oncocytic morphology have chromosomal changes and abnormalities in mitochondrial DNA like other thyroid tumors with oncocytic features.

PATHOLOGY: Follicular cancers vary in size, are yellow-tan and have thick white fibrous capsules. Areas of hemorrhage and necrosis and foci of cystic degeneration are not uncommon. FTCs are subdivided into minimally invasive and widely invasive variants.

Minimally invasive FTCs are well-defined, encapsulated tumors. They are soft and pale tan to pink, and bulge from within their capsules. Most resemble follicular adenomas, although they tend more to microfollicular or trabecular patterns. Hemorrhagic necrosis may occur in their centers. Mitoses are common, which distinguishes follicular cancers from benign adenomas. The main difference from adenomas is at the border between the tumor capsule and normal parenchyma. In minimally invasive cancers, tumor extends into, but not entirely through, the capsule or shows areas of vascular invasion.

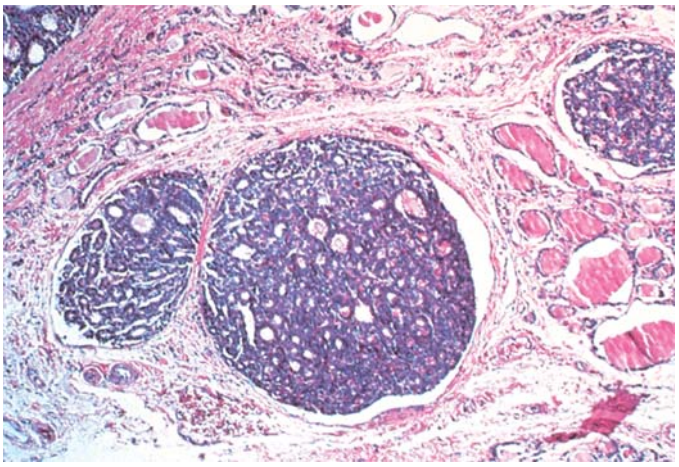

FIGURE 27-22. Follicular carcinoma of the thyroid. A microfollicular tumor has invaded veins in the thyroid parenchyma.

Invasive FTC usually presents few diagnostic problems, since it extends through its capsule or shows vascular invasion (Fig. 27-22), often within or adjacent to the capsule. The tumor may also extend into surrounding soft tissues. Proliferative markers such as Ki67 may in some instances assist in the diagnosis. These tumors stain positively for thyroglobulin and TTF1.

Oncocytic (Hürthle cell) carcinomas are tumors of follicular derivation composed mainly (>75%) of oncocytes. The criteria for malignancy are the same as for follicular cancer: capsular and vascular invasion. These tumors account for 4%–5% of thyroid malignancies and tend to behave more aggressively than regular follicular cancer.

FTC differs from PTC in that its metastases are bloodborne, not lymphatic, and go mainly to the lung and bones of the shoulder, pelvic girdle, sternum and skull.

CLINICAL FEATURES: Most follicular cancers present as solitary palpable nodules or enlarged thyroids. However, in some cases, the presenting sign is a pathologic fracture through a bony metastasis or a pulmonary lesion. Both primary tumors and metastases take up radiolabeled iodine, but thyroid scintiscans may show a cold nodule, as the normal thyroid accumulates iodine more efficiently. Nonetheless, the tumors' affinity for ^{131}I may be used therapeutically. Minimally invasive follicular tumors have a cure rate of at least 95%, compared with a survival of about 50% for the widely invasive form. FTC is treated with unilateral lobectomy. Metastases can be treated with radioiodine.

Medullary Thyroid Carcinoma Is Derived from C Cells of the Thyroid

Medullary thyroid carcinomas (MTC) make up not more than 5% of thyroid cancers. Their cells originate from the branchial pouches. They secrete multiple hormones, including calcitonin, serotonin, ACTH and somatostatin.

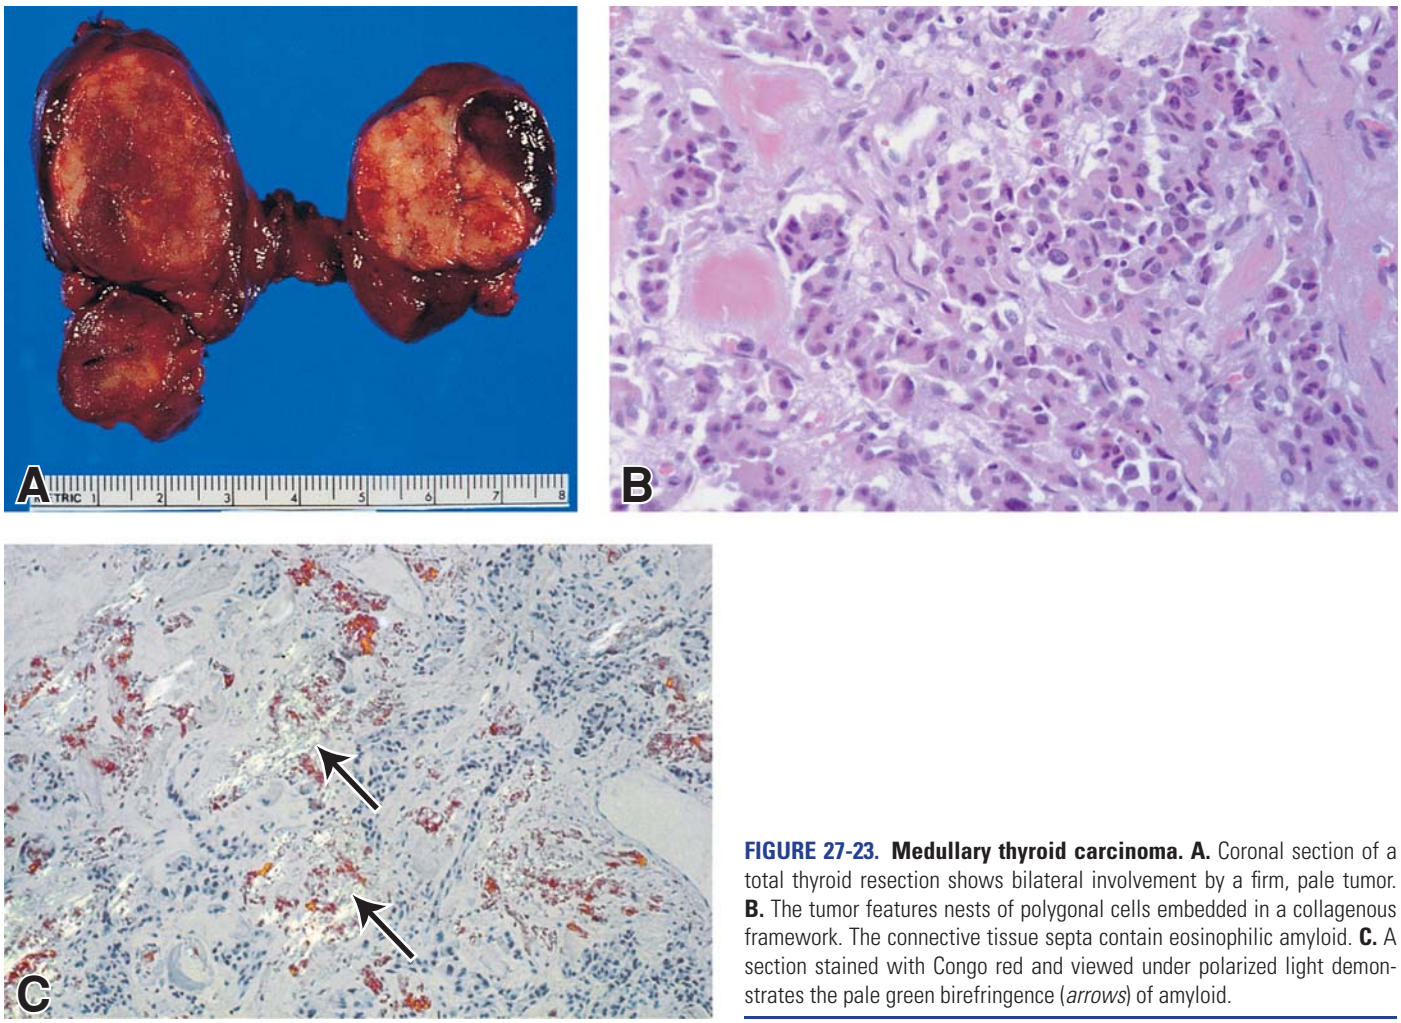

FIGURE 27-23. Medullary thyroid carcinoma. A. Coronal section of a total thyroid resection shows bilateral involvement by a firm, pale tumor. **B.** The tumor features nests of polygonal cells embedded in a collagenous framework. The connective tissue septa contain eosinophilic amyloid. **C.** A section stained with Congo red and viewed under polarized light demonstrates the pale green birefringence (*arrows*) of amyloid.

ETIOLOGY: The disease occurs in sporadic and familial forms, the latter accounting for **25%** of cases. Patients with familial forms of medullary carcinoma often have MEN type 2B or 2A. Tumors in patients with MEN type 2B occur in infancy; those in type 2A develop in adolescents. In familial cases, inheritance is autosomal dominant, and the sex distribution is equal. Sporadic cases present later in life and show slight female predominance (3:2). There are no known etiologic factors.

MOLECULAR PATHOGENESIS: Somatic mutations in *RET* proto-oncogene on chromosome 10 are present in 25%–70% of sporadic MTCs. Most of these are at codon 918 (ATG to ACG) in the tyrosine kinase domain of Ret protein and portend a poorer prognosis than in tumors without *RET* mutations. Other *RET* mutations at codons 768, 790, 791 and 804 may also occur. *RET* is discussed more fully in the section on MEN syndromes (below).

MTCs may show loss of heterozygosity involving several chromosomes such as 1p, 3p, 3q, 11p, 13q, 22q and others.

PATHOLOGY: These tumors tend to arise in the superior portion of the thyroid, which is the region richest in C cells. In the setting of MEN type 2, tumors are often multicentric and bilateral. MTCs are not encapsulated but are usually circumscribed. Cut surfaces are firm and grayish white. MTC histologies are highly variable. Characteristically, these tumors are solid with polygonal, granular cells separated by a highly vascular stroma (Fig. 27-23). However, architectural patterns and appearances of the cells are highly variable. *A conspicuous feature is stromal amyloid, representing deposition of procalcitonin.* Nests of tumor cells are embedded in a hyalinized collagenous framework. Focal calcification is often present and may be extensive enough to be detected radiologically. Besides amyloid, medullary carcinoma may contain mucin, melanin and many polypeptide hormones. Invasion into adjacent tissues is common.

By electron microscopy, the neoplastic C cells have dense-core secretory granules that are positive for several endocrine markers, including calcitonin, synaptophysin, chromogranin and neuron-specific enolase. Almost all of these tumors express carcinoembryonic antigen (CEA). Many are also positive for ACTH, serotonin, substance P, glucagon, insulin and human chorionic gonadotropin (hCG).

MTCs extend by direct invasion into soft tissues. They metastasize to regional lymph nodes and to lung, liver and bone. Sometimes, the initial presentation may be as metastatic disease. Metastases resemble primary tumors and also contain amyloid.

The precursor lesion of familial MTCs is C-cell hyperplasia. C-cell hyperplasia is composed of clusters of C cells with clear cytoplasm located near follicular cells. These nests of

cells express calcitonin. *RET* mutations may occur in these early lesions. Thus, patients with MEN types 2A and 2B (see section on adrenal medulla) who are at risk for MTC are monitored by periodic measurements of serum calcitonin, CEA and sometimes chromogranin. If these are elevated, the patient receives a total thyroidectomy.

CLINICAL FEATURES: Patients with MTC often suffer symptoms related to endocrine secretion, including carcinoid syndrome (serotonin) and Cushing syndrome (ACTH). Watery diarrhea in 1/3 of patients is caused by secretion of vasoactive intestinal peptide, prostaglandins and several kinins. In cases of familial MTC, patients may have hyperparathyroidism, episodic hypertension and other symptoms reflecting secretion of catecholamines by pheochromocytoma.

MTCs usually present as firm thyroid masses or cervical lymphadenopathy. By scintiscan, they are cold nodules. Treatment is total thyroidectomy, but tumors often recur locally. Thyroidectomies are also often performed in children belonging to families with known *RET* mutations and familial syndromes. Overall survival of patients with MTC is 86% at 5 years and 65% at 10 years. Prognosis depends on age (women do better), tumor size and stage. Other prognostic parameters include histologic type, mitotic count, necrosis and amount of calcitonin present. Other factors suggesting an ominous course include advanced age, advanced stage, prior neck surgery and associated MEN2B. Patients under 5 years old with MEN2A often undergo surgery to improve survival. All patients with MTC (whether familial or sporadic) should be tested for *RET* mutations; if they are positive, family members should also be tested.

Treatment is total thyroidectomy, but tumors recur locally in 1/3 of patients. Several new molecular targeted therapies with a tyrosine kinase inhibitor (vandetanib) have shown promising results in clinical trials for medullary thyroid cancer, with increased median progression-free survival.

Anaplastic (Undifferentiated) Thyroid Carcinoma Is Usually Fatal

Anaplastic thyroid cancer is a highly malignant tumor that mostly afflicts women (female-to-male ratio, 4:1) over age 60. This tumor constitutes 10% of thyroid cancers and is more common in areas endemic for goiter. In fact, overall, at least half of patients suffer from long-standing goiter. Many patients with anaplastic carcinoma also have histories of lower-grade thyroid cancers. Thus, the anaplastic variant probably often represents transformation of a benign or low-grade thyroid neoplasm into a more poorly differentiated, more aggressive cancer. External radiation appears to increase the risk of such an event.

MOLECULAR PATHOGENESIS: Anaplastic carcinomas have more chromosomal imbalances than types of other thyroid tumors. There are gains and losses at chromosomes 1q, 1p, 11, 17p, 22q, 9p, 16p and others. Tumors developing from earlier better-differentiated tumors show similar genetic alterations, although the anaplastic component may have higher mutation rates.

Mutations in *TP53*, which encodes *p53* tumor suppressor, are common in anaplastic cancers. Molecular analysis has shown the following mutations in anaplastic tumors: *RAS*, 60%; *TP53*, 48%; *RET/PTC*, 4%; *BRAF*, 23%; *PTEN*, 16%; and *PI3KCA*, 24%. Genetic alterations may sometimes overlap. Mutations in *PAX8* also occur.

PATHOLOGY: Anaplastic carcinoma of the thyroid presents as large poorly circumscribed masses in the gland, frequently extending into the soft tissues of the neck. The cut surface is hard and grayish white. The most common histologic pattern is a sarcoma-like proliferation of bizarre spindle and giant cells, with polyploid nuclei, many mitoses, necrosis and stromal fibrosis (Fig. 27-24). Other patterns include epithelial and giant cell differentiation. The tumor tends to invade veins and arteries, often occluding them and producing foci of infarction and necrosis within the tumor.

Immunohistochemistry in many cases is positive for cytokeratins and epithelial membrane antigen (EMA). However, TTF1 is negative.

CLINICAL FEATURES: Anaplastic carcinomas compress and destroy local structures. Accordingly, the tumor presents as a rapidly enlarging neck mass, with symptoms such as dysphagia, hoarseness,

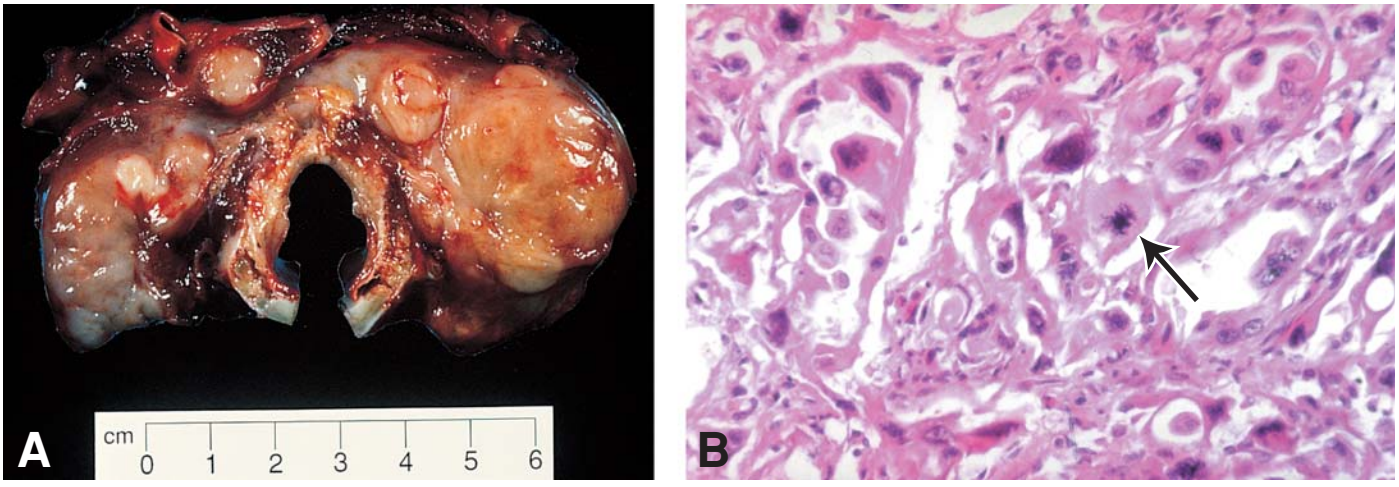

FIGURE 27-24. Anaplastic carcinoma of the thyroid. A. The tumor in transverse section partially surrounds the trachea and extends into the adjacent soft tissue. **B.** The tumor is composed of bizarre spindle and giant cells with polyploid nuclei and prominent mitotic activity (*arrow*).

dyspnea and enlargement of cervical nodes. Dysphagia and dyspnea are caused by tracheal compression or invasion. The prognosis is dismal, and widespread metastases are common. Under 10% of patients survive 5 years. Treatment with radiation and chemotherapy has had little success.

Lymphomas of the Thyroid Are Largely B-Cell Tumors

Lymphomas originating in the thyroid account for 2% of thyroid malignancies. Most, if not all, B lymphomas arise in glands with chronic thyroiditis. In fact, in regions where thyroiditis is frequent, up to 10% of thyroid malignancies are lymphomas.

Patients present with dyspnea, hoarseness and a mass in the neck. Like chronic thyroiditis, thyroid lymphoma occurs more commonly in women than in men (4:1), but the mean age at presentation (7th decade) is older. Their histology is similar to that of lymphomas at other sites; the most common subtype is the diffuse B large cell type.

Patients with thyroid lymphoma should be staged and treated as primary nodal lymphomas. Treatment with chemotherapy is similar to that for comparable nodal lymphomas. The prognosis of thyroid lymphomas of the MALT type (mantle zone lymphomas) is more favorable than those of some other B-cell types (see Chapter 26).

Parathyroid Glands

ANATOMY AND PHYSIOLOGY

The parathyroid glands are derivatives of branchial clefts III and IV. Most people have 4 glands, but numbers vary from 1 to 12. Normally, they are on the posterior thyroid surface, but they occasionally occur intrathyroidally or in ectopic locations such as mediastinum, pericardium or near the recurrent laryngeal nerve.

They are the size and color of a grain of saffron-cooked rice. All glands combined weigh about 130 mg. Individual gland weights vary considerably, but anything over 50 mg probably represents enlargement. They measure 4–6 mm in length. About 3/4 of the cells are chief and oxyphil cells, the remainder being fat cells scattered throughout the parenchyma. The amount of fat varies throughout life and it appears after puberty.

Chief cells secrete parathyroid hormone (PTH) and PTH-related protein. They are polyhedral cells with pale, eosinophilic-to-amphophilic cytoplasm that contains glycogen and fat droplets. Electron microscopy reveals cytoplasmic membrane-bound secretory granules. These cells stain positively for cytokeratins, chromogranin A and synaptophysin. Chief cells are the most sensitive to calcium concentrations. **Clear cells** are chief cells whose cytoplasm is packed with glycogen. **Oxyphil cells** appear after puberty, are larger than chief cells and have deeply eosinophilic cytoplasm, owing to many mitochondria. They have no secretory granules and do not secrete PTH.

The parathyroids respond to blood levels of ionized calcium and magnesium. In turn, PTH controls plasma calcium. Magnesium, a cation closely related to calcium, acts as a brake on PTH secretion. PTH is degraded in the liver and kidney. Other PTH functions also include regulation of renal phosphate excretion, increased tubular and intestinal reabsorption of calcium and bone resorption.

HYPOPARATHYROIDISM

Hypoparathyroidism results from decreased secretion of PTH or end-organ insensitivity to it (pseudohypoparathyroidism), whether congenital or acquired. It is clinically characterized by hypocalcemia and hyperphosphatemia.

Hypoparathyroidism Is Most Often Due to Surgical Removal of the Parathyroids at the Time of Thyroidectomy

The symptoms of hypoparathyroidism relate to hypocalcemia. Increased neuromuscular excitability may cause mild tingling in the hands and feet, severe muscle cramps, tetany, laryngeal stridor and convulsions. Neuropsychiatric manifestations include depression, paranoia and psychoses. High cerebrospinal fluid pressure and papilledema may mimic a brain tumor. Patients with all forms of hypoparathyroidism are successfully treated with vitamin D and calcium supplementation. Of patients undergoing surgery for primary hyperparathyroidism, 1% develop irreversible hypoparathyroidism. Radioactive iodine therapy can also cause hypoparathyroidism.

Familial hypoparathyroidism is a rare disease that can be inherited as autosomal dominant, X-linked recessive or autosomal recessive. It may also be part of a polyglandular syndrome that includes adrenal insufficiency and mucocutaneous candidiasis (see below). Hypoparathyroidism can occur with other congenital abnormalities as in DiGeorge syndrome (see Chapter 4), in which there is agenesis of the parathyroid glands. **Familial isolated hypoparathyroidism** has variable inheritance patterns, is rare and reflects deficient PTH secretion. Mutations in *GCM2* exon 3 may be responsible for some cases of congenital hypoparathyroidism. **Idiopathic hypoparathyroidism** is a heterogeneous group of rare disorders, sporadic and familial, that share deficient secretion of PTH.

Pseudohypoparathyroidism Reflects Target Organ Insensitivity to PTH

This group of hereditary conditions is characterized by hypocalcemia, hyperphosphatemia, increased serum concentration of parathyroid hormone and lack of response to PTH. It reflects mutation of the *GNAS1* gene on chromosome 20q, resulting in low activity of G_s, the G protein that couples hormone receptors to adenyl cyclase. Consequently, in renal tubular epithelium, cAMP production in response to PTH is impaired, causing inadequate calcium resorption from glomerular filtrate. Patients with pseudohypoparathyroidism (PHP) are also often resistant to other cAMP-coupled hormones, including TSH, glucagon, FSH and LH. These patients have a characteristic phenotype **(Albright hereditary osteodystrophy),** including short stature, obesity, mental retardation, subcutaneous calcification and a number of congenital anomalies of bone, particularly abnormally short metacarpals and metatarsals (Fig. 27-25). There are 3 forms of the disease: PHP type 1a, PHP type 1b and pseudopseudohypoparathyroidism (pseudo-PHP).

FIGURE 27-25. Pseudohypoparathyroidism. A radiograph of the hand reveals the characteristic shortness of the fourth and fifth metacarpal bones.

Some of those with pseudohypoparathyroidism have normal G_S activity and a normal phenotype. The basis for their resistance to PTH is unclear.

Pseudopseudohypoparathyroidism reads like a typographical error, but it refers to rare cases in which the phenotype of Albright hereditary osteodystrophy is associated with normal cAMP response to PTH. These patients also have reduced G_S activity like that reported in cases of pseudohypoparathyroidism. This condition is not caused by *GNAS1* mutations, but a candidate gene maps to a nearby part of chromosome 20.

PRIMARY HYPERPARATHYROIDISM

Primary Hyperparathyroidism Is Caused by Excessive PTH Secretion

In primary hyperparathyroidism, PTH production persists without intestinal or renal parathyroid gland stimulation. This condition is rare, with a probable incidence of 1 in 1000, and is most common in women in the 5th decade.

Patients present with hypercalcemia, hypophosphatemia, nephrolithiasis and bone disease. Some are asymptomatic and the only clinical finding is elevated serum calcium.

ETIOLOGY: Hyperparathyroidism may be due to a parathyroid adenoma (80%–90%), hyperplasia involving all parathyroids (10%–15%) or (rarely) parathyroid carcinoma (1%–5%). PTH can be sporadic or part of familial syndromes such as MEN1 or MEN2A. Other associations include mutations in *HRPT2* and *CASR*.

Parathyroid Adenomas Account for Most Cases of Hyperparathyroidism

Solitary parathyroid adenomas cause 85% of primary hyperparathyroidism.

MOLECULAR PATHOGENESIS: Parathyroid adenomas are monoclonal proliferations that arise sporadically or (20%) in the context of MEN1 (see below). In a small minority of cases of sporadic adenomas, the gene for cyclin D1 (*PRAD1*) has undergone rearrangement and the protein is overexpressed. This proto-oncogene is on chromosome 11 and shows breakpoints at 11q13 and 11p15. Comparative genomic hybridization studies of parathyroid adenomas have shown gains or losses in chromosomes 11q13, 11q23, 13q and 15q. Loss of heterozygosity at the MEN1 locus of 11q13 occurs in 20%–40% of adenomas with somatic mutations. *HRPT2* on chromosome 1q is the cause of the familial hyperparathyroidism–jaw tumor syndrome.

PATHOLOGY: Parathyroid adenomas are circumscribed, red-brown, 1–3-cm solitary masses, weighing 0.05–200 g. Hemorrhagic areas are common, and cystic changes are occasionally noted. Adenomas show sheets of neoplastic chief cells in a rich capillary network. A rim of normal parathyroid tissue is usually evident outside the capsule and distinguishes adenomas from parathyroid hyperplasias (Fig. 27-26). Adenoma cells mostly resemble normal chief cells. Immunostaining for PTH documents the tumor's activity. The other parathyroid glands tend to be atrophic. Surgical removal of the tumor relieves the symptoms of hyperparathyroidism. Most parathyroid adenomas only involve one gland, but one patient may rarely harbor two. Adenomas can also occur within the thyroid gland or in ectopic parathyroid tissue. Proliferative markers such as MiB1 show scant proliferation. A proliferative index over 5% should raise the possibility of an atypical gland or cancer.

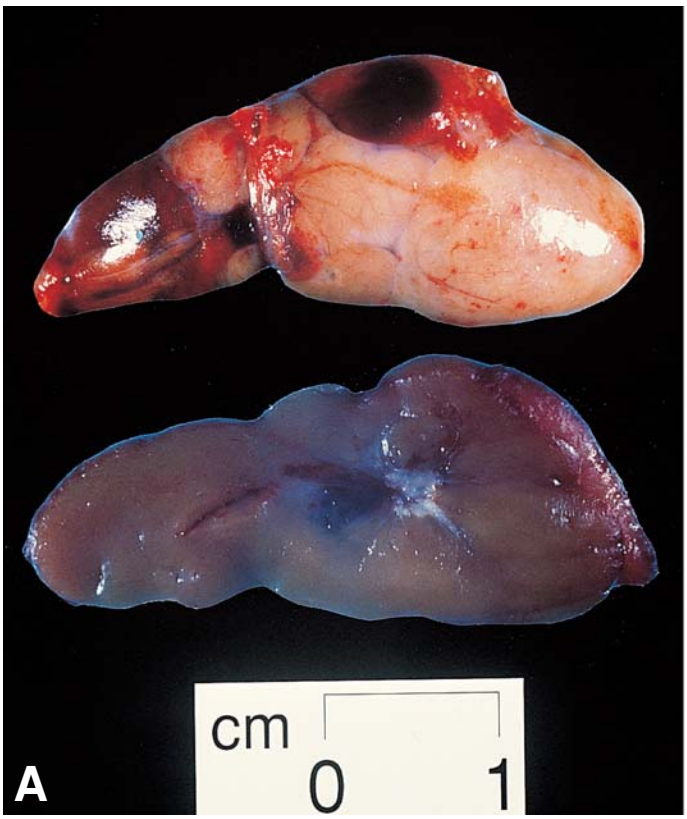
Primary Parathyroid Hyperplasia Causes 15% of Hyperparathyroidism

About 75% of parathyroid hyperplasias occur in women. Of these, 20% involve familial hyperparathyroidism or MEN syndromes (MEN types 1, 2A). A third of sporadic primary parathyroid hyperplasias are monoclonal, suggesting neoplastic proliferation. In such instances, both chief cell hyperplasia and multiple small adenomas occur in the same gland. Factors associated with sporadic primary hyperparathyroidism include external radiation and lithium ingestion.

PATHOLOGY: All 4 parathyroid glands are enlarged, with combined weights from less than 1 g to 10 g. In half of patients, one gland may be noticeably larger than the others, which may complicate the distinction from adenoma. In hyperplastic glands, the normal glandular adipose tissue is replaced by hyperplastic chief cells arranged in sheets or trabecular or follicular patterns (Fig. 27-27). Scattered oxyphil cells are common, and small foci of adipose tissue may remain. An important feature that distinguishes hyperplasia from adenoma is that hyperplasias lack cellular pleomorphism.

Parathyroid Carcinomas Account for 1% of Hyperparathyroidism

Parathyroid carcinomas are rare. They affect both sexes, mainly between the ages of 30 and 60. They are usually functioning tumors, and most patients present with symptoms of hyperparathyroidism. Hypercalcemia in these patients is often severe, with serum calciums in excess of 14 mg/dL.



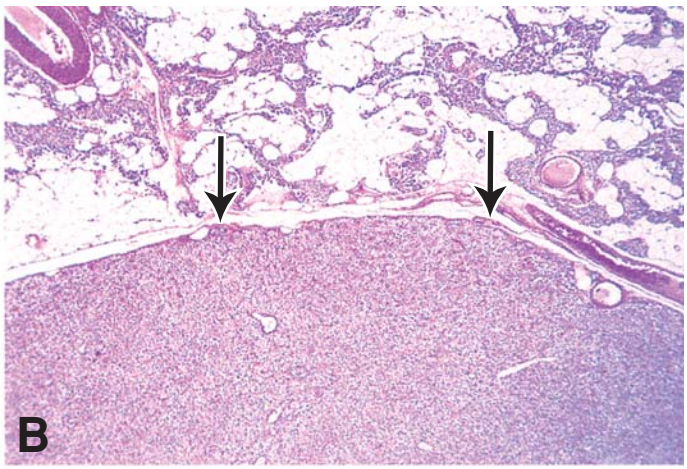


FIGURE 27-26. Parathyroid adenoma. A. External (*top*) and cross-section views (*bottom*) show a tan fleshy tumor. **B.** The tumor consists of sheets of neoplastic chief cells and is separated from normal parenchyma by a thin capsule (*arrows*).

ETIOLOGY: The etiology of these tumors is not known. Neck radiation and hereditary syndromes with histories of parathyroid adenomas are risk factors. Other syndromes of increased risk include hyperparathyroidism–jaw tumor syndrome and familial isolated hyperparathyroidism.

MOLECULAR PATHOGENESIS: Like functioning parathyroid adenomas, some parathyroid carcinomas overexpress cyclin D_1, suggesting that deregulation of this proto-oncogene may be important in parathyroid neoplasia in general. Most parathyroid carcinomas lack retinoblastoma protein (pRb; see Chapter 5), which is present in most adenomas. Losses in chromosome 13q and mutations of *HRPT2* occur. This tumor suppressor gene, at chromosome 1q25-31, is responsible for the hyperparathyroidism–jaw tumor syndrome. It encodes parafibromin, expression of which is low or absent in hyperparathyroid–jaw tumor syndrome and in carcinomas.

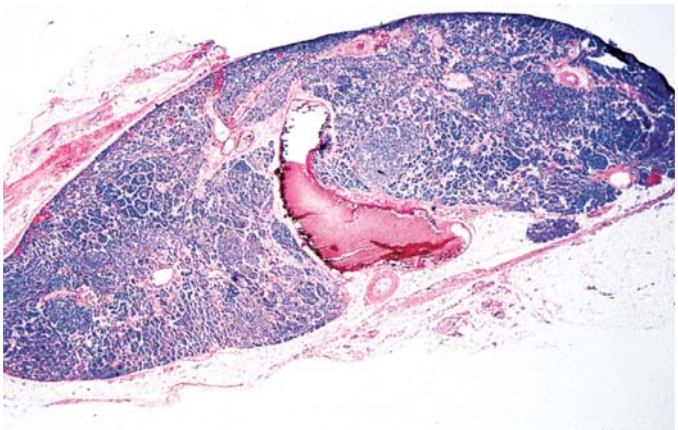

FIGURE 27-27. Primary parathyroid hyperplasia. The normal adipose tissue of the gland has been replaced by sheets and trabeculae of hyperplastic chief cells.

PATHOLOGY: Parathyroid carcinomas tend to be larger than adenomas and appear as lobulated, firm, tannish, unencapsulated masses. They often adhere to surrounding soft tissues. Most carcinomas show trabecular cell arrangements, with significant mitotic activity and thick fibrous bands. Tumors occasionally invade capsules or blood vessels. The cellular atypia that occurs often in parathyroid adenomas is rare in carcinomas. Proliferative markers such as MiB1 show a high proliferative index. Other markers suggestive of parathyroid malignancy include increased expression of galectin 3, loss of *APC* and negative staining for parafibromin.

Treatment of PTH carcinoma includes surgery and, when invasive disease or metastases are present, chemotherapy and radiation therapy. After surgical removal, local recurrence is common: about 1/3 of patients develop metastases to regional lymph nodes, lungs, liver and bone. If fatal, death is most often due to hyperparathyroidism rather than carcinomatosis. Ten-year survival is 50%.

Clinical Features of Hyperparathyroidism are Highly Variable

CLINICAL FEATURES: Some patients with hyperparathyroidism have asymptomatic hypercalcemia, detected on routine blood analysis. Others show florid systemic, renal and skeletal disease (Fig. 27-28).

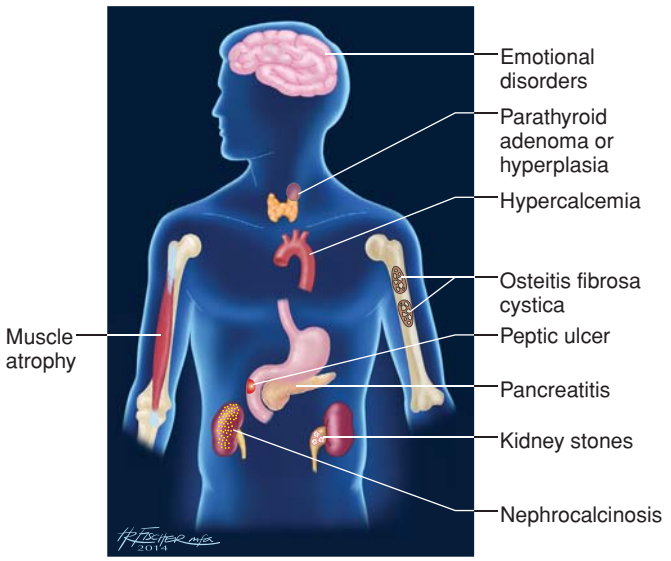

FIGURE 27-28. Major clinical features of hyperparathyroidism.

Hypercalcemia and hypophosphatemia are typical. High PTH levels cause excessive calcium loss from bones and enhanced calcium resorption by renal tubules. PTH also stimulates production of the activated form of vitamin D ($1,25[OH]_2D$) by renal tubules, thus increasing intestinal calcium absorption. The actions of PTH on the kidney, together with hypercalcemia, lead to hypophosphatemia. Common symptoms include nausea, vomiting, fatigue, weight loss, anorexia, polyuria and polydipsia. A neck mass is palpable in many patients. Other systems affected are:

SKELETAL SYSTEM: The classic bone lesions of hyperparathyroidism, **osteitis fibrosa cystica** (see Chapter 30), occur in a minority of patients who have an accelerated and serious form of the disease. These patients present with bone pain, bone cysts, pathologic fractures and localized bone swellings (brown tumors, epulis of the jaw). Chondrocalcinosis may be a complication of hyperparathyroidism.

KIDNEY: Renal colic due to kidney stones brings 10% of patients with primary hyperparathyroidism to medical attention. Nephrocalcinosis, observed radiologically as diffuse renal calcification, may also occur (see Chapter 22). Polyuria is caused by hypercalciuria and leads to polydipsia.

NERVOUS SYSTEM: Psychiatric changes are common. They include depression, emotional lability, poor mentation and memory defects. Reflexes are hyperactive. Peripheral neuropathy with skeletal muscle type 2 fiber atrophy leads to weakness.

GI TRACT: Peptic ulcer disease is increased in patients with hyperparathyroidism, possibly because hypercalcemia increases serum gastrin, thus stimulating gastric acid secretion. Peptic ulcers in MEN1, which includes parathyroid hyperplasia or adenoma, may be secondary to Zollinger-Ellison syndrome (see Chapter 21). Hypercalcemia may also cause constipation and chronic pancreatitis by means not well understood.

OTHER SYSTEMS: Half of patients with hyperparathyroidism are hypertensive, although the mechanism is not clear. Anemia of unknown origin is also frequent.

SECONDARY HYPERPARATHYROIDISM

Secondary parathyroid hyperplasia occurs mainly in patients with chronic renal failure, but also in association with vitamin D deficiency, intestinal malabsorption, Fanconi syndrome and renal tubular acidosis (Fig. 27-29). Chronic hypocalcemia due to renal retention of phosphate,

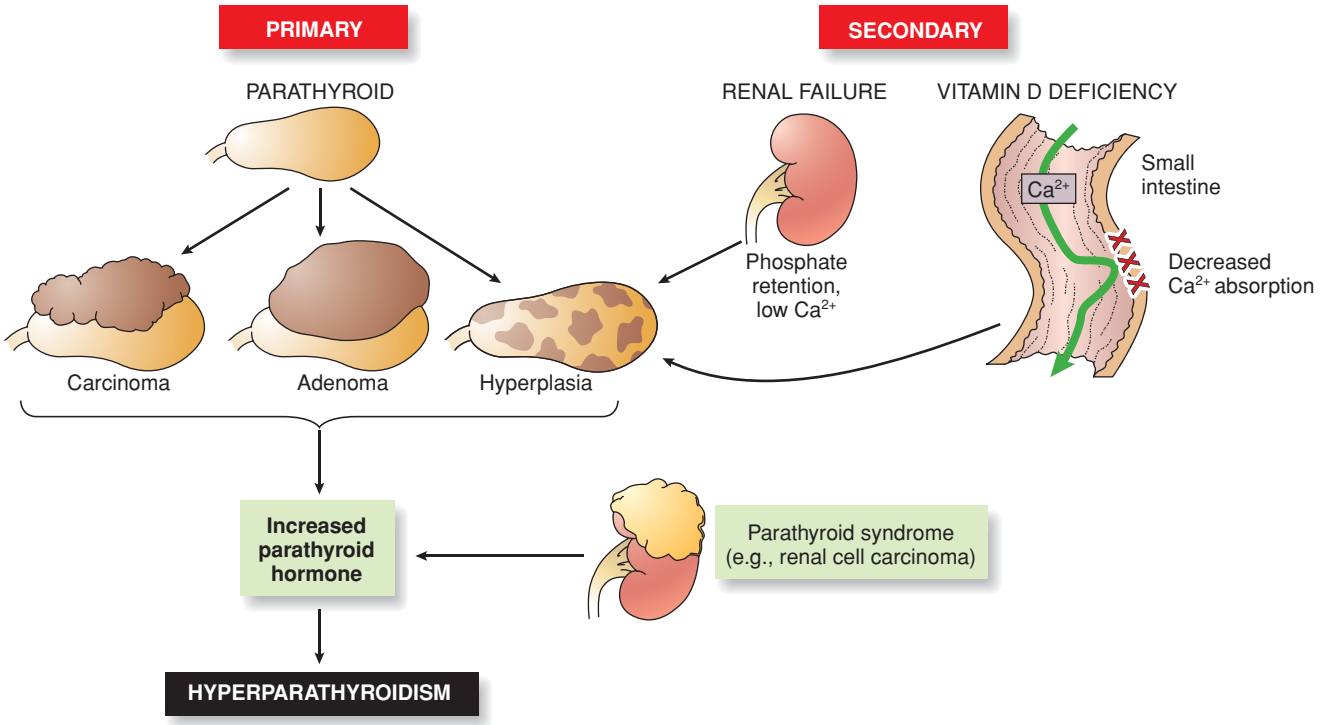

FIGURE 27-29. Major pathogenetic pathways leading to clinical primary and secondary hyperparathyroidism.

inadequate 1,25(OH)$_2$D production by diseased kidneys and some skeletal resistance to PTH all cause compensatory PTH hypersecretion.

Secondary hyperplasia of all parathyroids leads to excess levels of PTH, which produces the main clinical manifestations of skeletal pain and deformities, osteomalacia and osteitis fibrosis cystica and osseous manifestations of hyperparathyroidism, called **renal osteodystrophy** (see Chapter 30).

Pain, swelling and joint stiffness may be due to calcium deposits around joints. The parathyroids in secondary hyperplasia resemble those in primary chief cell hyperplasia. Treatment is surgical removal of the enlarged glands, with or without reimplantation.

Tertiary hyperparathyroidism is autonomous parathyroid hyperplasia following long-standing secondary hyperplasia because of renal failure. In such cases, parathyroid hyperplasia may not regress after renal transplantation, and parathyroidectomy is required. Two thirds of patients with long-standing uremia have monoclonal hyperplastic parathyroid proliferations.

Adrenal Cortex

ANATOMY

Each adrenal (or suprarenal) gland contains two independent endocrine organs: the cortex and the medulla. They are distinct anatomically, functionally and embryologically. The cortex arises from celomic mesenchymal cells near the urogenital ridge and secretes steroid hormones such as aldosterone, cortisol and testosterone. The medulla arises from neuroectoderm invading fetal adrenal glands. It produces catecholamines.

Adult adrenal glands are pyramidal organs above each kidney, found anteriorly in the retroperitoneum. Each gland is 4–6 cm in greatest dimension and weighs **4–6** g. The adrenal glands secrete steroid hormones or corticosteroids, regulate metabolism and immune system function and aid in responses to stress. Grossly, and on cut section, the cortex has a characteristic yellow color because of lipid deposits. The medulla is paler gray-tan. The cortex contains 3 layers or zones:

- The **zona glomerulosa** is the outermost layer. There, aldosterone production is stimulated by angiotensin and potassium and inhibited by atrial natriuretic peptide and somatostatin. The zona glomerulosa makes up 15% of the cortex, with indistinct spherical nests of cells with dark-staining nuclei and moderate numbers of cytoplasmic fat droplets.
- The **zona fasciculata** makes up 75% of the cortex and produces glucocorticoids, such as cortisol. It is not distinctly separated from the zona glomerulosa. This zone contains radial cords of larger cells, each with a small nucleus and a large, foamy, clear cytoplasm, representing stored lipid.
- The **zona reticularis** secretes androgens and is the innermost layer, adjacent to the medulla. Irregular anastomosing cords are composed of compact smaller cells with a lipid-poor, slightly granular eosinophilic cytoplasm and bland nuclei.

Electron microscopy shows that adrenal cortical cells have abundant smooth endoplasmic reticulum and many mitochondria with lamellar cristae, which is common for steroid-producing cells.

The medulla is in the center of the gland, surrounded by cortex. It secretes norepinephrine and adrenaline.

Ectopic adrenal tissue can occur in many places outside the gland, since the cells migrate alongside the gonads. Common locations include the retroperitoneum, the broad ligament near the ovary, near the epididymis, the kidney and the liver. Ectopic adrenal tissue contains only cortex, not medulla. Small nodules of adrenocortical cells often occur in the fibroadipose tissue that surrounds the adrenal gland.

Congenital Adrenal Hypoplasia

This condition is quite rare and may accompany renal agenesis. It has been reported in association with infant death syndrome and with hypogonadotrophic hypogonadism in adolescents. It is X linked, caused by mutations in the *DAX-1* gene at Xp21.

CONGENITAL ADRENAL HYPERPLASIA

ETIOLOGY AND PATHOPHYSIOLOGY: *Congenital adrenal hyperplasia (CAH) results from several autosomal recessive enzyme defects in the biosynthesis of cortisol from cholesterol* (Fig. 27-30). Deficiencies vary from mild to complete lack of cortisol. In general, impaired corticosteroid synthesis leads to unopposed action of ACTH and therefore adrenal hyperplasia. CAH occurs equally in males and females and is the most common cause of ambiguous genitalia in newborn girls (Fig. 27-31A).

PATHOLOGY: Adrenal glands are enlarged, weighing as much as 30 g (Fig. 27-31B). Their cut surfaces are soft, tan to brown and either diffusely enlarged or nodular. The cortex is widened between the medulla and zona glomerulosa (Fig. 27-31C). The hyperplastic zone is filled by compact, granular, eosinophilic cells. In most cases, the zona glomerulosa is also hyperplastic, but not to the extent of the other zones, especially the zona fasciculata. Ectopic adrenal tissues or nodules may be also hyperplastic, and if stimulation persists, adenomas can develop.

21-Hydroxylase, or P450$_{C21}$, Deficiency Is the Major Cause of CAH

It is responsible for up to 90% of cases. The gene for P450$_{C21}$ (CYP21) is linked to the *MHC* locus on the short arm of chromosome 6 (6p21.3) and is closely associated with *HLA-B* and *C4A* and *C4B* complement genes. The incidence of CAH varies from 1 in 10,000 among whites to 1 in 500 in Alaskan Eskimos.

P450$_{C21}$ is a microsomal enzyme that converts 17-hydroxyprogesterone to 11-deoxycortisol. A deficiency in this enzymatic activity limits cortisol biosynthesis. Accumulated precursors are instead converted to androgens.

CLINICAL FEATURES: Clinical manifestations are the result of cortisol or accumulation of steroids that may need to be synthesized in different pathways. There are different forms of CAH: 1, "classic"; 2, "nonclassic," a milder form that usually develops in late childhood or early adulthood; and 3, "cryptic," in which the

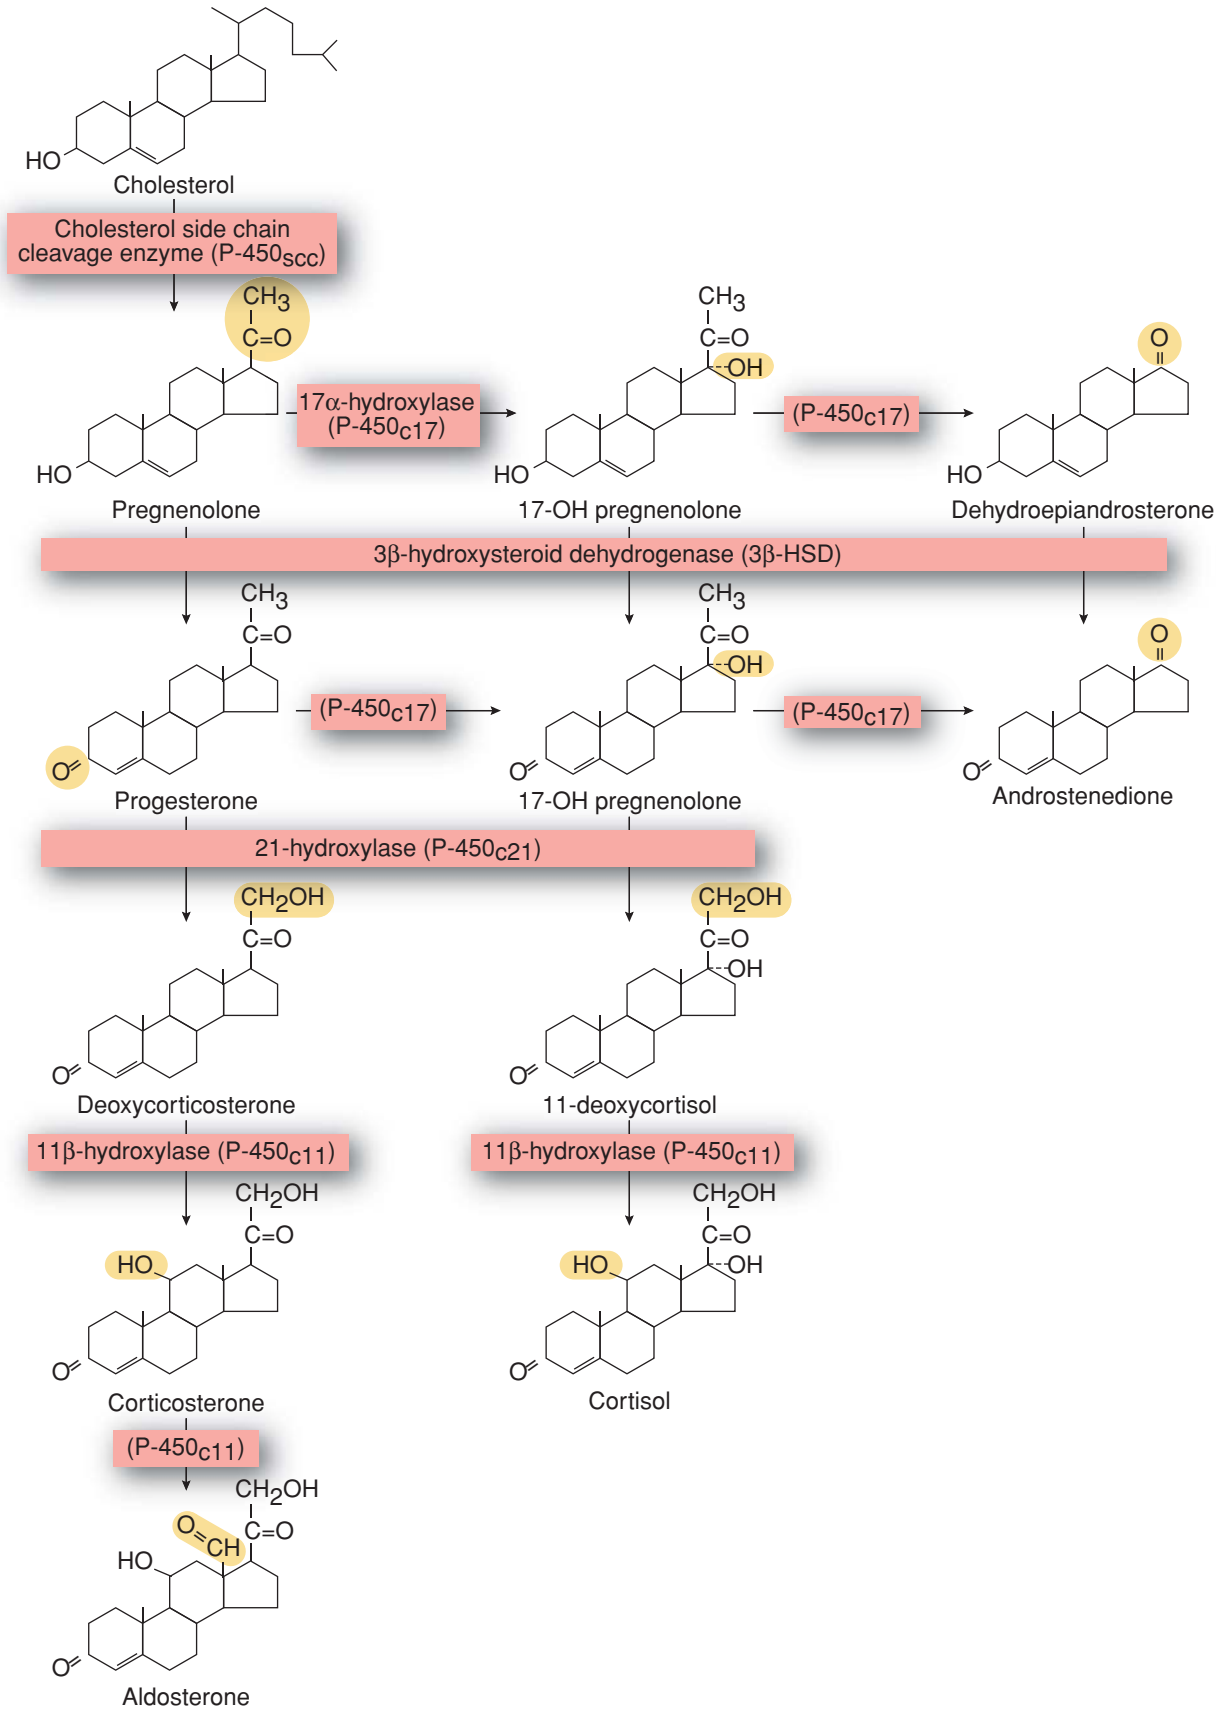

FIGURE 27-30. Biosynthetic pathways in the synthesis of adrenal corticosteroids.

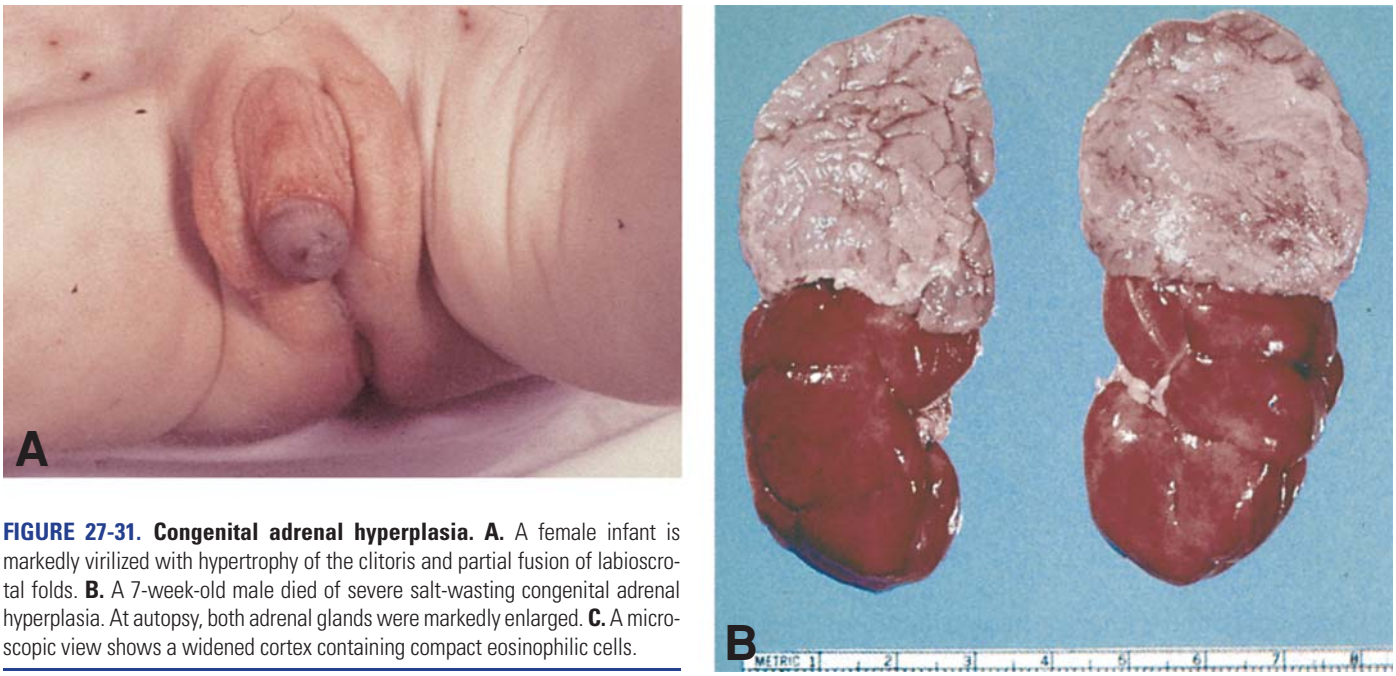

FIGURE 27-31. Congenital adrenal hyperplasia. A. A female infant is markedly virilized with hypertrophy of the clitoris and partial fusion of labioscrotal folds. **B.** A 7-week-old male died of severe salt-wasting congenital adrenal hyperplasia. At autopsy, both adrenal glands were markedly enlarged. **C.** A microscopic view shows a widened cortex containing compact eosinophilic cells.

biochemical abnormalities occur but patients do not have symptoms.

Classic CAH, the more severe form of the disease, is usually detected in infancy and is caused by $P450_{C21}$ deficiency. Two variants affect newborns. One is simple virilizing CAH; the other is a salt-wasting form that is linked to HLA-Bw47. There is also a less severe late-onset (nonclassic) variant. Mutations that result in complete inactivation of 21-hydroxylase lead to salt-wasting CAH, while those that reduce activity to 2% cause simple virilizing CAH. Late-onset CAH is intermediate.

SIMPLE VIRILIZING CAH: Female infants show pseudohermaphroditism; males have no abnormalities of the sexual organs. Conversion of cortisol precursors into adrenal androgens is amplified by the ACTH-dependent increase in the size of the gland. Female newborns exposed to a large excess of adrenal androgens in utero are born with fused labia, an enlarged clitoris and a urogenital sinus that may be mistaken for a penile urethra (Fig. 27-31A). As a result, the infant may be mislabeled as male.

Female external genitalia are not necessarily abnormal at birth, but infant girls may develop a syndrome of androgen excess, with clitoral enlargement and pubic hair. Infant boys exhibit sexual precocity. Eventually, the high levels of adrenal androgens lead to premature closure of epiphyses and short stature. Adult women with CAH tend to be infertile because elevated levels of androgens and progestogens interfere with the hypothalamic–pituitary–gonadal axis, disturb the menstrual cycle and inhibit ovulation. Men with CAH may be fertile, but some have azoospermia.

SALT-WASTING CAH: Owing to 21-hydroxylase deficiency, aldosterone synthesis may be impaired. Hypoaldosteronism then develops in the first few weeks of life in 2/3 of cases of CAH. Hyponatremia, hyperkalemia, dehydration, hypotension and increased renin secretion are typical. These may be rapidly fatal if not treated (Fig. 21-31B).

Therapy for both infantile variants of CAH caused by $P450_{C21}$ deficiency includes glucocorticoids and mineralocorticoids to suppress ACTH and replace steroids. Reconstructive surgery may be necessary for virilized girls with ambiguous genitalia.

LATE-ONSET CAH: Patients with nonclassic variants of 21-hydroxylase deficiency show no abnormalities at birth but develop virilizing symptoms at puberty. In young women, late-onset CAH may closely resemble polycystic ovary syndrome (see Chapter 24). Most young men with the disorder are asymptomatic. This form of CAH is probably more common than is classic CAH, particularly among Ashkenazi Jews, Italians and people from the former Yugoslavia. Treatment is directed toward providing glucocorticoids to reduce hyperplasia and overproduction of androgens or mineralocorticoids.

11β-Hydroxylase Deficiency Causes 5% of CAH

This disorder is uncommon in the general population, but among Jews of Iranian or Moroccan ancestry in Israel, it is the most common cause of CAH. It is inherited as an autosomal recessive trait. The gene for 11β-hydroxylase is on chromosome 8q21-22 and so is unrelated to the *HLA* locus. 11β-Hydroxylase catalyzes terminal hydroxylation in cortisol biosynthesis. In addition to the androgenic complications of CAH, high levels of 11-deoxycortisol, which is a weak mineralocorticoid, often cause sodium retention and accompanying hypertension.

Rare forms of CAH include deficiencies of several enzymes of adrenocorticosteroid biosynthesis pathways. These lead to diverse combinations of electrolyte abnormalities and anomalies of the sex organs. Treatment of such conditions is lifelong glucocorticoid replacement sufficient to prevent adrenal insufficiency.

ADRENAL CORTICAL INSUFFICIENCY

Deficient production of adrenal cortical hormones can result from (1) adrenal gland destruction, (2) pituitary or

hypothalamic dysfunction with decreased ACTH production or (3) chronic corticosteroid therapy.

Primary Chronic Adrenal Insufficiency (Addison Disease) Often Reflects Autoimmune Destruction of the Adrenal

Addison disease is a fatal wasting disorder caused by failure of the adrenal glands to produce glucocorticoids, mineralocorticoids and androgens. It causes weakness, weight loss, muscle pain, gastrointestinal symptoms, hypotension, electrolyte imbalance and hyperpigmentation. Some patients may have cravings for salt or salty foods.

PATHOPHYSIOLOGY: When Addison described primary adrenal insufficiency in 1855, the most common cause of the syndrome was tuberculosis involving the adrenal glands. Worldwide, tuberculosis is probably still the most common cause of chronic adrenal insufficiency, but in Western societies, autoimmunity is responsible for 75% of cases. Autoimmune adrenalitis may be an isolated disorder or a part of two different polyglandular autoimmune syndromes. Sporadic cases may in fact be variants of type II polyglandular autoimmune syndrome (see below). Other causes of adrenal destruction include metastatic carcinoma, amyloidosis, hemorrhage, sarcoidosis and fungal infections. In idiopathic Addison disease, the biochemical defect of adrenoleukodystrophy (see Chapter 32) is common. Rarely, adrenal insufficiency is due to congenital adrenal hypoplasia or familial glucocorticoid deficiency (defective ACTH receptor).

The autoimmune pathogenesis of most cases of Addison disease is supported by:

- Lymphoid infiltrates in the adrenal gland
- Circulating antibodies to adrenal antigens
- Abnormal cell-mediated immunity
- Associations with other autoimmune endocrinopathies
- Genetic linkage with *HLA* loci

IMMUNE MECHANISMS: Antiadrenal antibodies that react with tissue from all three zones of the adrenal cortex are present in 2/3 of patients with chronic adrenal insufficiency that could not be attributed to a specific cause. The major autoantigens are adrenal steroidogenic enzymes, particularly $P450_{C21}$. In Addison disease, autoantibodies do occur, but cell-mediated immunity is probably predominantly to blame. Increased numbers of Ia+ T lymphocytes and decreased suppressor T-cell function are reported in blood from patients with the disorder.

POLYENDOCRINE SYNDROMES: Half of patients with autoimmune adrenal insufficiency suffer from other autoimmune endocrine diseases. These are grouped into two polyendocrine syndromes.

Type I polyendocrine autoimmune syndrome or **candidiasis–hypoparathyroidism–Addison disease syndrome** is a rare autosomal recessive condition with a slight female predominance. It is seen in older children and adolescents. In addition to adrenal insufficiency, most (60%) patients also have hypoparathyroidism and chronic mucocutaneous candidiasis. Insulin-dependent diabetes (type 1) is common. Premature ovarian failure, hypothyroidism, infertility, malabsorption syndromes, pernicious anemia, chronic hepatitis, alopecia totalis and vitiligo are also frequent.

Type I polyendocrine disease is prevalent among Finns and Iranian Jews. The gene associated with it is *AIRE* (autoimmune regulator; see Chapter 11) on chromosome 21q22. *AIRE* is expressed in thymus, lymph nodes and fetal liver, all of which are involved in immune system maturation and immune tolerance. Like the common form of autoimmune Addison disease, sera from patients with type I polyendocrine disease recognize steroidogenic autoantigens and other targets.

Type II polyendocrine autoimmune syndrome (Schmidt syndrome) is more common than type I and always includes adrenal insufficiency. Women are affected twice as often as men. The disorder usually presents in young adults, ages 20–40. Half of cases are familial, but several modes of inheritance are known. HT and occasionally Graves disease occur in over 2/3 of cases. Insulin-dependent diabetes mellitus and premature ovarian failure are common. Rarely, other autoimmune diseases are present. This condition is considered as a polygenic disorder linked to HLA-DR3. Patients have a specific human leukocyte antigen genotype (*DQ2, DQ8* and *DRB1*0404*).

GENETIC FACTORS: Half of patients with autoimmune adrenal insufficiency as part of a polyendocrine syndrome have family histories of autoimmune endocrinopathy. If Addison disease occurs alone, 1/3 have an affected relative. Cases that are part of polyglandular syndrome type I are not linked to any *HLA* alleles. Otherwise, there is strong linkage between autoimmune adrenalitis and HLA-B8, HLA-DR3 and HLA-DR4.

PATHOLOGY: Over 90% of the adrenal gland must be destroyed in order for chronic adrenal insufficiency to be symptomatic. If specific infectious, neoplastic or metabolic disorders are involved, there is corresponding evidence of the underlying disorder in the adrenals. Autoimmune adrenalitis leads to pale, irregular, shrunken glands, weighing 2–3 g or less. The medulla is intact but surrounded by fibrous tissue with small islands of atrophic cortical cells (Fig. 27-32). Depending on the stage of the disease, variably intense lymphoid infiltrates, mainly T cells, may occur.

CLINICAL FEATURES: Addison's original description of the clinical features of chronic adrenal insufficiency still applies to untreated cases. Patients had "general languor and debility, remarkable feebleness of the heart's action, irritability of the stomach and a peculiar change of the colour of the skin." Typically, the first symptom is insidious onset of weakness, which may become so profound that a patient is bedridden. Anorexia and weight loss are always present. A diffuse, tan pigmentation usually develops on the skin, and dark patches may appear on the mucous membranes. This hyperpigmentation is related to pituitary POMC stimulation of skin melanocytes. Hypotension, with blood pressures around 80/50 mm Hg, is the rule. A variety of

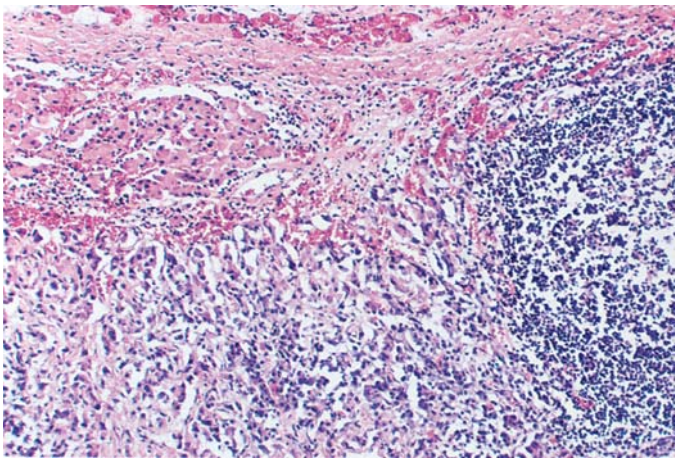

FIGURE 27-32. Autoimmune adrenalitis. A section of the adrenal gland from a patient with Addison disease shows chronic inflammation and fibrosis in the cortex, an island of residual atrophic cortical cells and an intact medulla.

GI symptoms, including vomiting, diarrhea and abdominal pain, affect most patients and may be the presenting complaint. Patients with Addison disease often show marked personality changes and even organic brain syndromes.

Deficient mineralocorticoid secretion, together with other metabolic derangements, leads to low serum sodium and high potassium levels. The absence of glucocorticoids leads to lymphocytosis and mild eosinophilia. The diagnosis is made by measuring corticosteroid blood levels after ACTH stimulation. With glucocorticoid and mineralocorticoid replacement, patients live normal lives.

Acute Adrenal Insufficiency Is a Life-Threatening Emergency

In acute adrenal insufficiency, or adrenal crisis, there is sudden loss of adrenal cortical function. Symptoms relate more to mineralocorticoid deficiency than to inadequate glucocorticoids. Adrenal crisis occurs in three settings:

- Abrupt withdrawal of corticosteroid therapy in patients with adrenal atrophy due to long-term steroid administration. This is the most common cause of acute adrenal insufficiency.
- Stress of infection or surgery may precipitate sudden, devastating worsening of chronic adrenal insufficiency.
- ***Waterhouse-Friderichsen syndrome*** *is acute, bilateral, hemorrhagic infarction of the adrenal cortex, most often secondary to meningococcus or* Pseudomonas *septicemia* (see Chapter 7). Adrenal hemorrhage in these circumstances is thought to be a local manifestation of a generalized Shwartzman reaction with disseminated intravascular coagulation. Acute adrenal insufficiency due to adrenal hemorrhage is also seen in newborns subjected to birth trauma.

CLINICAL FEATURES: The initial manifestations of adrenal crisis are usually hypotension and shock. Nonspecific symptoms commonly include weakness, vomiting, abdominal pain and lethargy, which may progress to coma. Typically in Waterhouse-Friderichsen syndrome, a young person suddenly develops hypotension and shock, abdominal or back pain, fever and purpura. Adrenal crisis is almost always fatal unless diagnosed quickly and prompt and aggressive therapy is instituted with corticosteroids and supportive measures.

Secondary Adrenal Insufficiency Reflects Lack of ACTH

Destruction of the pituitary and consequent panhypopituitarism (see above) result in secondary adrenal insufficiency. Causes include pituitary tumors, craniopharyngioma, empty sella syndrome and pituitary infarction. Trauma, surgery and radiation therapy may also cause loss of pituitary function. Isolated ACTH deficiency is often associated with autoimmune endocrinopathies.

Any disorder that interferes with secretion of corticotropin (ACTH)-releasing hormone (CRH) by the hypothalamus (e.g., tumors, sarcoidosis) can lead to inadequate ACTH secretion. The fact that patients can secrete glucocorticoids in response to ACTH distinguishes this from primary adrenal insufficiency. Pigment and electrolyte abnormalities are typically absent in secondary adrenal insufficiency because these processes are not regulated by ACTH.

ADRENAL HYPERFUNCTION

Excess corticosteroid secretion occurs in adrenal hyperplasia or neoplasia (Fig. 27-33). Such hyperfunction may take one of two forms: **hypercortisolism** (Cushing syndrome) or **hyperaldosteronism** (Conn syndrome), for the two major classes of adrenal steroids.

Early in the 20th century, the neurosurgeon Harvey Cushing associated "painful obesity, hypertrichosis and amenorrhea" with the presence of a pituitary tumor. The combination of pituitary hyperfunction plus the signs and symptoms of chronic glucocorticoid excess was called Cushing disease. This constellation of clinical features due to high glucocorticoid levels can also result from adrenal tumors, ectopic ACTH or CRH secretion by tumors or exogenous corticosteroid administration. *Hypercortisolism from any cause is now called* ***Cushing syndrome;*** *the term* ***Cushing disease*** *is reserved for excessive ACTH secretion by pituitary corticotrope tumors.*

The most common cause of Cushing syndrome in the United States is chronic corticosteroid administration to treat immune and inflammatory disorders. The second most common cause is paraneoplastic syndromes associated with nonpituitary cancers that inappropriately produce ACTH (see below). Cushing disease is 5-fold more common than the type of Cushing syndrome associated with adrenal tumors.

ACTH-Dependent Adrenal Hyperfunction Is of Pituitary Origin, or Ectopic

PATHOPHYSIOLOGY: Women, usually ages 25–45, are 5 times more likely than men to develop Cushing disease. Excessive ACTH secretion leads to adrenal cortical hyperplasia. ACTH-dependent adrenal hyperfunction results from:

- Ectopic ACTH production by a nonpituitary tumor
- Primary hypersecretion of ACTH by the pituitary (Cushing disease)

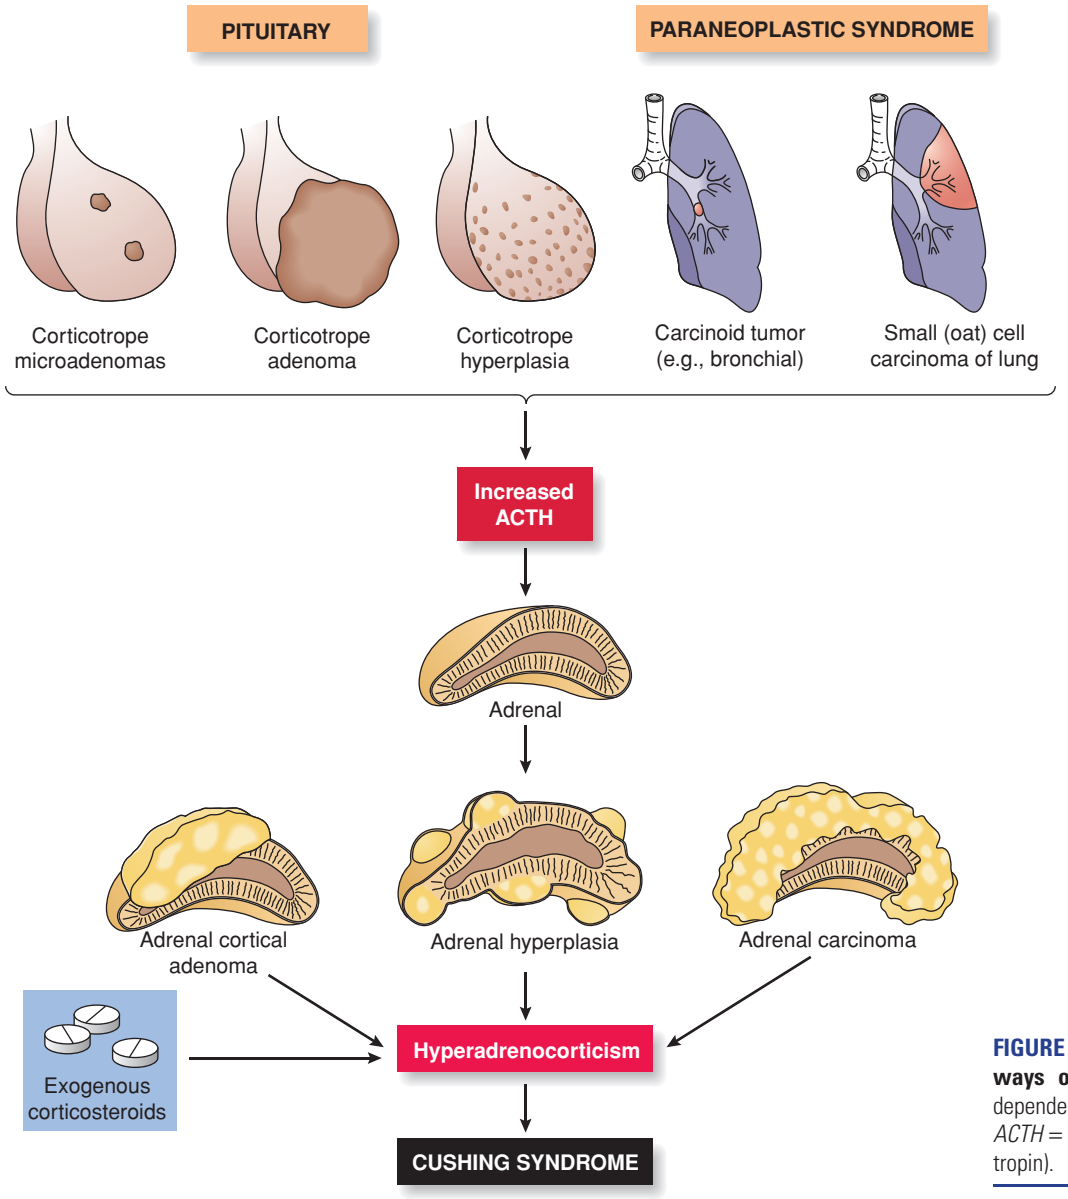

FIGURE 27-33. The pathogenetic pathways of Cushing syndrome. The ACTH-dependent pathway is called Cushing disease. *ACTH* = adrenocorticotropic hormone (corticotropin).

- Inappropriate secretion of CRH by tumors arising outside the hypothalamus, with secondary pituitary hypersecretion of ACTH

ECTOPIC PRODUCTION OF ACTH: Inappropriate ACTH secretion by a malignant tumor accounts for most cases of ACTH-dependent hyperadrenalism. Cancers of the lung, particularly small cell carcinoma, are responsible for over half of the cases of ectopic ACTH syndrome. The remainder are mainly due to carcinoids and neural crest tumors (pheochromocytomas, neuroblastomas, medullary thyroid carcinomas), thymomas and islet cell tumors of the pancreas.

PRIMARY HYPERSECRETION OF ACTH: Cushing disease usually results from pituitary corticotrope microadenomas, although it may be due to a macroadenoma or, rarely, diffuse corticotrope hyperplasia. Adenomas are clearly monoclonal, arising from one progenitor cell, but corticotrope hyperplasia reflects chronic CRH hypersecretion.

ECTOPIC CRH PRODUCTION: Ectopic CRH syndrome is like ectopic ACTH syndrome, except that the tumor secretes CRH. In turn, CRH stimulates pituitary ACTH secretion, leading to adrenal hyperplasia.

PATHOLOGY: Cushing disease is characterized by bilateral, diffuse (75%) or nodular (25%) adrenal hyperplasia. Each gland usually weighs 8–10 g but may weigh as much as 20 g.

In **diffuse adrenal hyperplasia,** the cortex is grossly visible and broadened, with an inner brown layer and a yellow, lipid-rich cap. The inner third of the cortex is composed of a compact cell layer. The outer zone, corresponding to the zona fasciculata, has large clear cells packed with lipid. The zona glomerulosa varies: it may sometimes be prominent and at other times difficult to identify.

Nodular adrenal hyperplasia is limited to grossly visible nodules up to 2.5 cm (microscopic nodules are common in

diffuse hyperplasia). Bilateral, multiple nodules compress the overlying cortex, and intervening parenchyma shows diffuse hyperplasia. However, nodular hyperplasia may be asymmetric and the two glands may differ significantly in weight. Hyperplastic nodules contain large, lipid-laden, clear cells.

ACTH-Independent Adrenal Hyperfunction Is Caused by Adrenal Tumors

In adults, the incidence of adrenal carcinoma peaks at age 40, and that of adenoma a decade later. In children, adrenal carcinomas account for half of cases of Cushing syndrome; 15% are caused by adenoma. At all ages, the female-to-male ratio is 4:1.

Adrenal Adenomas

Adrenal adenomas derive from the cortex. They produce SF-1Ad4BP, a binding protein secreted by adrenocortical cells. The incidence of these lesions is unknown because they are so often asymptomatic. Adenomas are frequently identified as part of syndromes such as MEN1, Carney complex and McCune Albright syndrome. Adenomas can produce hormones, the most common being cortisol and aldosterone.

PATHOLOGY: A typical adenoma is 1–4 cm, encapsulated, firm, yellow and slightly lobulated (Fig. 27-34). These tumors usually weigh 10–50 g, although they may reach 100 g. Cut surfaces are mottled yellow and brown, and occasionally black, owing to lipofuscin pigment deposition. A thin rim of compressed normal adrenal cortex surrounds the tumor. Necrosis and calcifications are rare. Adenomas show clear, lipid-laden (fasciculata type) cells arranged in sheets or nests. They are often interspersed with clusters of compact, lipid-depleted, eosinophilic (reticularis type) cells. Large tumors may have myelolipomatous foci or calcification. The cortex of the involved, contralateral gland is generally atrophic or may show small micronodules.

Nonfunctional adrenal cortical adenomas occur in as many as 5% of adult autopsies, but less than 10% of surgically removed benign adrenal tumors are hormonally silent. Nonfunctional adenomas are pathologically identical to their functional counterparts.

Adrenal Cortical Carcinomas

Adrenal cortical carcinomas (ACCs) are rare and aggressive tumors that have an incidence of 1 case per million per year. Sixty percent of adrenal cortical carcinomas are functional and secrete glucocorticoids and androgens. They occur more in women and have a poor prognosis. Computed tomography scans show a mass, usually larger than 5 cm. Positron emission tomography scanning with 18-fluorodeoxyglucose is useful to identify the primary tumor and its metastasis. Median survival is 30 months. The tumor metastasizes to lung, liver and lymph nodes. Local recurrences are common.

ETIOLOGIC FACTORS: The etiology of these cancers is not known. Most cases are sporadic, but ACCs occur in association with Li-Fraumeni and Beckwith-Wiedemann syndromes and congenital adrenal hyperplasia.

MOLECULAR PATHOGENESIS: No specific genetic alterations are characteristic for ACCs. However, overexpression of IGF-II in sporadic tumors; duplication of the paternal allele; and loss of heterozygosity at 11p15, 17p13 (p53 locus), 1p, 3p and 9p all occur in these tumors. Some tumors overexpress epidermal growth factor receptor and p21 and p16 genes (see Chapter 5). Diverse chromosomal gains and losses can occur, and rarely there can be alterations in other genes such as *RAS, RET* and *ATR1.* CXCL10 and CDH2 are downregulated. ACCs have shown MiR483-3p overexpression (68%) in comparison with adenomas (12%).

PATHOLOGY: The tumors vary in weight and may reach up to 5 kg. Improvements in diagnostic imaging have helped to identify smaller tumors at earlier stages. ACCs are soft, circumscribed, lobulated and bulky (Fig. 27-35). Cut surfaces are variegated pink, brown or yellow, often with necrosis, hemorrhage and cystic change. Local invasion is common, and remnants of normal adrenal are difficult to identify. The diagnosis of ACC is based on the

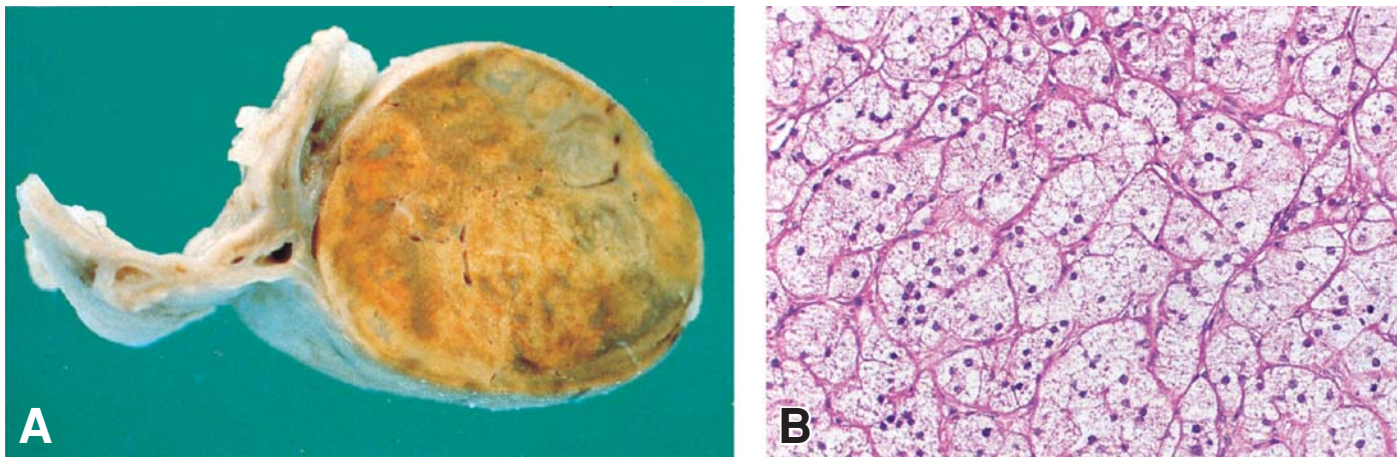

FIGURE 27-34. Adrenal adenoma. A. The cut surface of an adrenal tumor removed from a patient with Cushing syndrome is a mottled yellow with a rim of compressed normal adrenal tissue. **B.** A microscopic view reveals nests of clear, lipid-laden cells.

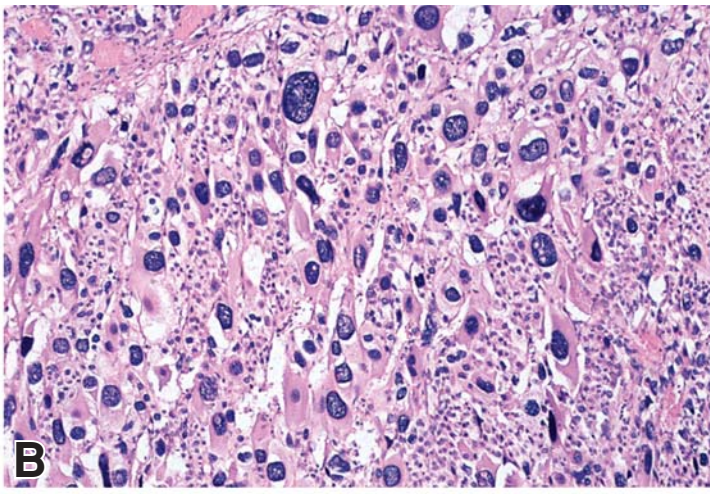

FIGURE 27-35. Adrenal cortical carcinoma. A. The bulky tumor on section is yellow to tan with areas of necrosis and cystic degeneration. **B.** A microscopic section demonstrates marked anisocytosis and nuclear pleomorphism.

modified criteria described by Weiss, which include mitotic figures (>5 per 50 high-power fields), clear cell cytoplasm, necrosis, nuclear pleomorphism, atypical mitosis, capsular or vascular invasion and diffuse architecture. In functional carcinomas, the contralateral adrenal cortex is atrophic. ACCs stain positively for synaptophysin, inhibin, MelanA/MART1, calretinin and CAM 5.2.

Most adrenal cortical carcinomas cannot be resected completely, and micrometastases in other organs are almost always already present. Surgery and adrenalectomy, followed by adjuvant therapy with mitotane plus radiation, offer the best hope of delaying tumor recurrence. Metastases to lung, liver and bone are common. The 5-year survival for patients with ACC limited to the adrenal gland is better (65%) than for patients with distant metastases (18%).

Nonfunctional adrenal cortical carcinomas tend to be highly malignant and often weigh more than 1 kg. They are morphologically identical to functional cancers.

Other Causes of ACTH-Independent Cushing Syndrome Include Chronic Corticosteroid Administration and Bilateral Micronodular Hyperplasia

Many immunologic and inflammatory diseases are treated with glucocorticoids, thus constituting by far the most common cause of Cushing syndrome. The synthetic hormones ordinarily used (e.g., dexamethasone, prednisone) have only glucocorticoid activity and little or no mineralocorticoid or androgen effect. Thus, hypertension and hirsutism, features common in Cushing syndrome due to adrenal hyperplasia or neoplasia, are usually absent in this iatrogenic disorder.

Bilateral adrenal cortical micronodular hyperplasia (Carney complex or **primary pigmented nodular adrenocortical disease)** is a rare cause of ACTH-independent Cushing syndrome, usually in children or young adults. Half have an autosomal dominant disease with pigmented skin lesions over much of their bodies, a variety of myxomas, testicular (Leydig cell) tumors and pituitary somatotrope adenomas. The adrenals contain small, brown or black nodules, up to 0.5 cm, with large eosinophilic cells laden with lipofuscin granules. The lesions appear as primary pigmented nodular adrenocortical disease (PPNAD). Half of patients with Carney complex carry mutations in a tumor suppressor gene (17q22-24), *PRKAR1A,* that encodes a regulatory subunit of protein kinase A. Another gene at 2p16 also is linked to the disease.

Clinical Features of Cushing Syndrome Are Seen in Many Organs

CLINICAL FEATURES: The manifestations of Cushing syndrome (Fig. 27-36) depend on the degree and duration of excessive corticosteroid levels, as well as on levels of adrenal androgens and mineralocorticoids. Most (70%) patients are females, and fewer than 20% of cases occur before puberty.

OBESITY: Typically, the patient notes gradual onset of obesity of the face (moon face), neck (buffalo hump), trunk and abdomen (Fig. 27-37). The extremities are characteristically unaffected or even wasted.

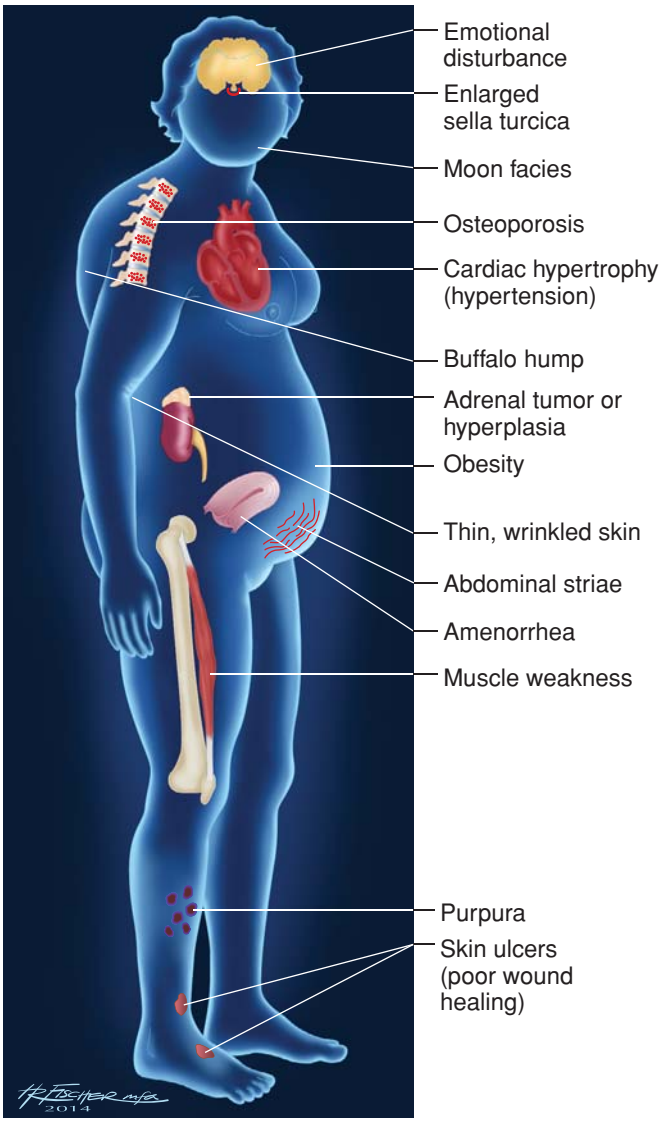

FIGURE 27-36. Major clinical manifestations of Cushing syndrome.

FIGURE 27-37. Cushing syndrome. A woman who had a pituitary adenoma that produced adrenocorticotropic hormone (ACTH) exhibits a moon face, buffalo hump, increased facial hair and thinning of the scalp hair.

SKIN: The skin is atrophic. Subcutaneous fat is decreased. The abdomen and other areas of fat deposition are prominent, stretching the skin thin and producing purplish striae. These represent venous channels that are visible through the attenuated dermis. Hyperpigmentation, similar to, but less severe than, that in Addison disease, may occur because of pituitary POMC hypersecretion. Acanthosis nigricans is increased in Cushing syndrome.

MUSCULOSKELETAL SYSTEM: Increased bone resorption causes osteoporosis. Back pain is common, and up to 1/5 of patients have radiologic evidence of vertebral compression fractures. Fractures of ribs and occasionally long bones may occur. Proximal muscle wasting **(steroid myopathy)** causes weakness, which may be so severe that the patient cannot rise from sitting or climb a flight of stairs.

CARDIOVASCULAR SYSTEM: Hypertension is common in Cushing syndrome, often reflecting excessive mineralocorticoid activity. In older patients, congestive heart failure may also result.

SECONDARY SEX CHARACTERISTICS: Women with Cushing syndrome tend to be virilized, with increased facial hair, thinning of scalp hair, acne and oligomenorrhea. Excess glucocorticoids in men cause erectile dysfunction, and both sexes experience decreased libido.

EYES: One fourth of patients have increased intraocular pressure, which may be a problem if there had been preexisting glaucoma.

GLUCOSE INTOLERANCE: Stimulation of gluconeogenesis by glucocorticoids leads to glucose intolerance and hyperinsulinemia. Diabetes mellitus develops in 15% of patients, usually in those with a family history of diabetes.

PSYCHOLOGICAL CHANGES: Most patients with Cushing syndrome, both endogenous and iatrogenic, undergo distinct personality changes. These include irritability, emotional lability, depression and paranoia. Disturbed mentation may be so severe that patients may become suicidal.

LABORATORY FINDINGS: Half of patients exhibit an absolute lymphopenia, and 1/3 have abnormally low eosinophil counts. Hypercalciuria is common, but serum calcium levels remain unchanged. Serum cholesterol and triglyceride levels are frequently elevated.

In all forms of Cushing syndrome, glucocorticoid levels are increased. The dexamethasone suppression test distinguishes ACTH-dependent and ACTH-independent forms of Cushing syndrome. Dexamethasone suppresses pituitary ACTH secretion, and hence hypercortisolism, but it is without effect on adrenal tumors.

Cushing syndrome is treated by (1) removal (surgery or irradiation) of pituitary, adrenal or ectopic ACTH-producing tumors; (2) stopping corticosteroid therapy; or (3) giving adrenal enzyme inhibitors (e.g., aminoglutethimide, ketoconazole, metapyrone). Except for ectopic ACTH syndrome and adrenal carcinoma, in which patients die of cancer rather than of hypercortisolism, Cushing syndrome is highly curable.

Primary Aldosteronism (Conn Syndrome) Leads to Hypertension and Hypokalemia

Excess secretion of aldosterone occurs with adrenal adenomas or hyperplasia. Such overproduction causes potassium to be lost in the urine and sodium retained.

Aldosterone-secreting adenomas are more common in women than in men (3:1) and usually occur between the ages of 30 and 50 years.

MOLECULAR PATHOGENESIS: Most (75%) primary aldosteronism is due to solitary adrenal adenomas (aldosteronoma). In 1/4 of cases, adrenal hyperplasia is responsible. The rest reflect bilateral adrenal zona glomerulosa hyperplasia. Only a few cases of primary aldosteronism are caused by adrenal carcinomas.

There are 3 types of familial hyperaldosteronism. **Type I (glucocorticoid suppressible)** is an autosomal dominant disease caused by abnormal fusion of two genes, *CYP11B1* and *CYP11B2*, on chromosome 8. In these cases, hypertension generally appears in childhood. ACTH-responsive regulators of the 11β-hydroxylase gene fuse to the aldosterone synthase gene and create a hybrid constitutively active gene in the zona fasciculata. Bilateral hyperplasia of this zone results. By suppressing ACTH release, glucocorticoids prevent type I disease, which also responds to glucocorticoids.

In contrast, adrenal cortical adenomas are usually responsible for **type II familial hyperaldosteronism,** which therefore does not turn off with glucocorticoid administration. In type II, hypertension usually appears in early adulthood. **Type III hyperaldosteronism** is characterized by marked adrenal enlargement. Patients suffer childhood onset of severe hypertension that eventually may damage the heart and kidneys.

The underlying genetic defect(s) in familial hyperaldosteronism type II and type III are unknown. Early-onset hypertension and severe target organ damage are hallmarks of the heritable forms.

Aldosterone hypersecretion enhances renal tubular sodium reabsorption, thus increasing body sodium. Hypertension results not only from retention of sodium and consequent volume expansion but also from increased peripheral vascular resistance. Hypokalemia reflects aldosterone-induced loss of potassium in the distal renal tubule.

PATHOLOGY: Most aldosterone-secreting adenomas measure less than 3 cm, weigh less than 6 g and are yellow. However, their sizes vary, and tumors up to 50 g may occur. The dominant cells are clear, lipid rich like the zona fasciculata and arranged in cords or alveoli. There is little nuclear pleomorphism. In contrast to cortisol-producing adenomas, the nontumorous cortex in cases of hyperaldosteronism is not atrophic, because aldosterone does not inhibit ACTH secretion by the pituitary.

If bilateral nodular adrenal hyperplasia causes Conn syndrome, adrenals contain yellow cortical nodules, usually less than 2 cm. These are formed by clear cells that show no nuclear pleomorphism.

CLINICAL FEATURES: Most patients with primary aldosteronism present with asymptomatic diastolic hypertension. Skeletal muscle weakness and fatigue are caused by potassium depletion. Polyuria and polydipsia result from impaired renal concentrating capacity, probably due to hypokalemia. Metabolic alkalosis and an alkaline urine are common.

Primary aldosteronism caused by an adenoma is curable by surgical removal of the tumor. Dietary sodium restriction and treatment with the aldosterone antagonist spironolactone are also frequently effective. Bilateral adrenal hyperplasia in Conn syndrome is treated medically with aldosterone antagonists, and sometimes with dexamethasone in the case of glucocorticoid-suppressible hyperaldosteronism.

MISCELLANEOUS ADRENAL TUMORS

Adrenal myelolipomas are mixtures of mature adipose tissue and hematopoietic marrow, notable because they may be very large. They rarely cause hypertension.

Adrenal cysts are rare. Most are actually pseudocysts derived from degeneration in benign adrenal tumors or resolution of hemorrhage. In some cases, they represent remnants of an underlying vascular lesion.

Metastatic cancers to the adrenal glands usually originate in the lungs or breast, or may be malignant melanomas. The glands may be unilaterally or bilaterally hugely enlarged, up to 20–45 g. They are largely replaced by cancer, often with necrosis and hemorrhage. Usually, enough functional adrenal cortex remains so that Addison disease does not develop, particularly in view of the limited survival of these patients.

Adrenal Medulla and Paraganglia

ANATOMY AND FUNCTION

The adrenal medulla is entirely surrounded by the adrenal cortex and accounts for 10% of the gland's weight. It consists of neuroendocrine cells, or **chromaffin cells,** derived from the primitive pheochromoblasts of the developing sympathetic nervous system (Fig. 27-38). Chromaffin cells

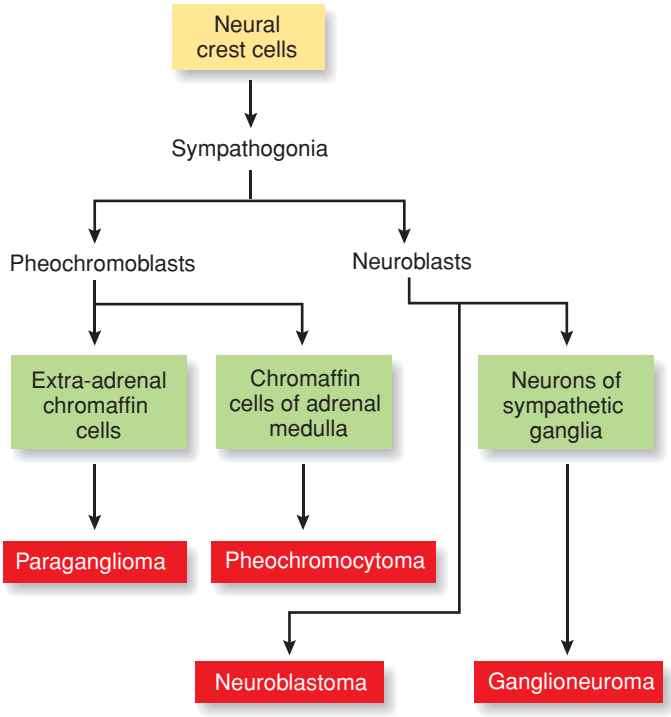

FIGURE 27-38. Histogenesis of tumors of the adrenal medulla and extra-adrenal sympathetic nervous system.

are so named because catecholamines in their cytoplasmic granules bind chromium salts and darken on oxidation by potassium dichromate. These cells are also present at extra-adrenal sympathetic nervous system sites, such as the preaortic sympathetic plexuses and paravertebral sympathetic chain.

Chromaffin cells appear as nests of small polyhedral cells with pale amphophilic cytoplasm and vesicular nuclei. The cells of the adrenal medulla have many electron-dense, 100–300-nm chromaffin (catecholamine-containing) granules, resembling those of sympathetic nerve endings. Epinephrine accounts for 85% of the content of these granules, with the remainder being norepinephrine and other noncatecholamine hormones. Interspersed among the chromaffin cells are postganglionic neurons and small autonomic nerve fibers. Stored catecholamines are secreted on sympathetic stimulation as a response to stress (exercise, cold, fasting, trauma) or emotional excitation accompanying fear and anger.

The adrenal medulla is supplied by arterial and portal venous circulations that originate in the zona reticularis of the cortex. Most of the blood to the hormonally active cells of the medulla is from the portal system. The medulla is innervated from the splanchnic nerves by cholinergic preganglionic sympathetic neurons.

PHEOCHROMOCYTOMA

Pheochromocytomas Are Rare Catecholamine-Secreting Tumors of Chromaffin Cells of the Adrenal Medulla and Elsewhere

Pheochromocytoma may arise in extra-adrenal sites, in which case they are called **paragangliomas**. Other catecholamine-producing tumors (e.g., chemodectoma and ganglioneuroma) may also cause a syndrome like that caused by pheochromocytomas.

Pheochromocytomas are rare tumors, somewhat more common in women than in men. They may occur at any age, including infancy, but are uncommon after age 60. *The presenting symptoms reflect sustained or episodic hypertension.* Other symptoms include headaches, pallor, anxiety and cardiac arrhythmias. Although they account for less than 0.1% of cases of hypertension, pheochromocytomas should be considered in evaluating any hypertensive patient. If detected early, they are amenable to surgical resection, but if left untreated, patients can die of complications of prolonged hypertension. Most pheochromocytomas are unexpected findings at autopsy, indicating that some curable cases of hypertension escaped clinical detection. Imaging using iodine-metaiodobenzylguanidine (I-MIBG), an analog of guanethidine that identifies several neuroendocrine tumors, may be useful in locating these tumors. Bilateral tumors strongly suggest familial disease.

PATHOPHYSIOLOGY: Pheochromocytomas are mostly sporadic. A minority are inherited, either alone or as part of hereditary syndromes, such as MEN types 2A or 2B, **paraganglioma-pheochromocytoma syndrome,** von Hippel-Lindau disease, neurofibromatosis type 1 or McCune-Albright syndrome.

The features of autosomal dominant MEN syndromes are (Fig. 27-39):

- **MEN type 1 (Wermer syndrome)** includes (1) pituitary adenoma, (2) parathyroid hyperplasia or adenoma and (3) islet cell tumors of the pancreas (e.g., insulinomas, gastrinomas). The pancreatic tumors tend to be multicentric and more malignant than in sporadic cases. Most (2/3) patients have adenomas of two or more endocrine organs, and 20% develop tumors of three or more. Carcinoid, adrenocortical and lipoid tumors may also occur in MEN1. Almost all people with MEN type 1 (>95%) have primary hyperparathyroidism. Mutation of the *MEN1* tumor suppressor gene (chromosome 11q13) is responsible. This gene encodes a nuclear protein, **menin,** which is thought to interact with the transcription factor junD.

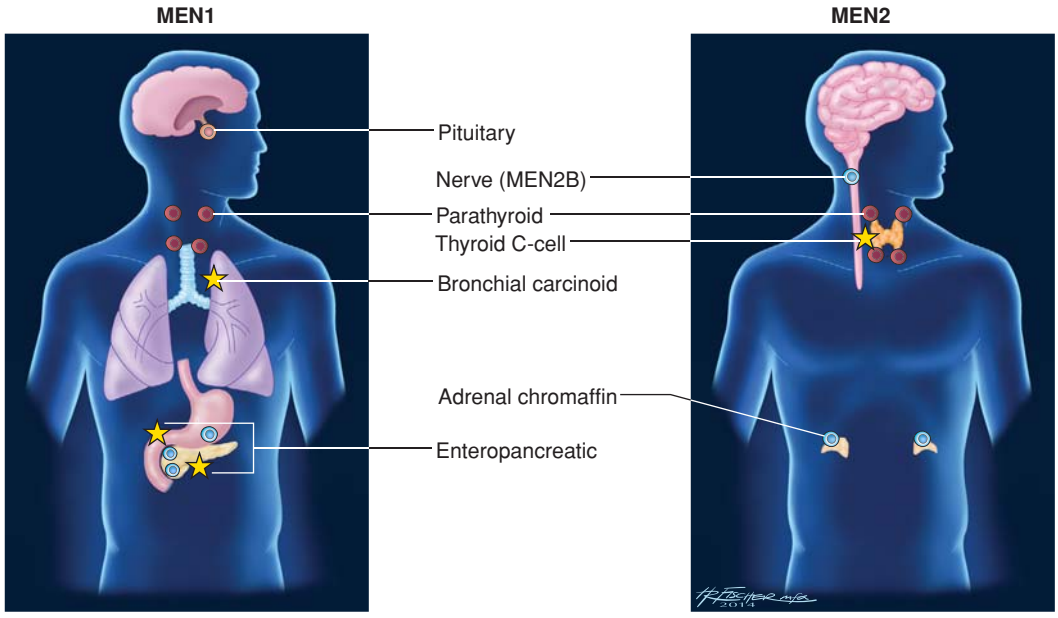

FIGURE 27-39. Multiple endocrine neoplasia (MEN) syndromes. The locations of the most common endocrine tumors in hereditary MEN syndromes types 1 and 2 are shown.

- **MEN type 2 syndromes** almost always include MTCs, and pheochromocytoma is included in half.

MEN2A (SIPPLE SYNDROME): Most (95%) MEN2 patients are classified as type 2A. In addition to MTC and pheochromocytoma, 1/3 of patients show hyperparathyroidism due to parathyroid hyperplasia or adenomas. Several neural crest tumors may occur in MEN type 2A, including gliomas, glioblastomas and meningiomas. Hirschsprung disease is also associated with MEN type 2A.

MEN2B: This disorder resembles MEN2A, but it develops about 10 years earlier and rarely includes parathyroid disease. The **mucosal neuroma syndrome** (ganglioneuromas of the conjunctiva, oral cavity, larynx and gut) is a feature of MEN2B. Mucosal neuromas are always present, but only half of patients express the full phenotype. Many patients have a habitus resembling that of Marfan syndrome.

FAMILIAL MEDULLARY THYROID CARCINOMA: There are families who have at least 4 members with this tumor but no evidence of other features of MEN2.

Adrenal medullary hyperplasia occurs in some patients with MEN2A or -2B. Just as C-cell hyperplasia precedes medullary thyroid carcinomas, adrenal medullary hyperplasia may precede pheochromocytomas in these cases. Lesions are usually less than 1 cm. In these cases, an enlarged adrenal shows an expanded medulla. Chromaffin cells are larger than normal and are arranged in distinct nests or cords.

The *RET* proto-oncogene on chromosome 10q11.2 is responsible for MEN2 syndromes. *RET* encodes a transmembrane tyrosine kinase receptor whose ligands are glia-derived growth factor and neurturin. Several germline, missense and activating mutations in the cysteine-rich extracellular domain of RET occur in 95% of families with MEN2A, and in 85% of those with familial thyroid carcinomas (Fig. 27-40). The most common mutation (codon 634) constitutively activates the receptor by promoting its dimerization, which recapitulates the result of ligand binding.

A point mutation at codon 918 of the tyrosine kinase domain of *RET* is present in 95% of patients with MEN2B. This mutation constitutively activates the receptor's tyrosine kinase function and also causes it to phosphorylate substrates ordinarily preferred by other kinases (e.g., c-*src* and c-*abl*).

Identification of RET *mutations confirms the diagnosis of MEN2 and identifies family members who are asymptomatic.* People with *RET* mutations are screened for thyroid cancer, pheochromocytoma and hyperparathyroidism between ages 6 and 35 and are offered prophylactic thyroidectomy.

Somatic mutations in *RET* occur in 10%–20% of cases of sporadic pheochromocytomas. In addition, some sporadic pheochromocytomas have mutations in the von Hippel-Lindau (*VHL*) and neurofibromatosis type 1 (*NF1*) genes.

PATHOLOGY: In sporadic pheochromocytomas, 80% of tumors are unilateral, 10% are bilateral and 10% are in extraadrenal locations; 10% are malignant and 10% occur in children. Tumors occurring in the context of MEN are usually bilateral. Tumors vary from 1 cm to large masses of more than 2 kg. Most are 5–6 cm and weigh 80–100 g.

Pheochromocytomas tend to be encapsulated, spongy and reddish, with prominent central scars, hemorrhage and foci of cystic degeneration (Fig. 27-41A). Their histology is highly variable. Typically, circumscribed nests **(zellballen)** of polyhedral to fusiform neoplastic cells contain granular, amphophilic or basophilic cytoplasm and vesicular nuclei. Eosinophilic cytoplasmic globules are common. Cellular pleomorphism may be prominent, including multinucleated

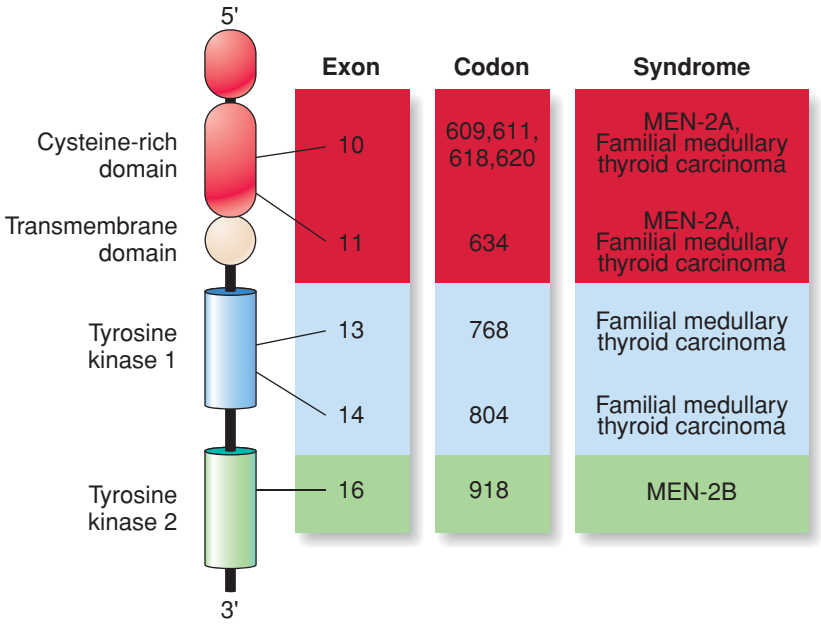

FIGURE 27-40. Representative RET proto-oncogene mutations in multiple endocrine neoplasia type 2 (MEN2).

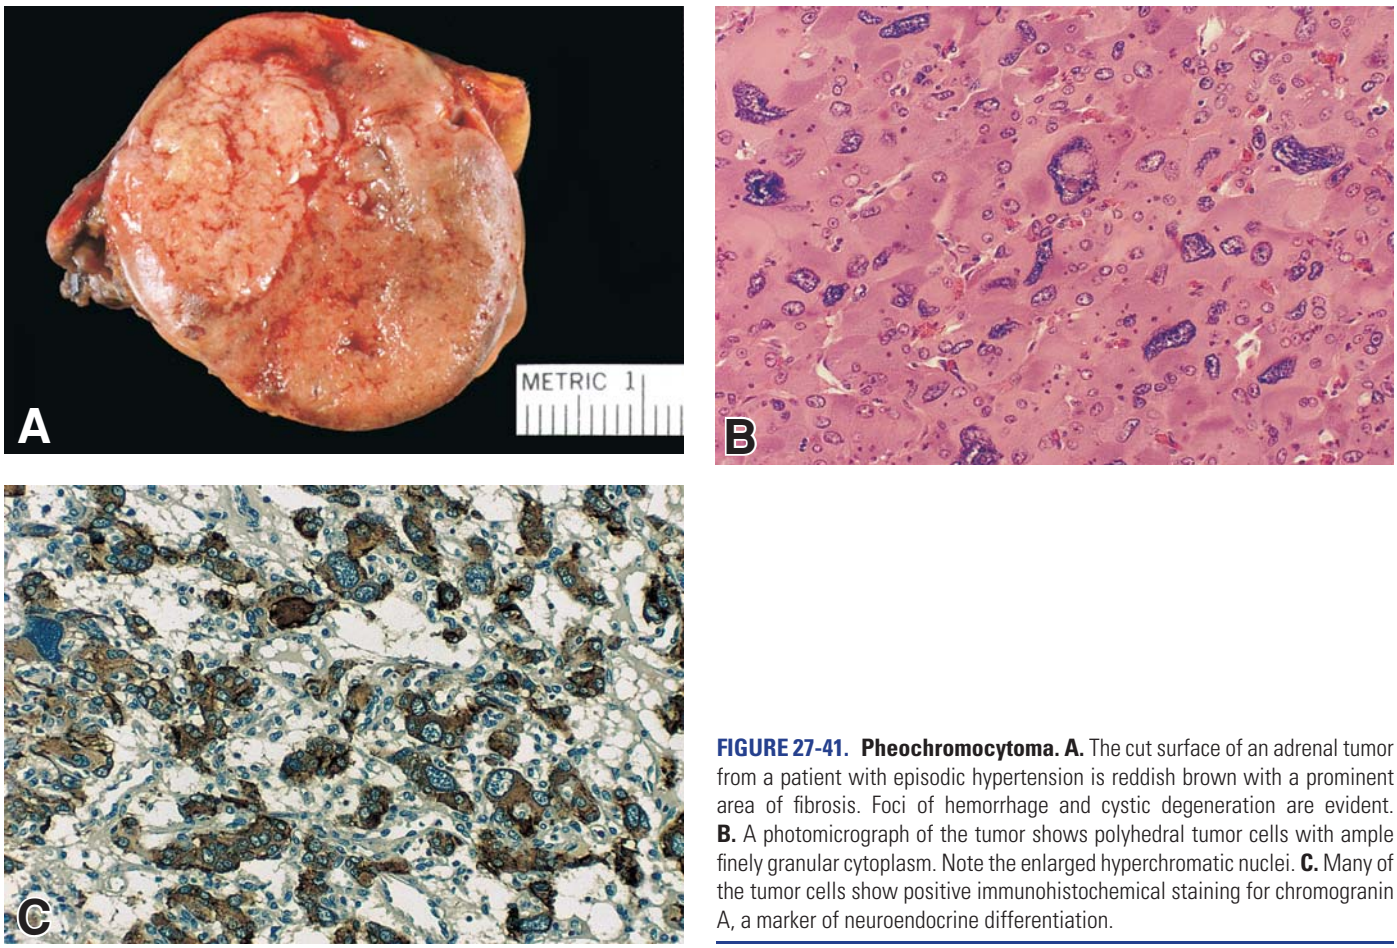

FIGURE 27-41. Pheochromocytoma. A. The cut surface of an adrenal tumor from a patient with episodic hypertension is reddish brown with a prominent area of fibrosis. Foci of hemorrhage and cystic degeneration are evident. **B.** A photomicrograph of the tumor shows polyhedral tumor cells with ample finely granular cytoplasm. Note the enlarged hyperchromatic nuclei. **C.** Many of the tumor cells show positive immunohistochemical staining for chromogranin A, a marker of neuroendocrine differentiation.

tumor giant cells (Fig. 27-41B). Tumors are highly vascular, with many capillaries. Trabecular or solid patterns, with only indistinct **zellballen,** are uncommon.

Electron microscopy shows membrane-bound, dense core granules, corresponding to stored catecholamines. Immunostains attest to the neuroendocrine nature of the tumor and show neuron-specific enolase, chromogranin (Fig. 27-41C) and synaptophysin.

Of adrenal pheochromocytomas, 5%–10% are malignant. Malignancy is more common among extra-adrenal tumors. *Only a tumor's behavior (i.e., metastases), and not its histology, defines malignancy: both benign and malignant pheochromocytomas show mitoses, cellular pleomorphism, capsular or vascular invasion and necrosis.* The tumors spread most often to regional lymph nodes, bone, lung and liver.

CLINICAL FEATURES: With few exceptions, the clinical features of pheochromocytomas are caused by catecholamine release by the tumor. Patients may come to medical attention because of (1) asymptomatic hypertension discovered on routine physical examination; (2) symptomatic hypertension resistant to antihypertensive therapy; (3) malignant hypertension (e.g., encephalopathy, papilledema, proteinuria); (4) myocardial infarction or aortic dissection; or (5) paroxysms of convulsions, anxiety or hyperventilation.

Typically, episodic catecholamine release leads to paroxysms or crises, of up to several hours, with severe throbbing headache, sweating, palpitations, tachycardia, abdominal pain and vomiting. Blood pressure may be elevated, often to an extreme degree. Paroxysms can be triggered by activities that place pressure on the abdominal contents (including the tumor), such as exercise, lifting, bending or vigorous abdominal palpation. Anxiety may occur during a paroxysm but is not an initiating factor.

Over 90% of patients with pheochromocytoma show hypertension. It is sustained in 2/3 of them and so resembles essential hypertension. In these patients, blood pressure rises to even higher levels during paroxysms. In the others, hypertension is episodic. Episodic hypertension may become sustained and evolves into malignant hypertension in many untreated patients.

There are other consequences of high catecholamine levels. Orthostatic hypotension results from decreased plasma volume and poor postural tone. Increased basal metabolism, sweating, heat intolerance and weight loss may mimic hyperthyroidism. Angina and myocardial infarction occur in the absence of coronary artery disease. The cardiac complications reflect myocardial necrosis caused by elevated catecholamine levels ***(catecholamine cardiomyopathy)***.

Increased urinary levels of catecholamine metabolites, particularly vanillylmandelic acid (VMA), metanephrine and unconjugated catecholamines, help to confirm that a patient has a pheochromocytoma. Treatment for pheochromocytoma is surgical removal. β-Adrenergic blocking agents may help control hypertensive crises, and β-adrenergic receptor antagonists are helpful adjuncts.

Paragangliomas Are Pheochromocytomas Arising at Extra-Adrenal Sites

Paragangliomas may arise in paraganglia in any location, including the retroperitoneum, neck and bladder. They are frequently familial and inherited as autosomal dominant traits, with germline mutations in *SDHB, SDHC,* ***SDHA*** or *SDHD* genes.

Carotid body tumors *are prototypical paragangliomas.* They arise at the carotid bifurcation and form palpable masses in the neck. Interestingly, carotid body tumors are 10-fold more common in people living at high altitude than in those at sea level, suggesting that these tumors reflect hyperplastic responses to prolonged carotid body sensing of hypoxia.

Autosomal dominant transmission of paragangliomas occurs in some families, and **hereditary paraganglioma** was the first hereditary tumor syndrome reported to be caused by a germline mutation in a gene encoding a mitochondrial protein. It is linked to the *SDHD* gene (11q23), which encodes a subunit of cytochrome B that may participate in oxygen sensing. All affected patients, whether male or female, inherit the disease from their fathers. *SDHB*-related syndromes are associated with malignant pheochromocytomas that metastasize to distant organs such as lung and bone.

NEUROBLASTOMA

Neuroblastomas are embryonal malignant tumors of neural crest origin. They originate in the adrenal medulla, paravertebral sympathetic ganglia and sympathetic paraganglia and are composed of neoplastic neuroblasts. Neuroblasts derive from primitive sympathogonia and are an intermediate stage in the development of sympathetic ganglion neurons (Fig. 27-38). *These are the most common solid extracranial neoplasms of childhood, accounting for up to 10% of childhood cancers and 15% of cancer deaths in children.* Overall incidence peaks in the first 3 years and is 1 in 7000.

MOLECULAR PATHOGENESIS: The tumors are congenital in some cases and even occur in premature stillborns. In fact, they account for half of cancers diagnosed in the first month of life. Adolescents or adults may rarely develop them. Although neuroblastomas are sporadic, a few instances are familial. Those genetically predisposed to this disease usually have multifocal tumors at an early age and follow autosomal dominant inheritance. The short arm of chromosome 16 appears to be the affected locus. These tumors may occur with neurofibromatosis type 1, Beckwith-Wiedemann syndrome and Hirschsprung disease. Germline mutations in *PHOX2A* or *KIF1B* genes may be responsible for familial cases. These tumors have also been linked to copy number variations within the *NBPF10* gene, which results in the 1q21.1 deletion syndrome.

Embryogenesis of the adrenal medulla and presumably of other parts of the sympathetic nervous system continues during the first year of life. Persistence and transformation of these embryonal structures may be related to the pathogenesis of these tumors. Neuroblastomas carry frequent deletions on chromosome 1 (1p35-36), with unbalanced translocation with 17q. Extrachromosomal double minutes and homogeneously staining regions (HSRs) occur on chromosome 2. The HSRs represent amplification of N-*myc* (*MYCN*), which is a key determinant of tumor aggressiveness. The locus on chromosome 1 may suppress N-*myc* amplification.

PATHOLOGY: Neuroblastomas can arise at any site with neural crest–derived cells (i.e., from the posterior cranial fossa to the coccyx). One third are in the adrenal, another 1/3 elsewhere in the abdomen and 20% in the posterior mediastinum.

The tumors vary from minute, barely discernible nodules to tumors readily palpable through the abdominal wall. They are round, irregularly lobulated masses that may weigh 50–150 g or more (Fig. 27-42A). Their cut surfaces are soft, friable and variegated maroon in color. Necrosis, hemorrhage, calcification and cystic change are common.

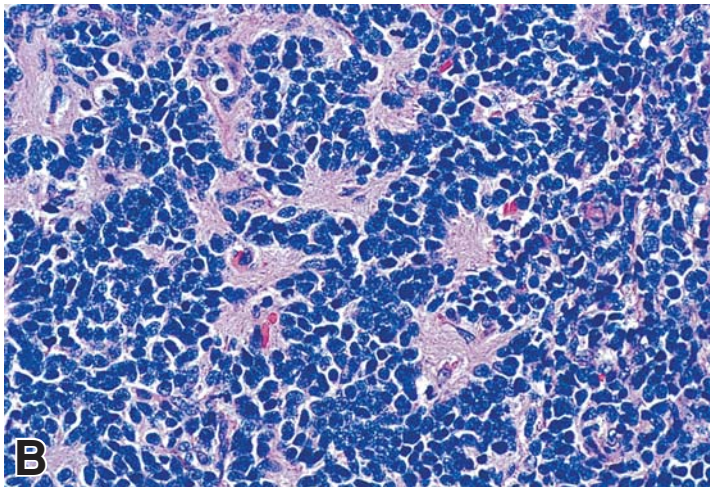

FIGURE 27-42. Neuroblastoma. A. A large, lobulated, hemorrhagic and cystic tumor, adherent to the upper pole of the kidney, was removed from a child who presented with an abdominal mass. **B.** A photomicrograph illustrates the characteristic rosettes, formed by small, regular, dark tumor cells arranged around a central, pale fibrillar core.

Neuroblastic tumors are classified as belonging to 1 of 4 categories:

- **Neuroblastoma** (Schwannian stroma poor)
- **Ganglioneuroblastoma, intermixed** (Schwannian stroma rich)
- **Ganglioneuroma** (Schwannian stroma dominant)
- **Ganglioneuroblastoma, nodular** (composite Schwannian stroma rich/stroma dominant and stroma poor).

Each category may have one or more subtypes.

Neuroblastomas contain dense sheets of small, round to fusiform cells with scant cytoplasm and hyperchromatic nuclei, resembling lymphocytes. There is limited or no Schwannian proliferation, and mitoses are frequent. Characteristic Homer Wright rosettes are defined by a rim of dark tumor cells in a circumferential arrangement around a central pale fibrillar core (Fig. 27-42B). By electron microscopy, malignant neuroblasts show peripheral dendritic processes with longitudinally oriented microtubules and neurosecretory granules and filaments.

Neuroblastomas readily infiltrate surrounding structures and metastasize to regional lymph nodes, liver, lungs, bones and other sites. The tumors may differentiate into ganglioneuromas (see below).

CLINICAL FEATURES: Clinical presentations are highly variable, reflecting the many sites where the primary tumors may develop and metastasize. The first sign is often an enlarging abdomen in a young child. Examination discloses a firm, irregular, nontender mass. Metastases may enlarge the liver and cause ascites. Marked irritability may reflect pain from bony metastases. Respiratory distress accompanies large masses in the thorax, and tumors in the pelvis may obstruct the bowel or ureters. Spinal cord compression may lead to gait disturbance and sphincter dysfunction. Tumor secretion of vasoactive intestinal peptide may cause diarrhea. Some patients show paraneoplastic opsoclonus-myoclonus syndrome, which usually indicates an excellent prognosis, although some may develop permanent neurologic deficits.

Urinary catecholamines and their metabolites are almost invariably elevated, particularly **norepinephrine, VMA, homovanillic acid** (HVA) and **dopamine**.

Several factors are useful in predicting the outcome of neuroblastomas:

- **Age:** Age at diagnosis is one of the most important predictors of survival. Children under 1 year old have better prognoses than do older patients with the same stage of disease. Spontaneous tumor regression occurs commonly at this age.
- **Site:** Extra-adrenal tumors tend to be better differentiated and so less aggressive.
- **Stage:** Survival is 90% in stage I (tumor confined to the organ of origin) and decreases to less than 3% in stage IV (widespread metastases). An exception is stage IVS (special), in which tumors lack the characteristic chromosomal abnormalities. Even with liver and bone marrow metastases, patients with stage IVS may undergo spontaneous remissions and have 60%–90% survival.
- **Tumor histology:** Low-grade (better-differentiated) tumors do better than high-grade (undifferentiated) tumors. If the **VMA/HVA ratio** is less than 1, the tumor is deficient in dopamine β-hydroxylase and likely to be more aggressive.
- **DNA ploidy:** A DNA index near the diploid/tetraploid range is unfavorable, but hyperdiploid or near-triploid neuroblastomas have a good prognosis. DNA ploidy has less prognostic value in patients older than 2 years.
- **Genomic alterations:** *MYCN* amplification occurs in 20%–25% of cases and suggests poor outcome. Tumors with *MYCN* amplification often have chromosome 1p deletions (especially del 1p36.3). Allelic gain of 17q implies more aggressiveness.

Neuroblastomas can express several tyrosine kinase neurotropin receptors: TrkA, TrkB and TrkC. High levels of TrkA correlate with younger age, lower stage, absence of *MYCN* amplification and favorable prognosis. Conversely, TrkB expression correlates with an invasive phenotype, high-risk disease and chemoresistance. TrkC occurs in lower-stage tumors. High-level expression of *EPHB6, CD44, EFNB2* and *EFNB3* correlates with good clinical outcome.

Prognosis also correlates with cytogenetic findings:

- Lack of significant chromosome changes portends excellent survival.
- Tumors with any chromosome copy number changes tend to relapse.
- Tumors with segmental alterations, *MYCN* amplification, 1p and 11q deletions and 1q gain imply overall poor survival.

Localized neuroblastomas are treated by surgical resection alone. Patients with disseminated tumors receive chemotherapy and sometimes irradiation.

Ganglioneuromas Are Mature Variants of Neuroblastic Tumors

Ganglioneuromas, like neuroblastomas, are tumors of neural crest origin. They occur in older children and young adults. *Ganglioneuromas are benign and arise in sympathetic ganglia, typically in the posterior mediastinum.* Up to 30% of these tumors develop in the adrenal medulla. In keeping with their degree of differentiation, ganglioneuromas do not manifest chromosomal abnormalities characteristic of neuroblastomas (see above).

PATHOLOGY: Ganglioneuromas are well encapsulated, with myxoid, glistening cut surfaces. They show well-differentiated, mature ganglion cells associated with spindle cells in a loose, abundant fibrillar stroma (Fig. 27-43). The fibrils represent neurites extending from tumor cell bodies. Cytoplasmic processes of ganglion cells contain neurosecretory granules and may form synaptic junctions. Typical neuroendocrine substances, such as neuron-specific enolase and certain peptide hormones, are abundant. Neuroblastomas may differentiate into a ganglioneuromas.

Pineal Gland

ANATOMY AND FUNCTION

The pineal gland resembles a 5–7-mm minute pine cone. It is below the posterior edge of the corpus callosum, suspended from the roof of the third ventricle over the superior colliculi. The pineal has a lobulated architecture, compartmentalized

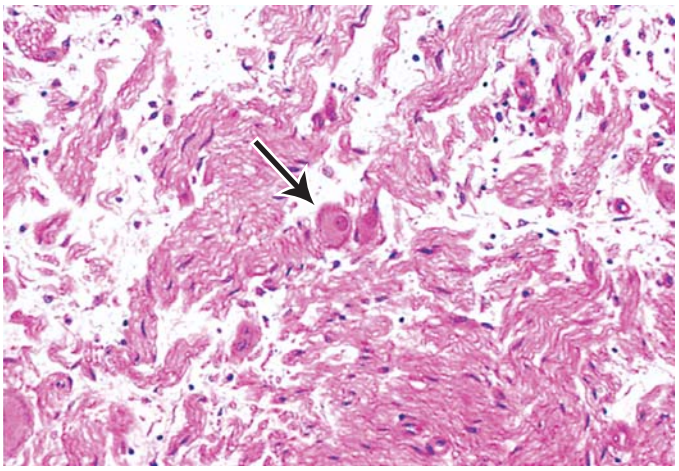

FIGURE 27-43. Ganglioneuroma. A photomicrograph shows mature ganglion cells (*arrow*) interspersed among wavy spindle cells embedded in a myxoid matrix.

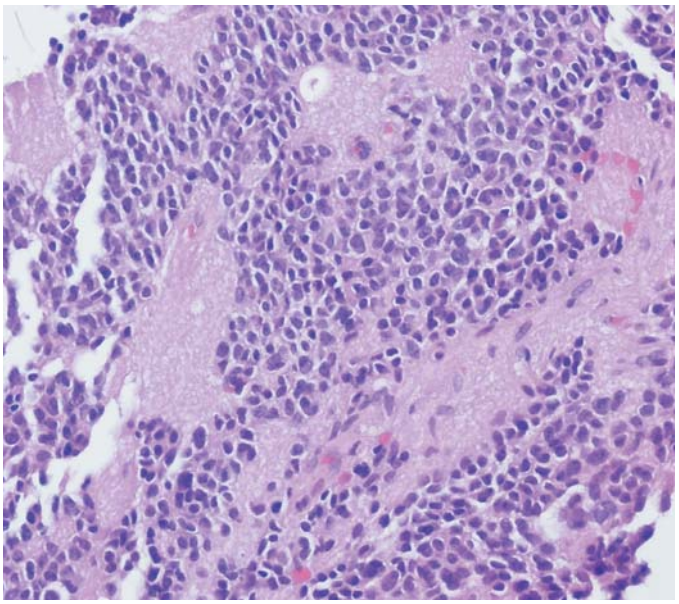

FIGURE 27-44. Pineocytoma. A photomicrograph shows nests of tumor cells with round nuclei and eosinophilic cytoplasm separated by connective tissue.

by fibrovascular septa, with cords and clusters of large epithelial-like cells, **pinealocytes**. These have modified photosensory and neuroendocrine functions. Astrocytes make up 10% of pineal gland cellularity.

The pineal gland produces several neurotransmitters, of which **melatonin** is among the most abundant. Since melatonin levels are distinctly higher at night than during waking hours, it may act as a sleep inducer.

Serotonin and several other substances are also produced by the pineal. The most significant of these is arginine vasotocin, a hormone that has important antigonadotropic activity. Melatonin may be a releasing factor for arginine vasotocin.

Beginning at about the time of puberty, calcifications (corpora arenacea or "brain sand") develop in the pineal gland, as visualized in autopsy specimens or by various radiographic techniques. These mineralized concretions accumulate increasingly with age and are accompanied by cystic degeneration and gliosis.

NEOPLASMS

Tumors of the pineal gland are rare. They represent less than 1% of brain tumors. Pineal tumors include neoplasms (1) originating from the pineal parenchyma, presumably from pinealocytes; (2) in the pineal gland region **(astrocytomas)** but derived from cells other than pinealocytes; and, rarely, (3) metastasis from other sites.

PATHOLOGY:

- **Germ cell tumors:** These are the most common pineal neoplasms. They apparently derive from misplaced germ cells. Of these, 60% are germinomas, or dysgerminomas, indistinguishable from their gonadal counterparts. Germ cell tumors are often immunopositive for placental alkaline phosphatase, CD117/c-kit and OCT4.
- **Pineocytomas:** These benign tumors are solid, well-circumscribed masses that replace the pineal body. Small tumor cells with round nuclei and eosinophilic cytoplasm grow in nests and rosettes separated by thin strands of connective tissue (Fig. 27-44). They resemble paragangliomas, but pineocytomas lack neurosecretory granules.
- **Pineoblastomas:** These highly malignant tumors are extremely rare and occur in young adults. Soft masses, often with hemorrhagic and necrotic areas, invade and infiltrate surrounding structures. Pineoblastomas consist of clusters of densely packed small oval cells, with dark nuclei and scanty cytoplasm, resembling medulloblastomas or neuroblastomas and with rosette formation. Mitoses are abundant. These tumors are immunopositive for synaptophysin and negative for glial fibrillary acidic protein. Metastasis to the central nervous system and spine are common.

CLINICAL FEATURES: Regardless of histologic type, pineal gland tumors present with signs and symptoms owing to their impact on surrounding structures, including headaches and visual and behavioral disturbances. In children, these tumors may precipitate precocious puberty, especially in boys. The prognosis of pineoblastoma is poor. However, even benign pineal tumors and nonneoplastic pineal cysts carry guarded prognoses and pose a great threat to life, because they are difficult to excise surgically.

PARANEOPLASTIC SYNDROMES WITH ENDOCRINE FUNCTION

Tumors May Produce Ectopic Peptide Hormones with Systemic Effects

Malignant tumors may produce diverse peptide hormones whose secretion is not under normal regulatory control. Most of these hormones are normally present in the brain,

gastrointestinal tract or endocrine organs. Their inappropriate secretion can cause a variety of effects.

CUSHING SYNDROME: Ectopic secretion of ACTH by a tumor leads to features of Cushing syndrome, including hypokalemia, hyperglycemia, hypertension and muscle weakness. ACTH production is most commonly seen with cancers of the lung, particularly small cell carcinoma. It also complicates carcinoid tumors and other neuroendocrine tumors, such as pheochromocytoma, neuroblastoma and medullary thyroid carcinoma.

INAPPROPRIATE ANTIDIURESIS: Production of arginine vasopressin (ADH) by a tumor may cause sodium and water retention to such an extent that it is manifested as water intoxication, resulting in altered mental status, seizures, coma and sometimes death. The tumor that most often produces this syndrome is small cell lung carcinoma. It is also reported with carcinomas of the prostate, gastrointestinal tract and pancreas and with thymomas, lymphomas and Hodgkin disease.

HYPERCALCEMIA: A paraneoplastic complication that afflicts 10% of cancer patients, hypercalcemia is usually caused by metastatic disease of bone. However, in about one tenth of cases, it occurs in the absence of bony metastases. The most common cause of paraneoplastic hypercalcemia is the secretion of a parathormone-like peptide by an epithelial tumor, usually squamous cell lung carcinoma or breast adenocarcinoma. In multiple myeloma and lymphomas, hypercalcemia is attributed to the secretion of osteoclast-activating factor. Other mechanisms of hypercalcemia involve the production of prostaglandins, active metabolites of vitamin D, transforming growth factor-α (TGF-α) and TGF-β.

HYPOCALCEMIA: Cancer-induced hypocalcemia is actually more common than hypercalcemia and complicates osteoblastic metastases from cancers of the lung, breast and prostate. The cause of hypocalcemia is not known. Low calcium levels have been reported in association with calcitonin-secreting medullary carcinoma of the thyroid.

GONADOTROPIC SYNDROMES: Gonadotropins may be secreted by germ cell tumors, gestational trophoblastic tumors (choriocarcinoma, hydatidiform mole) and pituitary tumors. Less commonly, gonadotropin secretion is observed with hepatoblastomas in children and cancers of the lung, colon, breast and pancreas in adults. High gonadotropin levels lead to precocious puberty in children, gynecomastia in men and oligomenorrhea in premenopausal women.

HYPOGLYCEMIA: The best-understood cause of hypoglycemia associated with tumors is excessive insulin production by pancreatic islet cell tumors (see Chapter 21). Other tumors, especially large mesotheliomas, fibrosarcomas and primary hepatocellular carcinoma, are associated with hypoglycemia. The cause of hypoglycemia in nonendocrine tumors is not established, but the most likely candidate is production of somatomedins (IGFs), a family of peptides normally made by the liver, under regulation by growth hormone.

Paraneoplastic Syndromes Involving the Skin

The skin is an optimal organ for studying fundamental principles of pathology because lesions on its surface are readily apparent and easily biopsied. Most classes of disease manifest in the skin. Some diseases, such as the blistering diseases, are mainly present in the skin.

Considering the imperatives of appearance in human interactions, a changed appearance of the skin may at times be the most important feature of cutaneous disease. Many cutaneous diseases have only minor symptoms, and some have no symptoms at all. Few are life-threatening, and many are self-limited. However, even self-limited, asymptomatic cutaneous diseases are often of great concern to the patient. For example, the symptoms of acne are systemically minor, but the disease can change a life. Although scalp hair is unneeded, baldness may cause considerable distress. Vitiligo, a completely asymptomatic, progressive, depigmentation disorder, often creates emotional havoc for an otherwise normal person of color.

ANATOMY AND PHYSIOLOGY OF THE SKIN

The skin is a protective barrier; microorganisms find it almost impossible to penetrate intact epidermis from the outside, and water loss is limited from the inside. The organ is vital in regulating temperature and protecting against ultraviolet (UV) light. Diverse sensory receptors communicate details of the immediate environment. The skin plays a prominent role in immune regulation through its associated lymphoid tissues, which include lymphocytes and antigen-presenting cells that travel between the skin and regional lymph nodes via the lymphatics and bloodstream. Keratinocytes, Langerhans cells, mast cells, lymphocytes and macrophages all participate in immune responses. Epidermal keratinocytes produce many cytokines, notably interleukin-1α (IL-1α) and IL-1β eicosanoids and melanocortin. The ability of keratinocytes to participate in immunity, inflammation and pigment production by melanocytes is necessary in an organ relentlessly exposed to the external environment. Langerhans cells, the dendritic antigen-presenting cells of the skin, are bone marrow–derived, epidermal immigrant cells. They are central to development and regulation of contact hypersensitivity, allograft rejection and graft-versus-host disease.

KERATINOCYTES: The epidermis is a multilayered sheet of keratin-producing cells. It forms undulating folds at the interface with the dermis, called dermal papillae. A progressive change in morphology occurs from the replicating

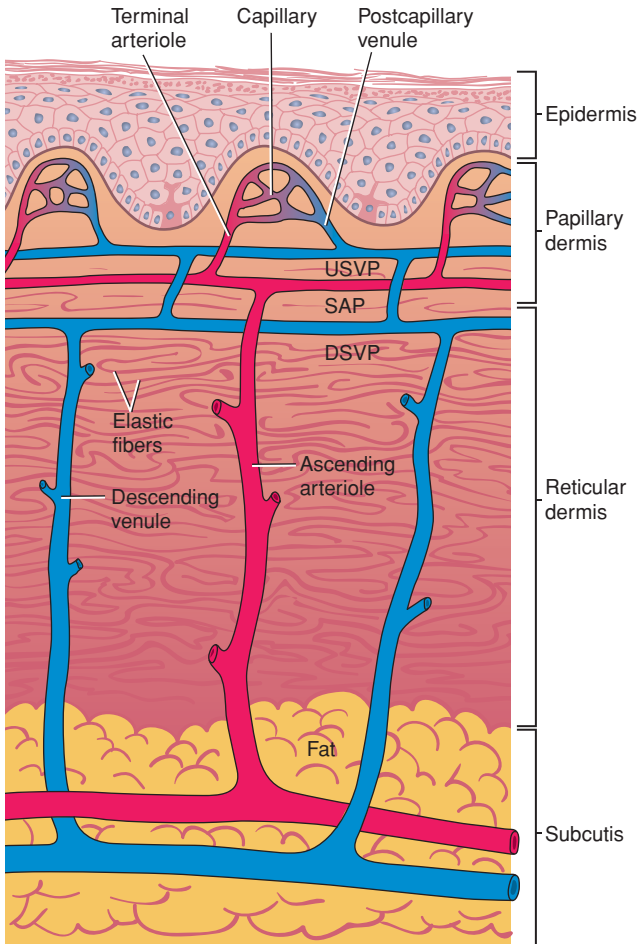

FIGURE 28-1. The dermis and its vasculature. The dermis is divided into two distinct anatomic regions. The papillary dermis with its vascular plexus and the epidermis usually react together in diseases that are primarily limited to the skin. The reticular dermis and the subcutis are altered in association with systemic diseases that manifest in the skin. *DSVP* = deep superficial venular plexus; *SAP* = superficial arterial plexus; *USVP* = upper superficial venular plexus.

columnar cells of the basal layer **(stratum basalis)** through the spinous layer **(stratum spinosum)** and the granular layer **(stratum granulosum)** to the nonviable flattened cells of the cornified layer **(stratum corneum)** (Figs. 28-1 and 28-2). The basal cells harbor most of the mitotic activity of the epidermis. As keratinocytes approach the surface, they lose their nuclei and form flattened plates of dead cells on the outer boundary of the skin (the cornified or keratin layer). Keratinocytes synthesize a sulfur-poor, filamentous **tonofibril,** which is related to the keratin molecules of the stratum corneum. Tonofibrils are composed of varying blends of acidic and basic intermediate keratin filaments; they result in over 30 different keratins that are responsible for structures such as the stratum corneum, hair and nails. Bundles of tonofibrils converge on, and terminate at, the plasma membrane in attachment plates called **desmosomes** (Fig. 28-3).

Keratinocytes are also distinguished by two other structural products: "keratohyaline granules" and **"Odland bodies."** Keratohyaline granules are the defining feature of the granular layer and are composed of a histidine-rich, electron-dense, basophilic protein—profilaggrin—which is associated with intermediate filaments. Odland bodies, also known as keratinosomes or membrane-coating granules, are the only structurally distinctive, epidermal secretory product (Fig. 28-3). They form in the outer spinous and granular layers and discharge their contents into intercellular spaces, appearing there as lamellar masses parallel to the surface of the skin. Odland bodies and the discharged lamellated products are most obvious in the outer granular layer and are related to epidermal barrier function.

The epidermis harbors immigrant cells of neuroectodermal and mesenchymal origin that do not synthesize keratin but which have their own highly distinctive organelles. Their numbers vary among the several different levels of the epidermis. Two of these cells, **melanocytes** and **Langerhans cells,** are dendritic. The third, the **Merkel cell,** is associated with a terminal neuronal axon (Fig. 28-2).

MELANOCYTES: Melanocytes are dendritic cells of neural crest origin that largely determine skin color. They lie in the basal layer of the epidermis, separated from the dermis by the epidermal basement membrane zone. A single melanocyte may supply dendrites to over 30 keratinocytes (Fig. 28-4).

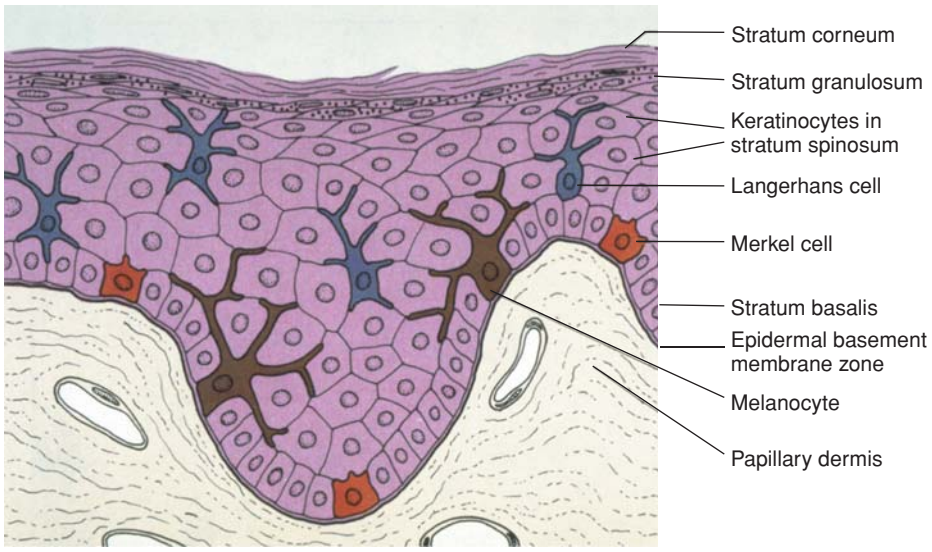

FIGURE 28-2. Normal epidermis and the epidermal immigrant cells. Keratinocytes form the multilayered epidermis, protecting against water loss and bacterial invasion. Melanocytes provide color as well as protection against ultraviolet radiation. Langerhans cells are among the cells responsible for the skin's function as an immunologic organ. Merkel cells may represent one of the enablers of tactile function of the skin.

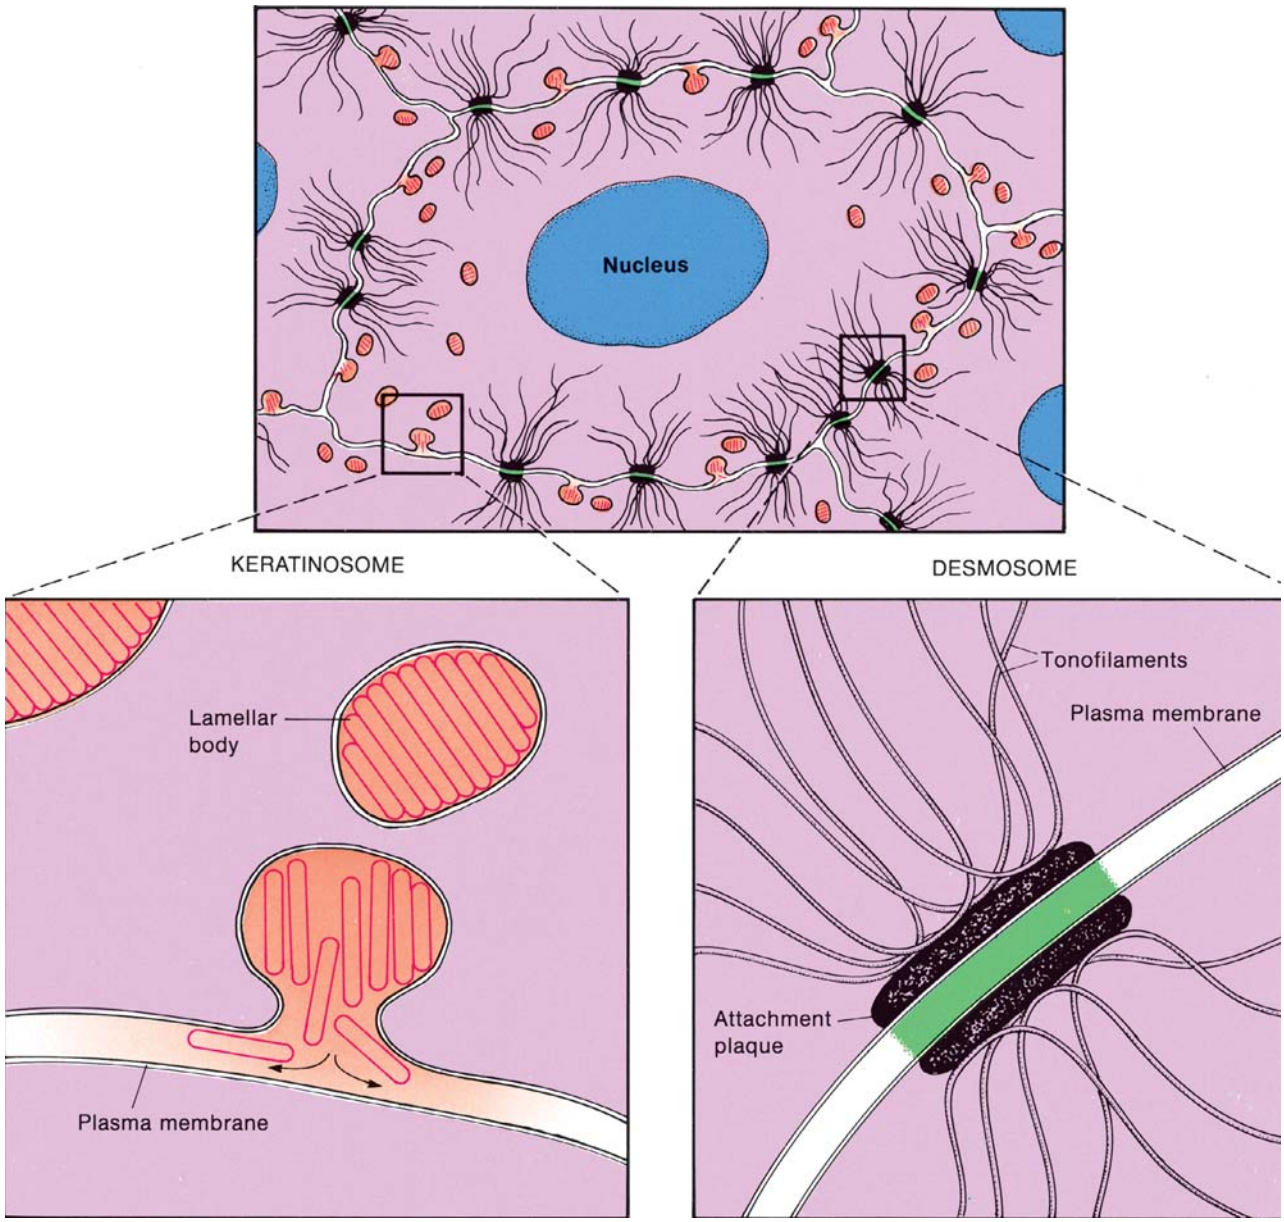

FIGURE 28-3. The keratinocyte, keratinosome and desmosome. The keratinocyte cytoplasm is dominated by delicate keratin fibrils, the tonofilaments. These are part of the cytoskeleton of the cell and loop within the attachment plaque of the desmosome. The lamellar body of the keratinocyte extrudes its contents into the intercellular space. This material probably has a role in cellular cohesion.

The **melanosome** is a cytoplasmic membrane–bound complex in which melanin is synthesized. When melanin synthesis is active, melanosomes contain filaments in parallel arrays along the long axis of the organelle (Fig. 28-4). As they mature, melanosomes' orderly internal structure is progressively obliterated, and they become electron-opaque granules. These are transferred to keratinocytes, where they form a supranuclear cap, protecting the nuclear material from ultraviolet light.

Skin color is largely based on the number, size and packaging of melanosomes in keratinocytes. In hair and epidermal keratinocytes, melanins are packaged and absorb and reflect visible light, thus forming the integumentary colors.

LANGERHANS CELLS: These cells arrive in embryonic skin in the last month of the first trimester, following the melanocytes by a month. These human leukocyte antigen (HLA)-DR–positive cells allow skin to recognize and process antigens, and so become a part of the immune system. These cells are uncommon in the dermis but are distributed throughout the nucleated layers of the epidermis, where they constitute about 4% of the cells. They are difficult to see by routine light microscopy because their cytoplasm is translucent and is formed of a perikaryon and dendrites. Langerhans cells do not have specialized attachments to the apposed keratinocytes. In electron micrographs, their cytoplasm contains a moderate number of specialized organelles, **Birbeck granules**. In two dimensions, these structures appear to be racquet shaped, but three-dimensional reconstruction shows them to be cup shaped (Fig. 28-5). These unique organelles are derived from the plasma membrane and probably participate in antigen presentation by Langerhans cells (antigenic material being internalized into Birbeck granules).

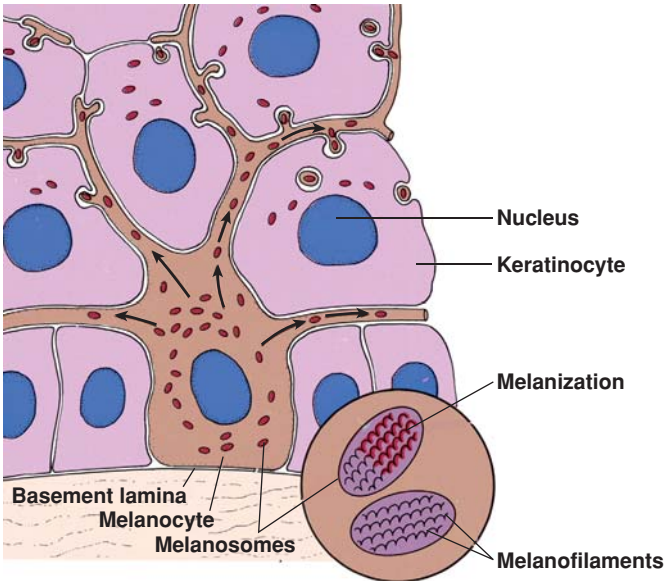

FIGURE 28-4. A melanocyte supplies over 30 keratinocytes with melanin granules by way of complex dendritic cytoplasmic extensions. Melanin granules are transferred to keratinocytes and come to lie in a supranuclear cap, a site indicating their protective function. Pigment granules are actually formed in the melanocytes within distinctive organelles—the melanosomes. Pigment is synthesized on small filaments within this organelle (*inset*).

In Langerhans cell histiocytoses, Birbeck granules attach to the plasma membrane of proliferating cells and communicate directly with the extracellular space. Furthermore, they have a fuzzy coat of clathrin, a feature of "coated pits," suggesting a relationship to receptor-mediated antigen processing and recognition. Langerhans cells express major histocompatibility complex I (MHC-I), MHC-II and receptors for Fc IgG and Fc IgE. They express CD1a and, less specifically, S-100 protein.

MERKEL CELLS: Although sometimes classified as "immigrant" cells, Merkel cells may be specialized basal keratinocytes. They form desmosomes with keratinocytes and express keratins similarly to keratinocytes. They project short, blunt cytoplasmic fingers into adjacent keratinocytes. Merkel cells do not appear in all areas of the epidermis but are seen in special regions such as the lips, oral cavity, external root sheaths of hair follicles and palmar skin of the digits. They have a distinctive organelle, a membrane-bound, dense-core granule, 100 nm or wider (Fig. 28-6). Immunohistochemical and ultrastructural studies suggest that Merkel cells have a neurosecretory function. The basal aspect of the cell is apposed to a small nerve plate that connects to a myelinated axon by a short, nonmyelinated axon. This complex structure may be a tactile mechanoreceptor.

BASEMENT MEMBRANE: The basement membrane zone (BMZ) is an interface between the dermis and epidermis and is as diverse in function as it is complex in structure (Fig. 28-7). It mediates dermal–epidermal adherence and

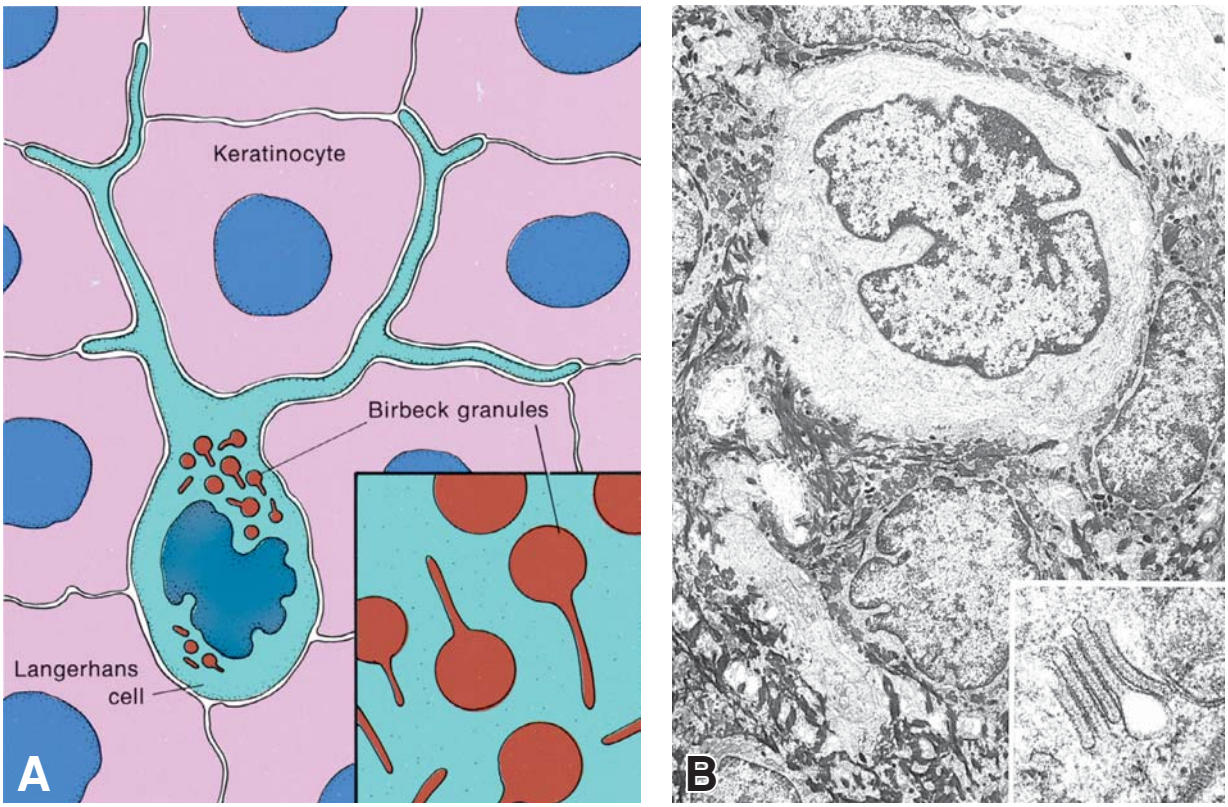

FIGURE 28-5. The dendritic Langerhans cell can recognize and process antigens. A. The unique racket-shaped organelles, called *Birbeck granules,* may be important in antigen presentation. **B.** An electron micrograph of a Langerhans cell shows a high-power view of the racket-shaped organelles (*inset*). The Langerhans cell body (*mid-upper portion*) is pale compared to the surrounding keratinocytes, whose cytoplasm contains electron-dense packets of tonofilaments. A dendrite is present (*arrow*).

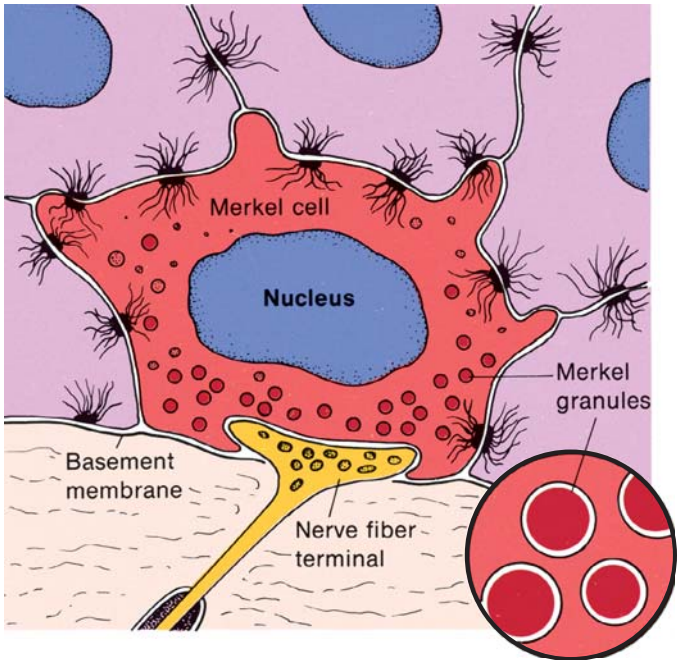

FIGURE 28-6. The Merkel cell, which differs from other immigrant cells, forms desmosomes with keratinocytes and is attached to a small nerve plate (nerve fiber terminal). The membrane-delimited, dense core granule is distinctive (*inset*).

probably acts as a selective macromolecular filter as well. It is also a site of immunoglobulin and complement deposition in certain cutaneous diseases. Most structures of the BMZ are elaborated by epidermal cells. The basal lamina is the primary organizational feature of the BMZ and is responsible for epithelial cell polarity as well as some keratin gene expression. Ultrastructurally, the basal lamina includes:

- **Deep aspects of basal keratinocytes** including plasma membrane and tonofilaments, which attach to the deep face of the hemidesmosome
- **Hemidesmosome,** with its subdesmosomal dense plate
- **Anchoring filaments,** which extend from subdesmosomal dense plates across the lamina lucida and insert into the lamina densa
- **Lamina lucida,** an electron-lucent layer containing adherence proteins
- **Lamina densa,** composed principally of type IV collagen
- **Anchoring fibrils,** which are arrays of type VII collagen extending from the inner face of the lamina densa for a short distance into the papillary dermis
- **Microfibrils,** which feature delicate, long, elastic fibrils that blend with the underlying elastic fibrillary system of the skin

Certain antigenic components have been identified in the BMZ, some of which play identified roles in cutaneous disease, particularly blistering disorders. **Laminin** is a glycoprotein in the lamina lucida and lamina densa of all BMZs. It helps to organize BMZ macromolecules and promotes cell attachment to extracellular matrix. Laminin binds **type IV collagen**.

Bullous pemphigoid (BP) antigens were identified with antibodies from patients with the blistering disorder BP (see below). The antigens BPAG1 and BPAG2 **(type XVII collagen)** are normal constituents of the dermal–epidermal junction but are absent in BMZs around adnexal structures and blood vessels. These BP antigens localize in hemidesmosomes and cytoplasm of basal keratinocytes. Type IV collagen, in the lamina densa of all BMZs, is the most superficial component of the complex collagen fiber network of the dermis. It is important in dermal–epidermal attachment. **Type VII collagen** is present on the deep aspect of the basal lamina in anchoring fibrils. Anchoring fibril antigens (AF-1 and AF-2) reside within anchoring fibrils and possibly within the lower lamina densa.

The **dermis** is a complex organization of connective tissue deep to the BMZ, containing mostly collagen, which is embedded in a ground substance rich in hyaluronic acid. The dermis has two zones:

PAPILLARY DERMIS: The papillary dermis is a narrow zone just below the BMZ of the epidermis. It has a pale pink eosinophilic appearance and has little organization when viewed with the light microscope (Figs. 28-1 and 28-2). Delicate collagen fibrils are the most apparent structures. This delicate connective tissue extends into the dermal papillae, and also as a sheath about blood vessels, nerves and adnexal structures. This entire network of collagen is known as the **adventitial dermis**.

The papillary dermis is generally altered in epidermal diseases and disorders affecting the superficial vascular bed. The epidermis, papillary dermis and superficial vascular bed react jointly and influence each other in complex ways. Some primary skin diseases with few, if any, systemic manifestations, such as psoriasis and lichen planus, involve these superficial structures.

RETICULAR DERMIS: The reticular dermis is deep to the papillary dermis and contains most of the dermal collagen, which is organized into coarse bundles and associated with elastic fibers (Fig. 28-1). The reticular dermis and subcutis (also recognized as a cutaneous structure) are less common sites of pathologic change. If they are diseased, it is often as a manifestation of systemic disease (e.g., scleroderma [progressive systemic sclerosis] and erythema nodosum).

CUTANEOUS VASCULATURE: Circulating blood in the skin has a number of functions. The skin, via its vascular network, is important in temperature regulation. Many aspects of cutaneous inflammation involve the superficial cutaneous vasculature.

An ascending arteriole arises from arteries in the subcutis and directly crosses much of the reticular dermis (Fig. 28-1). In the outer part of the reticular dermis, in conjunction with other similar ascending arterioles, a superficial arteriolar plexus is formed. A terminal arteriole extends from this plexus into each dermal papilla, where an arterial capillary is formed. The arterial capillary makes a U-turn and on its descent becomes a venous capillary and then a postcapillary venule. These venules join to form a complex venular plexus in the reticular dermis, just under the papillary dermis. The venular end of this vascular structure is important in cutaneous inflammatory responses.

Cutaneous lymphatic vessels form a random network, starting as lymphatic capillaries near the epidermis. A superficial lymphatic plexus then sends forth lymphatic channels to drain to regional lymph nodes. Lymphatic channels are involved in drainage of tissue fluids and metastasis of cutaneous cancers, especially malignant melanoma. Cutaneous lymphatics have, at best, an incomplete basal lamina.

Mast cells are derived from bone marrow and are normally present around dermal venules. They release vasoactive

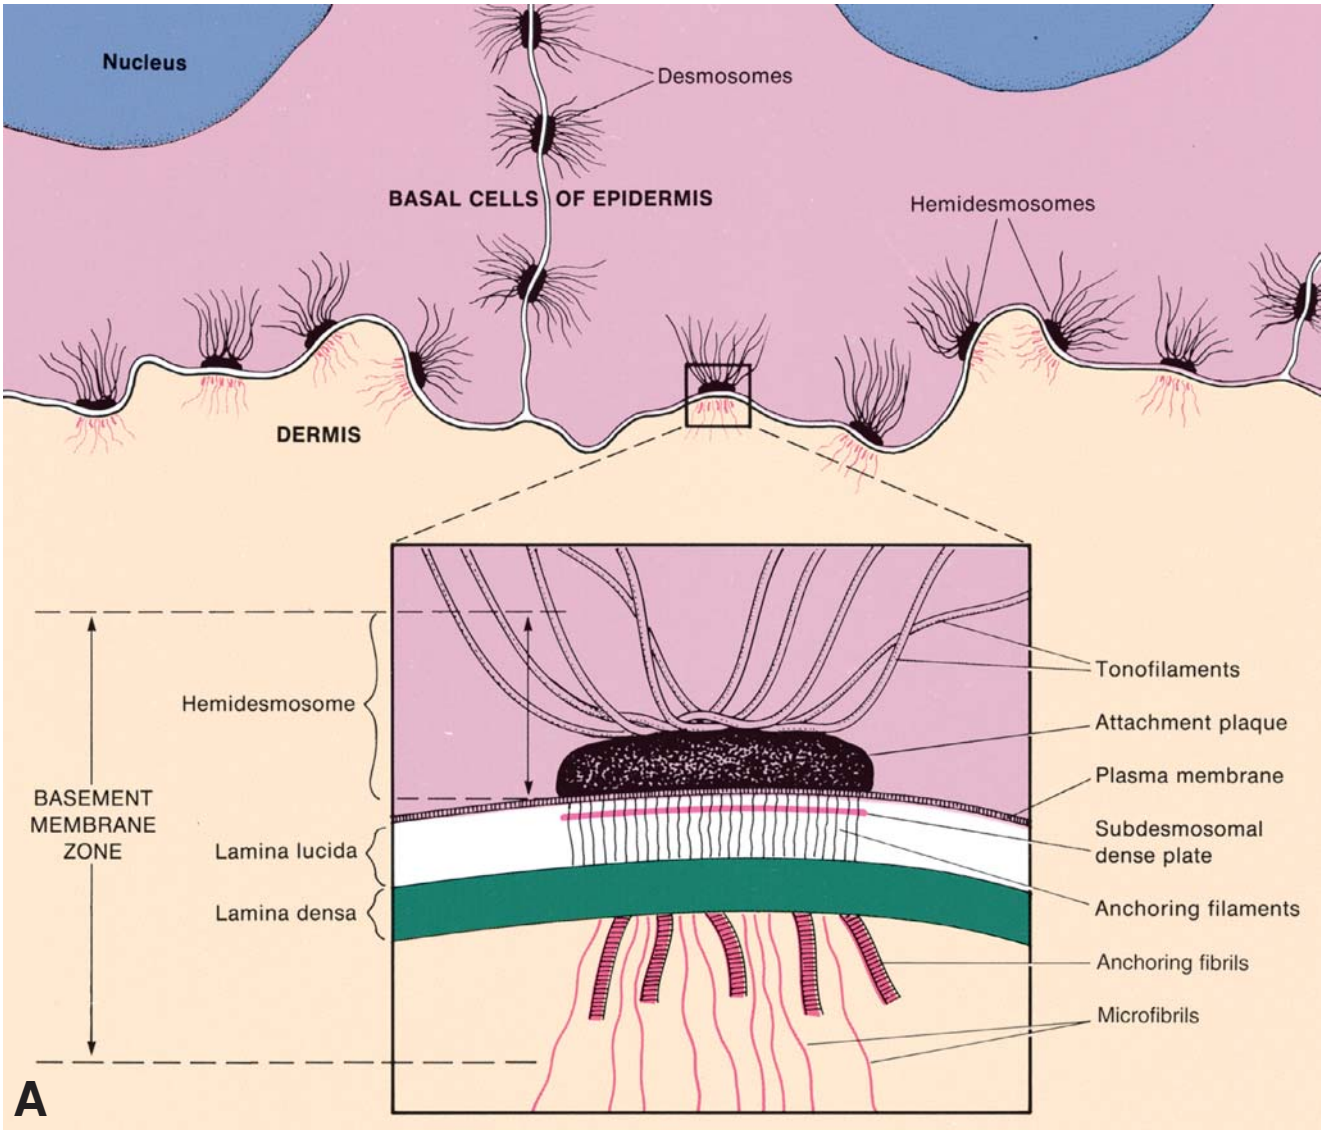

FIGURE 28-7. The dermal–epidermal interface and the basement membrane zone. A. This epithelial–mesenchymal interface is the site of the basement membrane zone, a complex structure that is mostly synthesized by the basal cells of the epidermis. Each of its complex structures is a site of change in specific disease, from tonofilaments and attachment plaques of basal cells to anchoring fibrils and microfibrils. **B.** An electron micrograph shows the hemidesmosomal attachment plaques with their inserting tonofilaments (*arrow*). The subdesmosomal dense plates, the lamina lucida, the lamina densa and the subjacent anchoring fibrils are well demonstrated.

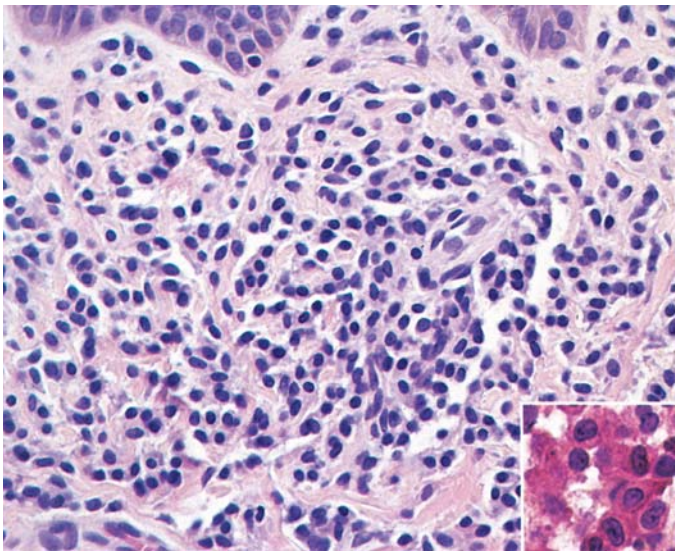

FIGURE 28-8. Urticaria pigmentosa. Mast cells fill and expand the papillary dermis. The cytoplasm of mast cells contains chloracetate esterase–rich granules, giving them a red hue in this Leder stain (*inset*), a useful distinguishing feature.

and chemotactic substances, mediate all types of inflammation and proliferate in a spectrum of diseases, called **urticaria pigmentosa** (Fig. 28-8).

HAIR FOLLICLES: Hair follicles originate in the primitive epidermis. They grow downward through the dermis and upward through the epidermis. Growing hairs of the scalp and beard have bulbs of epithelial and mesenchymal tissue firmly embedded in the subcutis. A vertical cross-section of a bulb reveals a cap of actively dividing, keratin-synthesizing cells that become arrayed in layers that join at the top of the bulb to form the cylindrical hair shaft. The differentiating hairs form the roof of the epithelial bulb and interact with an island of melanocytes that contribute melanin to the passing keratinocytes. This process results in hair color. The colored keratinocytes lose their nuclei as they form the final product, the cylindrical hair shaft. Curly hair is formed from angulated bulbs; straight hair develops from round bulbs.

THE HAIR CYCLE: Hair grows in a cyclical fashion. At any given time, 90% of hairs are normally in the actively growing, or **anagen,** phase. These are interspersed with hairs that show no evidence of active growth, **telogen** hairs. Hairs in the process of ceasing growth, **catagen** hairs, still have hair shafts. Catagen hairs end in the lower reticular dermis as slightly widened club-like structures, each surrounded by a rim of nucleated keratinocytes. Hair bulbs are no longer evident, and the lamina densa around the catagen hair is strikingly thickened.

As the **telogen** phase (resting follicle) is reached, the end of the hair retreats to the level of the arrector pili muscle. The hair shaft may be missing: it is no longer tethered at the base and leaves only a remnant of the original follicle. However, a delicate vascularized mesenchymal tract, the telogen tract, extends from the attenuated tip. At the top of this tract, an early anagen hair forms again from follicular stem cells. With growth, it follows the delicate pathway through the reticular dermis into the panniculus, there forming a mature anagen follicle and a new hair.

ALOPECIA: Alopecia, commonly known as baldness, is loss of hair. **Androgenetic alopecia,** or **common alopecia,** affects both men and women and results from a complex and poorly understood interaction of heritable and hormonal factors. Men castrated before puberty retain scalp hair and fail to grow a beard. On the other hand, administering testosterone to such castrated men results in growth of a beard and may lead to male-pattern baldness. Loss of scalp hair leads to replacement of large terminal hair follicles by tiny "vellus" hair follicles, the source of the delicate "fuzz" on the cheeks of women and the upper cheeks of men.

Growing hair is a site of active mitosis. Many systemic diseases inhibit hair mitosis and give rise to alopecia. If the condition passes, mitotic activity is renewed and hair regrows. If a patient is treated with potent antimitotic drugs (e.g., chemotherapy), hair follicles stop growth, hair is lost and a telogen follicle follows. When therapy stops, hair cycling resumes. Almost any kind of follicular inflammation can trigger the telogen phase. The synchronous onset of telogen in multiple follicles may result in rapid hair loss, called "telogen effluvium." If fibrosis distorts the telogen tract (the regrowth pathway), scarring alopecia with permanent loss of that follicle is the result.

Alopecia areata is a circumscribed area of hair loss, usually on the scalp, although other body areas may be involved. Brisk lymphocytic infiltrates around the hair bulb result in formation of telogen hairs and hair loss. Alopecia areata may actually result from several diseases. This histologic pattern and the association of this phenomenon with the inheritance of HLA class II alleles (especially HLA-DQ3) have been interpreted as evidence for an autoimmune etiology. Generally, scarring does not occur and hair may regrow normally after varying time periods. **Alopecia totalis** is an autoimmune disease that causes loss of all body hair. Aside from cosmetic problems, it is harmless.

VELLUS HAIRS: These fine hairs may play a role in touch perception in many mammals, but in humans they have no function. Vellus hairs are diminutive anagen hairs, with a small active bulb high in the reticular dermis, together with small sebaceous glands.

SEBACEOUS FOLLICLES: These structures develop with puberty and are the sites of **acne**. Sebaceous follicles have a minute vellus hair at the base. The central face has large sebaceous glands that dwarf the vellus hairs and fill the follicular canal with sebum.

DISEASES OF THE EPIDERMIS

Ichthyoses Feature Epidermal Thickening and Scales

Ichthyosiform dermatoses, many of which are heritable, are diverse diseases showing striking thickening of the stratum corneum. The term **ichthyosis** reflects the similarity of the diseased skin to coarse, fish-like scales (Fig. 28-9). Several rare ichthyoses are associated with other abnormalities, such as abnormal lipid metabolism, neurologic or bone diseases and cancer.

MOLECULAR PATHOGENESIS: Three general defects are involved in the excessive epidermal cornification of ichthyoses:

- **Increased cohesiveness** of the cells of the stratum corneum, possibly reflecting altered lipid metabolism

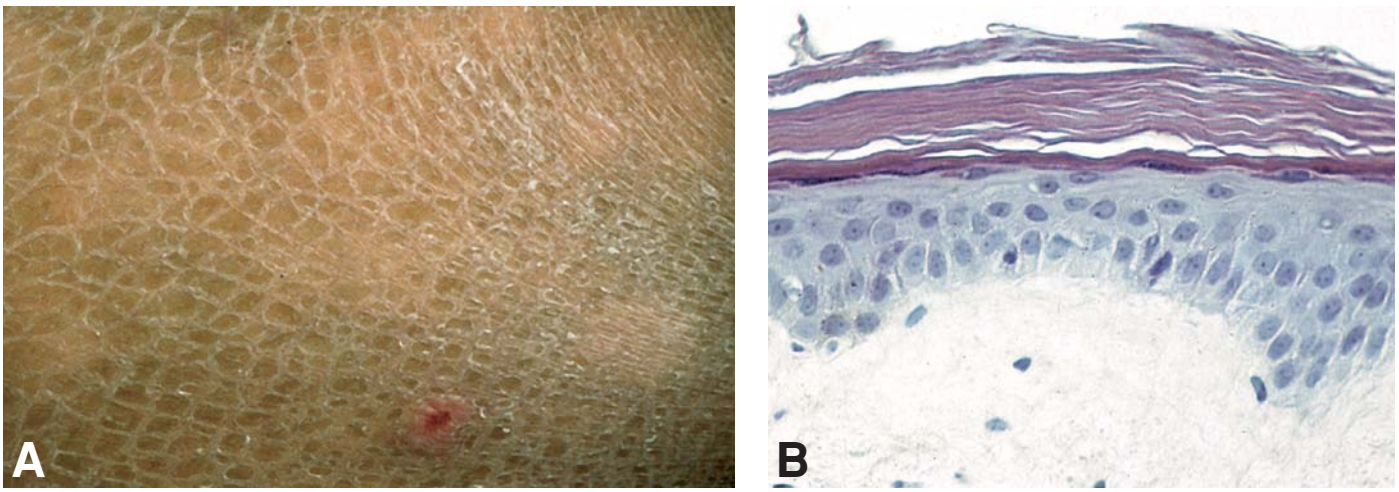

FIGURE 28-9. Ichthyosis vulgaris. A. Noninflammatory fish-like scales are evident on the thigh of a patient with a strong family history of ichthyosis vulgaris. **B.** There is disproportionate thickening of the stratum corneum relative to the normal thickness of the nucleated epidermal layer. The stratum granulosum is thin and focally absent.

- **Abnormal keratinization,** manifested as impaired tonofilament formation and keratohyaline synthesis and as excessive cornification
- **Increased basal cell proliferation,** associated with a decrease in transit time of keratinocytes across the epidermis

PATHOLOGY: In all ichthyoses (with the possible exception of lamellar ichthyosis), the stratum corneum is disproportionately thick compared to the nucleated epidermal layers. Virtually all diseases characterized by thickening of the nucleated epidermal layers also exhibit hyperkeratosis. For example, chronic scratching or rubbing of normal skin causes a thickened epidermis, hyperkeratosis and dermal fibrosis, a condition known as **lichen simplex chronicus**. In this entity, the nucleated epidermis and stratum corneum may each be 3-fold thicker than normal. By contrast, in ichthyosis, the stratum corneum may be five times thicker than normal, but it overlies a disproportionately thin nucleated epidermis.

Ichthyosis Vulgaris

Ichthyosis vulgaris is an autosomal dominant disorder of keratinization characterized by hyperkeratosis and reduced or absent epidermal keratohyaline granules (Fig. 28-10). Scaly skin results from increased cohesiveness of the stratum corneum. The attenuated stratum granulosum is a single layer with small, defective keratohyaline granules. ***Decreased or absent synthesis of* profilaggrin, *a keratin filament "glue," is responsible for these defects.***

Ichthyosis vulgaris is the prototype of disproportionate corneal thickening. The stratum corneum is loose and has a basket-weave appearance, which differs from normal only in amount. The granular layer is greatly diminished and often appears absent (Fig. 28-9B). Ultrastructurally, keratohyaline granules are small and sponge-like, which indicates defective synthesis. Basal and spinous layers appear normal. Thus, the primary defect in ichthyosis vulgaris is in the granular and cornified layers, the epidermal zones responsible for the final stage of keratinization and cornification.

CLINICAL FEATURES: Ichthyosis vulgaris is the most common of the ichthyoses. It begins in early childhood, often in people with family histories of this condition. Small white scales occur on the extensor surfaces of extremities and on the trunk and face. The disease is lifelong, but most patients can be maintained free of scales with topical treatment.

States similar to ichthyosis vulgaris may accompany other diseases or may follow certain drugs. Ichthyosis may occur with lymphomas, especially Hodgkin disease, other cancers, systemic granulomatous disorders and connective tissue disease. Drugs may produce ichthyosis by interfering with similar pathways of lipid metabolism.

X-Linked Ichthyosis

This is a heritable epidermal disorder that, in recessive form, is characterized by delayed dissolution of desmosomal disks in the stratum corneum, owing to deficiency of steroid sulfatase. Steroid sulfatase normally degrades the Odland body product, cholesterol sulfate, which provides cellular adhesion in the lower stratum corneum. Failure of steroid sulfatase action on cholesterol sulfate leads to persistent cohesion of the stratum corneum, but in this disease the granular layer is preserved.

Epidermolytic Hyperkeratosis

This congenital, autosomal dominant ichthyosis features generalized erythroderma, ichthyosiform skin and blistering and is thus also known as "bullous congenital ichthyosiform erythroderma."

MOLECULAR PATHOGENESIS: This ***disease results from mutations in the K1 or K10 keratin genes (chromosomes 12 and 17, respectively), which encode the keratins in the suprabasal epidermis.*** These mutations cause faulty assembly of keratin tonofilaments and impair their insertion into desmosomes. Cytoskeleton development is impaired, resulting in epidermal "lysis" and a tendency to form vesicles.

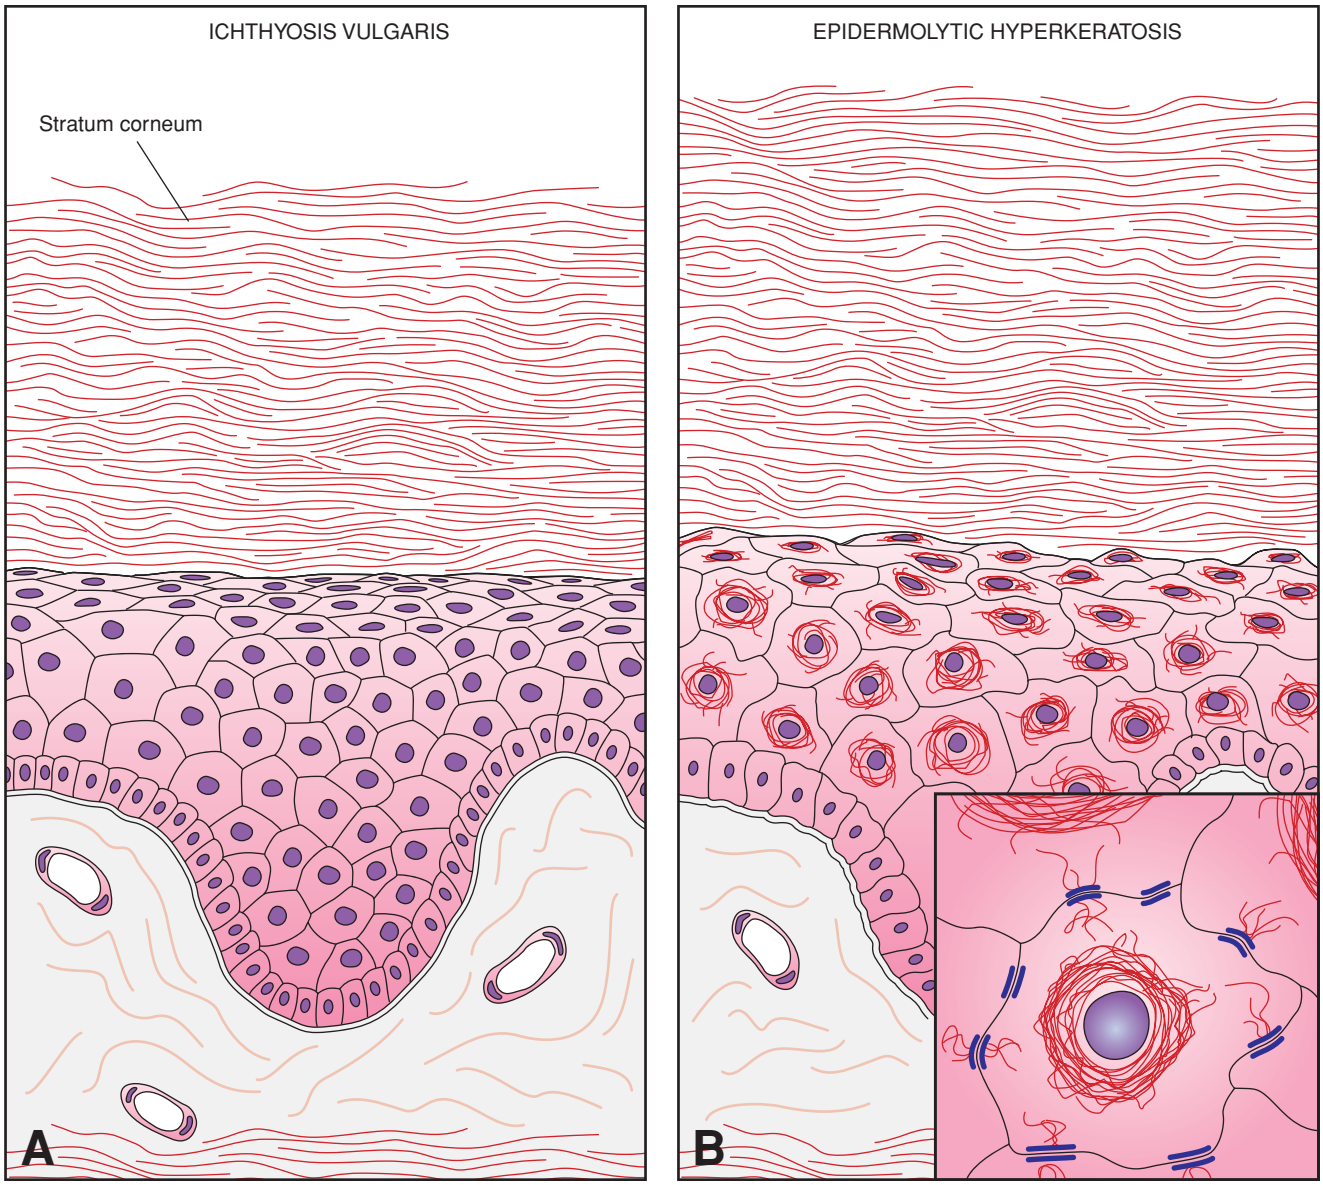

FIGURE 28-10. A. Ichthyosis vulgaris. B. Epidermolytic hyperkeratosis. Both diseases are characterized by thickening of the stratum corneum relative to the nucleated layers. Epidermolytic hyperkeratosis is characterized by abnormal keratin synthesis, manifested by whorled keratin filaments about the nucleus (*inset*).

In epidermolytic hyperkeratosis, suprabasal keratinocytes contain thick, eosinophilic tonofilaments that whorl around the nucleus in a concentric fashion (Fig. 28-11). The cytoplasm has a clear zone (vacuolization) around the perinuclear tonofilaments, but these filaments again condense at the outer margins of the cell. Enlarged keratohyaline granules are present. The stratum corneum is disproportionately thickened (Fig. 28-10).

CLINICAL FEATURES: Epidermolytic hyperkeratosis manifests with blistering at or shortly after birth. It may be generalized or localized to only several areas of the body. Lesions tend to appear dark and even verrucous. Other than cosmetic disfigurement, the major problem is secondary bacterial infection.

Lamellar Ichthyosis

This autosomal recessive congenital disorder of cornification is characterized by severe and generalized ichthyosis. Typically, increased cohesiveness of the stratum corneum is accompanied by numerous keratinosomes and an abnormally large amount of intercellular substance. ***The disease is genetically heterogeneous but is often caused by mutations in the gene encoding transglutaminase 1 (TGM1; chromosome 14q11), resulting in defective lamellar body secretion.***

Darier Disease Is an Autosomal Dominant Disorder of Keratinization

Also called **keratosis follicularis,** this disease is characterized by multifocal keratoses.

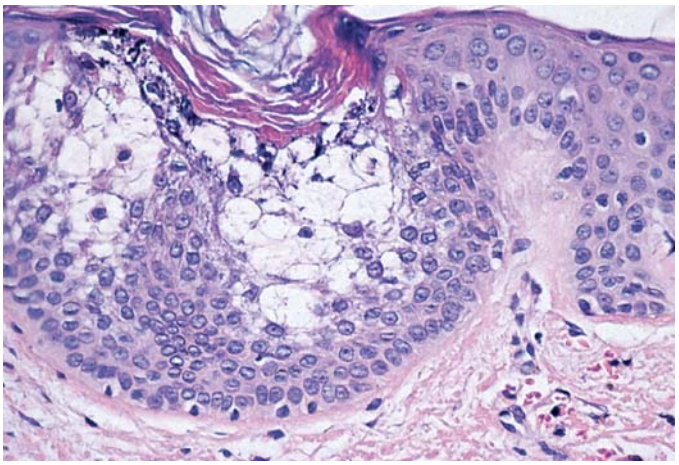

FIGURE 28-11. Epidermolytic hyperkeratosis. The keratinocytes of the stratum spinosum have clumped tonofilaments. As a result, their cytoplasm is relatively clear. In the outer stratum spinosum, the clumped fibrils are further compacted and whorl about the nuclei, resulting in dark cytoplasm condensed about the nuclei. These cells separate from each other to produce epidermolysis. A normal portion of epidermis is seen on the *right*.

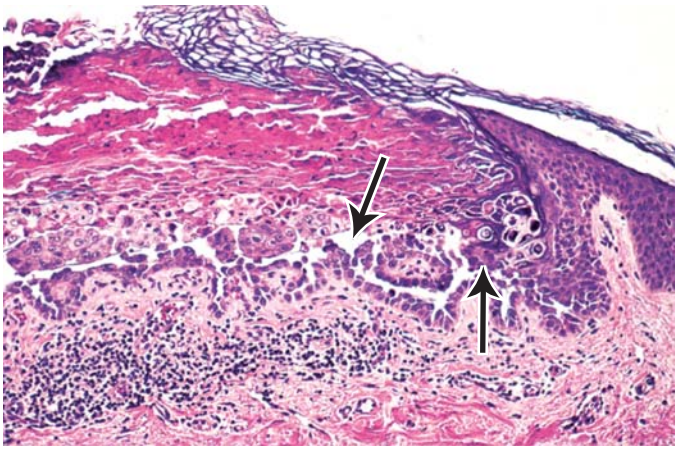

FIGURE 28-12. Darier disease. Virtually the entire epidermis exhibits focal acantholytic dyskeratosis. A small portion of normal epidermis is present (*right*). In the lesion, there is a suprabasal cleft (*arrows*) with a few dyshesive (acantholytic) keratinocytes surmounted by hyperkeratosis and parakeratosis. The cleft is not a vesicle because true vesicles contain inflammatory cells and tissue fluid. Dyskeratosis is present above the cleft.

MOLECULAR PATHOGENESIS: Darier disease is linked to a defect in the intercellular matrix. The gene, *ATP2A2* on chromosome 12q23-24, encodes a calcium pump of the endoplasmic reticulum, and its mutation may exert a direct effect on calcium-dependent desmosome assembly. These patients have many neuropsychiatric problems, also probably related to *ATP2A2* mutations.

A similar autosomal dominant disorder, Hailey-Hailey disease, involves chromosome 3q and the ATP2C1 gene, which is also believed to govern keratinocyte desmosomal interactions.

PATHOLOGY: The warty papule of Darier disease has a suprabasal cleft. Above and to the side of the cleft, dyskeratotic keratinocytes with eosinophilic cytoplasm contain keratin fibrils that whorl about the nucleus (Fig. 28-12). The roof of the cleft is formed by a column of compact keratotic material. Similar lesions may occur as an isolated scaly nodule called a "warty dyskeratoma." In the previously mentioned Hailey-Hailey disease, lesions resemble those of Darier disease, albeit with more acantholysis, or keratinocyte dyshesion. This condition is presumably caused by this altered desmosome function, which results in a characteristic "dilapidated brick wall" appearance (Fig. 28-13).

CLINICAL FEATURES: Darier disease first appears late in childhood or in adolescence as skin-colored papules that later become crusted. Affected areas have many warty elevations, 2–4 mm in diameter, largely on the chest, nasolabial folds, back, scalp, forehead, ears and groin.

Psoriasis Is a Proliferative Skin Disease with Persistent Epidermal Hyperplasia

Psoriasis is a chronic, frequently familial disorder that features large, erythematous, scaly plaques, commonly on extensor cutaneous surfaces. It affects 1%–2% of the population worldwide. Psoriasis may arise at any age but shows a peak in late adolescence. Interestingly, the condition is not seen among Native Americans and is infrequent among Asians.

MOLECULAR PATHOGENESIS: The pathogenesis of psoriasis is multifactorial, with genetic, immunologic and environmental factors contributing to the development of psoriatic lesions.

GENETIC FACTORS: Psoriasis unquestionably has a genetic component, although only 1/3 of patients with psoriasis have a family history of the disease. The more severe the illness, the greater is the likelihood of a familial background. Several observations support the notion that psoriasis may in part be heritable: (1) increased incidence among relatives and offspring of patients with psoriasis; (2) 65% concordance for psoriasis in monozygotic twins; and (3) increased prevalence with certain HLA haplotypes, especially HLA-B13, HLA-B17,

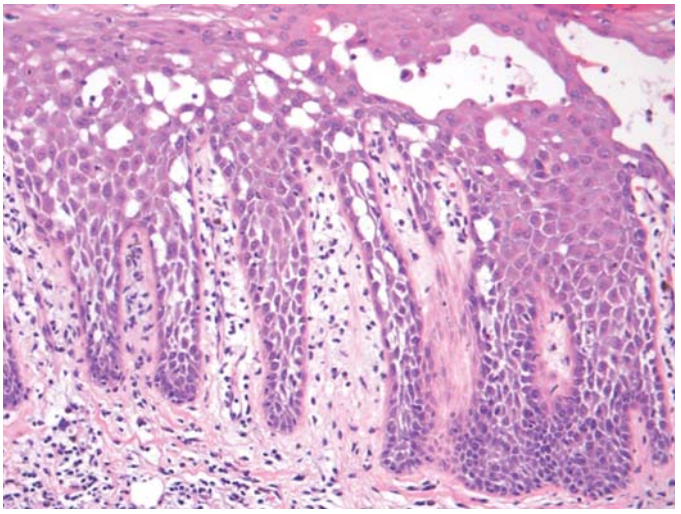

FIGURE 28-13. Hailey-Hailey disease. Hailey-Hailey disease shows acantholysis of the epidermis with dyskeratosis of keratinocytes, yielding a characteristic "dilapidated brick wall" appearance on histology.

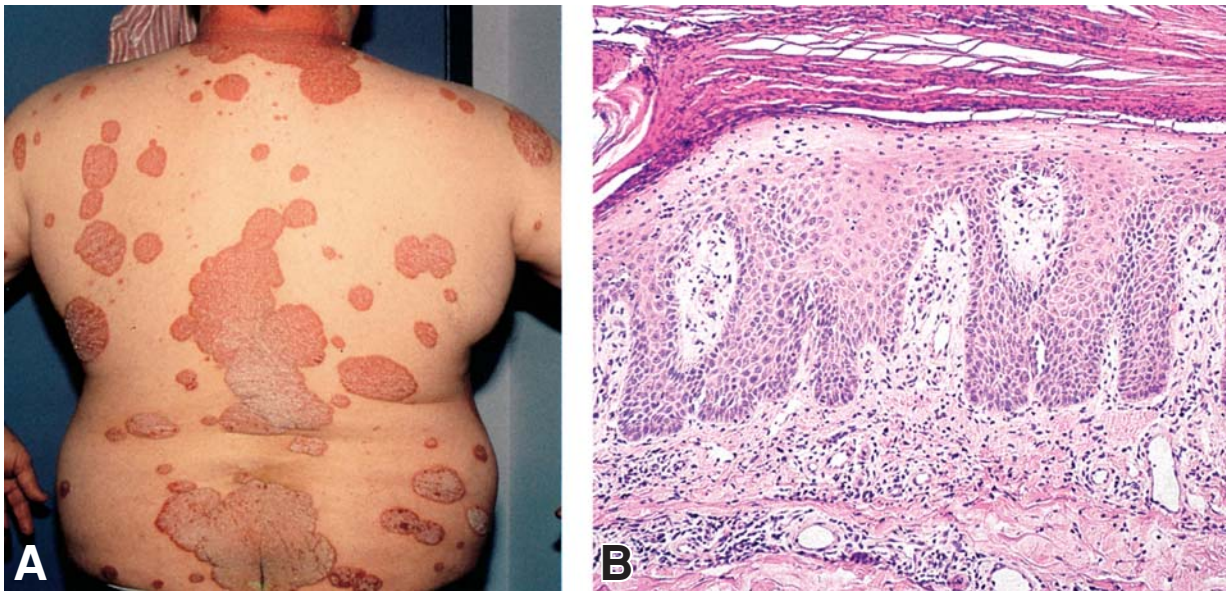

FIGURE 28-14. Psoriasis. This disorder is the prototype of psoriasiform epidermal hyperplasia. **A.** A patient with psoriasis shows large, confluent, sharply demarcated, erythematous plaques on the trunk. **B.** Microscopic examination of a lesion demonstrates that the rete ridges are uniformly elongated, as are the dermal papillae, giving an interlocking pattern of alternately reversed "clubs." The dermal papillae are edematous and reside beneath a thinned epidermis (suprapapillary thinning). There is striking parakeratosis, which is the scale observed clinically.

HLA-Bw57 and particularly HLA-Cw6. In fact, people with HLA-Cw6 are 10–15 times more likely to develop psoriasis than the general population. A 300-kb segment in the MHC-I region of chromosome 6p21, PSORS1, is felt to be a major genetic determinant of susceptibility.

IMMUNOLOGIC FACTORS: T lymphocytes are crucial to the pathogenesis of psoriatic lesions. T_H1 and T_H17 cells, subtypes of $CD4^+$ T cells, appear to drive the inflammatory response and subsequent dermatosis. These subsets of T cells, in addition to effector $CD8^+$ T cells and antigen-presenting dendritic cells, secrete proinflammatory cytokines, such as IL-12, IL-17, IL-22, IL-23, interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α), as well as keratinocyte growth factors. The combination of these proinflammatory cytokines and epidermal growth factors likely causes the constellation of changes seen in psoriasis. For these reasons, therapeutics targeting cytokines, such as TNF-α inhibitors, or those targeting IL-12, IL-17 and IL-23 are currently being used.

ENVIRONMENTAL FACTORS: Clinical lesions may occur anywhere on the skin. Stimuli such as physical injury ("Köbner phenomenon"), infection, certain drugs and photosensitivity may produce psoriatic lesions in apparently normal skin. The pathogenesis of psoriatic plaques may be appreciated by contrasting the effect of chronic cutaneous trauma in people with and without psoriasis. Chronic irritation of normal skin, as in repeated rubbing, produces a tough, scaly, cutaneous plaque that is clinically and histologically psoriasiform. However, the lesion disappears when the trauma ceases. In psoriatic patients, even less trauma generates psoriatic plaques that may persist for years after an initial injury.

PATHOLOGY: The most distinctive pathology is at the edges of chronic psoriatic plaques. The epidermis is thickened, with **hyperkeratosis** and **parakeratosis** (persistence of nuclei in cells of the stratum corneum, which occurs with increased epidermal turnover). Parakeratosis may be circumscribed and focal, or it may be diffuse, in which case the granular layer is diminished or absent. The nucleated layers of the epidermis are thickened severalfold in the rete pegs and are frequently thinner over dermal papillae (Fig. 28-14). In turn, the papillae are elongated and appear as sections of cones, with their apices toward the dermis. In chronic lesions, dermal papillae may appear as bulbous "clubs" with short handles (Figs. 28-14 and 28-15). The rete ridges of the epidermis have a profile reciprocal to that of the dermal papillae, resulting in interlocked dermal and epidermal "clubs," with alternately reversed polarity. Capillaries of dermal papillae are dilated and tortuous (Fig. 28-15). In very early lesions, changes may be limited to capillary dilation, with a few neutrophils "squirting" into the epidermis. Epidermal hyperplasia and hyperkeratosis occur mainly in chronic lesions.

Ultrastructurally, the capillaries are venule-like; neutrophils may emerge at their tips and migrate into the epidermis above the apices of the papillae. Neutrophils may become localized in the epidermal spinous layer or in small microabscesses (of Munro) in the stratum corneum and may be associated with limited areas of parakeratosis (Fig. 28-16). The dermis below the papillae contains variable mononuclear inflammation, mostly lymphocytes, around the superficial vascular plexus. The inflammatory process does not extend into the subjacent reticular dermis.

The psoriasiform histology is common in cutaneous pathology. Seborrheic dermatitis, reaction to chronic trauma (lichen simplex chronicus), subacute and chronic spongiotic dermatitis (eczema) and cutaneous T-cell lymphoma (mycosis fungoides) all may exhibit such change. However, these usually do not mimic psoriasis precisely.

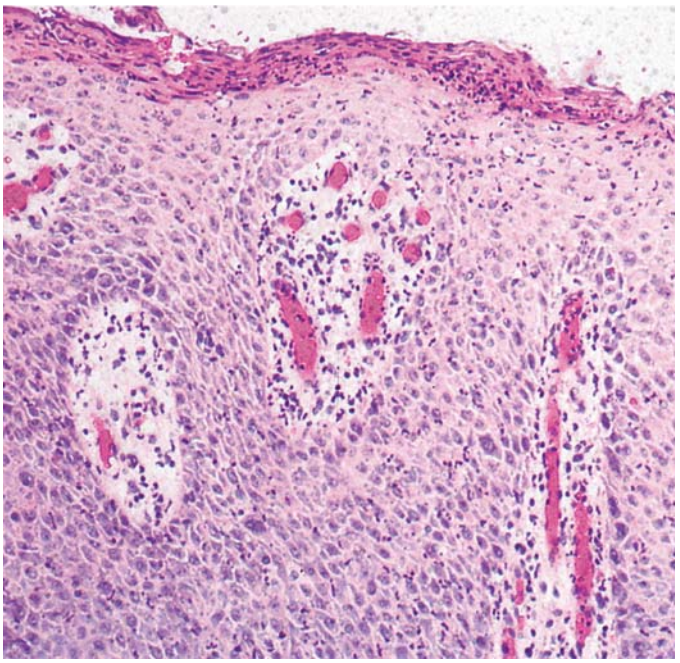

FIGURE 28-15. Psoriasis. The clubbed papillae contain tortuous dilated venules. The prominent venules are part of the venulization of capillaries, which may be of histogenetic importance in psoriasis. The papilla to the *right* has one cross-section of its superficial capillary venule loop, which is normal. The papilla in the *center* shows numerous cross-sections of its venule, indicating striking tortuosity.

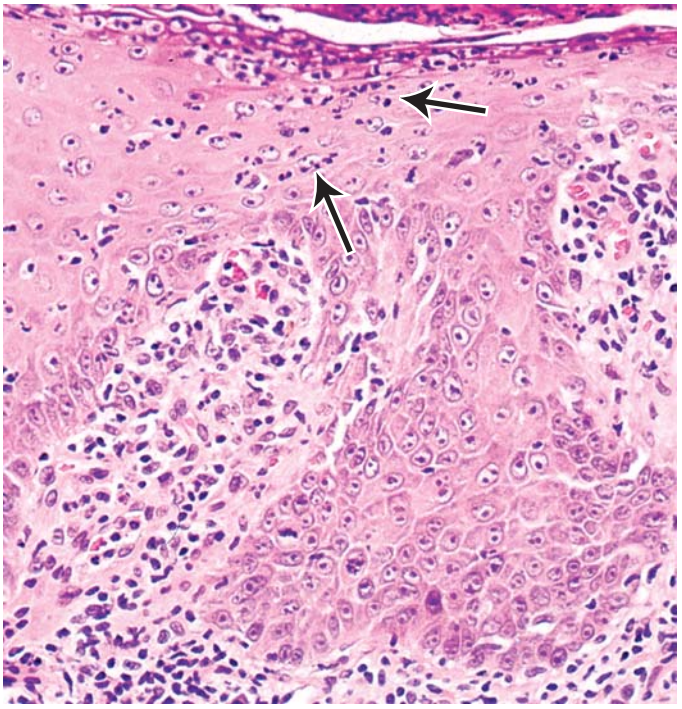

FIGURE 28-16. Psoriasis. Neutrophils migrate into the epidermis, emerging from the venulized capillaries at the tips of the dermal papillae. They migrate to the upper stratum spinosum and stratum corneum (*arrows*). In some forms of psoriasis, pustules are common clinical lesions.

CLINICAL FEATURES: The initial presentation of psoriasis is variable and disease activity is intermittent. Familial psoriasis tends to be more severe than sporadic types, but disease severity varies from annoying scaly lesions over the elbows to a serious debilitating disorder involving most of the skin and often associated with arthritis. A single lesion of psoriasis may be a small focus of scaly erythema or an enormous confluent plaque covering much of the trunk (Fig. 28-14A). A typical plaque is 4–5 cm, sharply demarcated at its margin and covered by a surface of silvery scales. If the scales are detached, pinpoint foci of bleeding from the dilated capillaries in the dermal papillae dot the underlying glossy erythematous surface ("Auspitz sign").

Seronegative arthritis develops in 7% of patients with psoriasis. The tendency to arthropathy is linked to several HLA haplotypes, particularly HLA-B27. Psoriatic arthritis closely resembles its rheumatoid counterpart, but it is usually milder and causes little disability.

In some variations of the disease, neutrophilic pustules (of Kogoj) dominate **(pustular psoriasis)**. Severe intractable psoriasis has been observed in some patients with AIDS.

Psoriasis has long been treated with coal tar or wood tar derivatives and anthralin, a strong reducing agent. Topical and systemic corticosteroids have also been used. Severe, generalized psoriasis justifies systemic treatment with methotrexate. Phototherapy ("PUVA") after administration of psoralens, a UV-absorbing compound that binds to DNA, is often effective. Synthetic vitamin A and vitamin D derivatives have also been used. More recently, treatments that target immunologic and inflammatory mediators have been used, such as anticytokine therapeutics (see above), with promising results.

Pemphigus Vulgaris Is a Blistering Disease Due to Antibodies to Keratinocytes

Dyshesive disorders are cutaneous diseases in which blisters form because of diminished cohesiveness between epidermal keratinocytes. Pemphigus vulgaris (PV) (Greek, *pemphix*, "bubble"), the prototype of dyshesive diseases, is a chronic, blistering skin disorder that is most common in people 40–60 years old but is seen at all ages, including children. All races are susceptible, but people of Jewish or Mediterranean heritage are at greatest risk.

MOLECULAR PATHOGENESIS: PV is an autoimmune disease: patients have circulating IgG against an epidermal surface antigen, **desmoglein 3,** a desmosomal protein. Antigen–antibody union results in dyshesion, which is augmented by release of plasminogen activator and, hence, activation of plasmin. This proteolytic enzyme acts on the intercellular substance and may be the dominant factor in dyshesion. Internalization of pemphigus antigen–antibody complexes, disappearance of attachment plaques and retraction of perinuclear tonofilaments may all act in concert with proteinases to cause dyshesion and vesiculation (Fig. 28-17). Blisters in PV are intraepidermal. In other blistering disorders that affect the basement membrane zone, discussed below, subepidermal blisters are formed.

PATHOLOGY: The outer epidermal layers separate from the basal layer. This suprabasal dyshesion results in a blister with an intact basal layer as

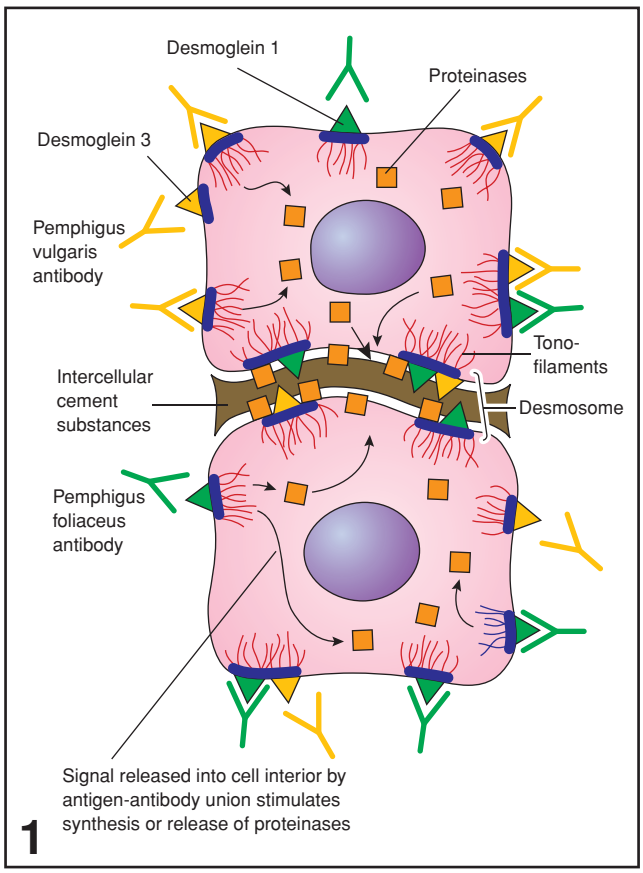

FIGURE 28-17. Pemphigus vulgaris. A pathogenetic mechanism of suprabasal dyshesion is shown. **1.** A circulating autoantibody binds to an antigen on the outer leaflet of the plasma membrane (desmosome) of the keratinocyte, especially in the basal regions. **2.** Antigen–antibody union results in release of a proteinase (plasmin). **3.** The proteinase interacts with intercellular cement, initiating dyshesion. (*continued*)

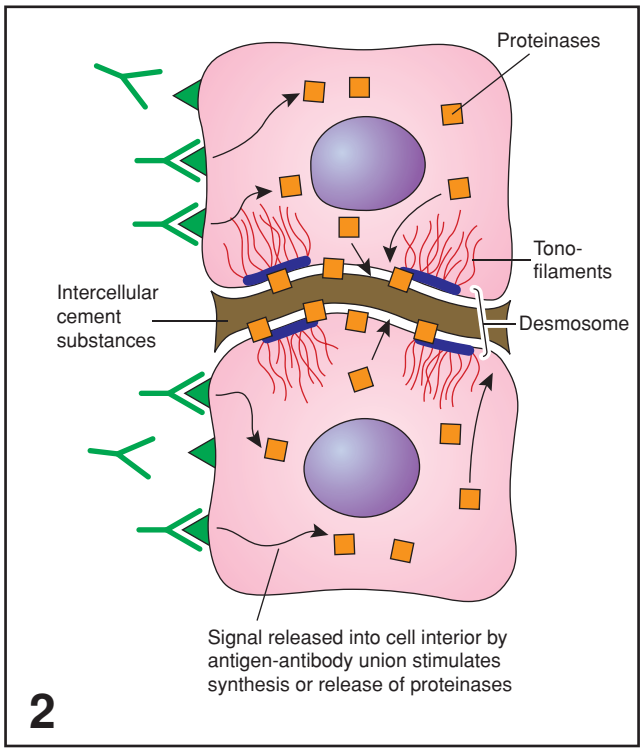

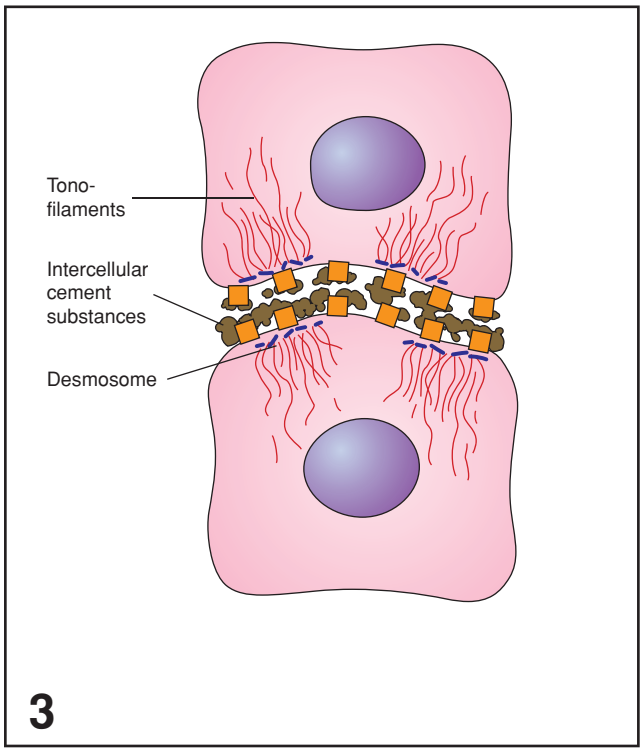

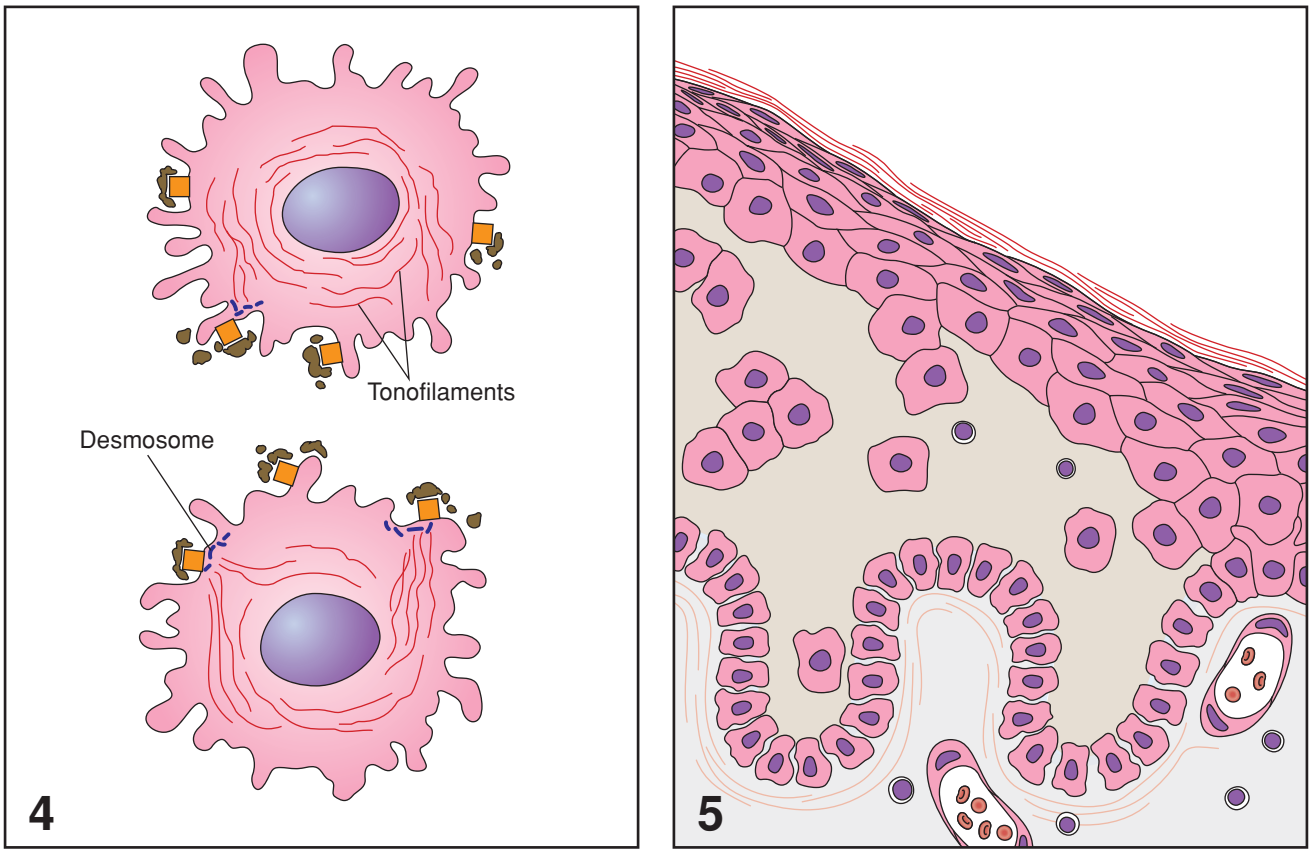

FIGURE 28-17. (*Continued*) **4.** Desmosomes deteriorate, tonofilaments clump about the nucleus, the cells round up and separation is complete. **5.** A vesicle, which is usually suprabasal, forms. Alternatively, acantholysis may occur by direct interference with desmosomal and adherence junction attachments.

a floor and the remaining epidermis as a roof (Fig. 28-18). Desmoglein 3 is concentrated in the lower epidermis, explaining the location of the blister. The blister contains moderate numbers of lymphocytes, macrophages, eosinophils and neutrophils. Distinctive, rounded keratinocytes, or acantholytic cells, are shed into the vesicle during dyshesion. Basal cells remain adherent to the basal lamina and form a layer of "tombstone cells." Dyshesion may extend along dermal adnexa and is not always strictly suprabasal. The subjacent dermis shows a moderate infiltrate of lymphocytes, macrophages, eosinophils and neutrophils, predominantly around the capillary venular bed.

CLINICAL FEATURES: The characteristic lesion of PV is a large, easily ruptured blister that leaves extensive denuded or crusted areas. They are most common on the scalp and mucous membranes and in periumbilical and intertriginous areas. Without corticosteroid treatment, PV is progressive and usually fatal. Much of the skin surface may become denuded. Immunosuppression is also useful for maintenance therapy. With appropriate treatment, the 10-year mortality rate for PV is less than 10%.

Other diseases caused by dyshesion that have pathogenetic mechanisms like PV include **pemphigus foliaceus, pemphigus erythematosus** and **drug-induced pemphigus** (mostly associated with penicillamine or captopril). In pemphigus foliaceus, antibodies against **desmoglein 1,** a desmosomal protein, cause dyshesion in the outer spinous and granular epidermal layers (vs. suprabasal dyshesion in PV) (Fig. 28-19). In pemphigus foliaceus and pemphigus erythematosus, dyshesion is in the spinous layer. **Paraneoplastic pemphigus** may occur with some cancers, usually lymphoproliferative tumors, and shows variable patterns of dyshesion and antigenic targets.

Pemphigus may accompany other autoimmune diseases, such as myasthenia gravis and lupus erythematosus, and may also be seen with benign thymomas. Other diseases may mimic the histology of PV, namely, familial benign chronic pemphigus (Hailey-Hailey disease) and transient acantholytic dermatosis (Grover disease). However, IgG antibodies do not react with epidermal antigens in these entities.

DISEASES OF THE BASEMENT MEMBRANE ZONE (DERMAL–EPIDERMAL INTERFACE)

In Epidermolysis Bullosa Blisters Form in the Basement Membrane Zone

Epidermolysis bullosa (EB) is a heterogeneous group of disorders loosely bound by their hereditary nature and by a tendency to form blisters at the sites of minor trauma. The clinical spectrum ranges from a minor annoyance to a widespread, life-threatening blistering disease. ***These blisters are almost always present at birth or shortly thereafter.*** The classification of these disorders is based on a combination of clinical features and site of blister formation in the BMZ. The different mechanisms of blister

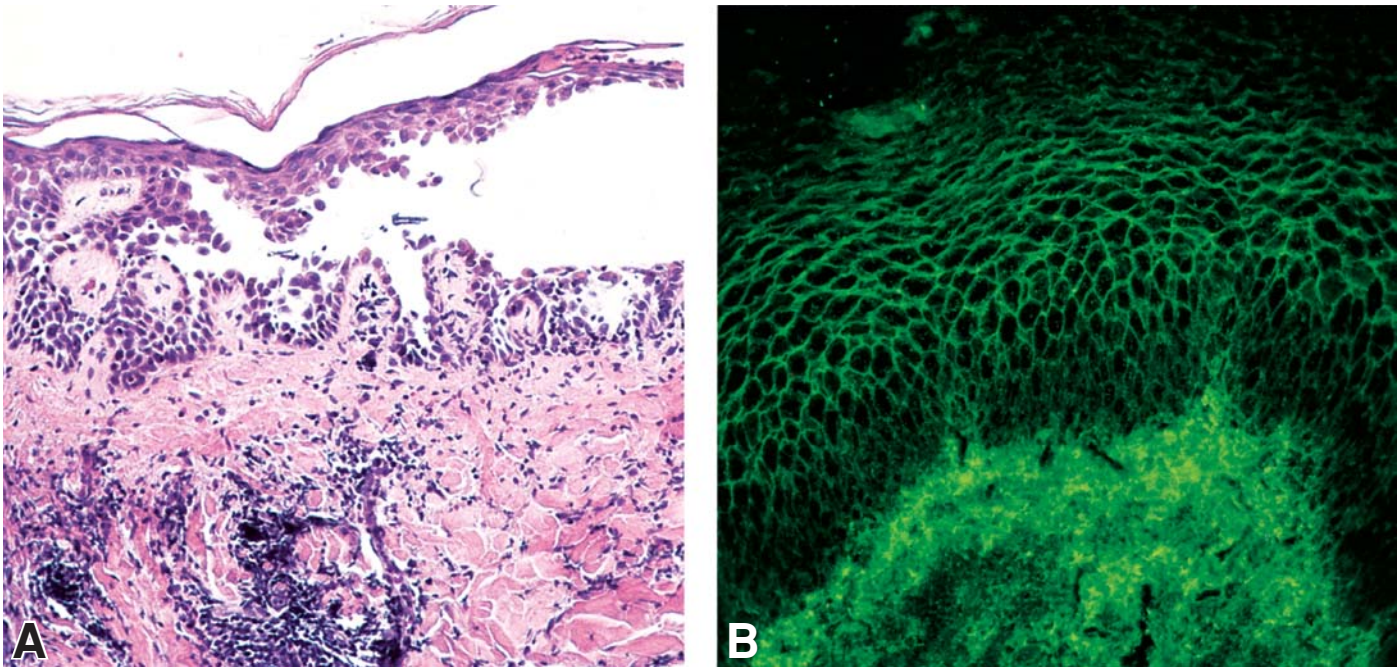

FIGURE 28-18. Pemphigus vulgaris. A. Suprabasal dyshesion leads to an intraepidermal blister containing acantholytic keratinocytes. The basal keratinocytes are slightly separated from each other and totally separated from the stratum spinosum. The basal keratinocytes are firmly attached to the epidermal basement membrane zone. **B.** Direct immunofluorescence examination of perilesional skin reveals antibodies, usually of the immunoglobulin G (IgG) type, deposited in the intercellular substance of the epidermis, yielding a lace-like pattern outlining the keratinocytes.

formation underlie each of the four major categories of EB (Fig. 28-20).

Epidermolytic Epidermolysis Bullosa

This disorder, also known as **EB simplex,** is a group of autosomal dominant and autosomal recessive skin diseases in which blisters form owing to disruption of basal keratinocytes. Blisters develop after minor trauma, such as merely rubbing the skin, but heal without scarring (thus the term "simplex"). Epidermolytic EB is cosmetically disturbing and sometimes debilitating but is not life-threatening.

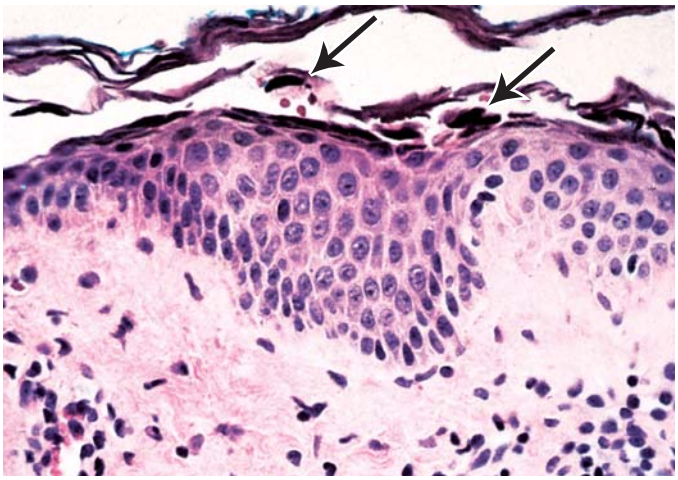

FIGURE 28-19. Pemphigus foliaceus. The dyshesion develops in the outer stratum spinosum and stratum granulosum. (Compare with that of pemphigus vulgaris, Fig. 24-18.) Dyshesive and dyskeratotic keratinocytes of the stratum granulosum (*arrows*) are important hallmarks.

MOLECULAR PATHOGENESIS: Epidermolytic EB has been attributed to mutations of genes encoding cytokeratin intermediate filaments (12q11-13, 17q21), which provide mechanical stability to the epidermis. Cytolysis of basal keratinocytes causes the blisters in the epidermolytic variety of EB. Initially, small, subnuclear, cytoplasmic vacuoles develop, enlarge and coalesce. They reflect abnormalities in keratins 5 and 14, which aggregate about the keratinocyte nuclei. The plasma membrane ruptures when the large vacuole reaches it, after which the cell is lysed.

PATHOLOGY: An intraepidermal vesicle results from lysis of several basal keratinocytes. The roof of the vesicle is an almost intact epidermis with a fragmented basal layer. The vesicle floor shows bits of basal cell cytoplasm attached to the lamina densa, which appears as a well-preserved pink line at the base of the vesicle. Inflammatory cells are sparse.

Junctional Epidermolysis Bullosa

This type of EB is a group of autosomal recessive skin diseases in which blisters form within the lamina lucida. Clinical expression ranges from a benign disease with no effect on life span to a severe condition that may be fatal within the first 2 years of life. There may be associated abnormalities of the nails and teeth.

MOLECULAR PATHOGENESIS: In the severe form, mutations in the genes for certain isoforms of laminin and the integrins are reported (1q25-31,

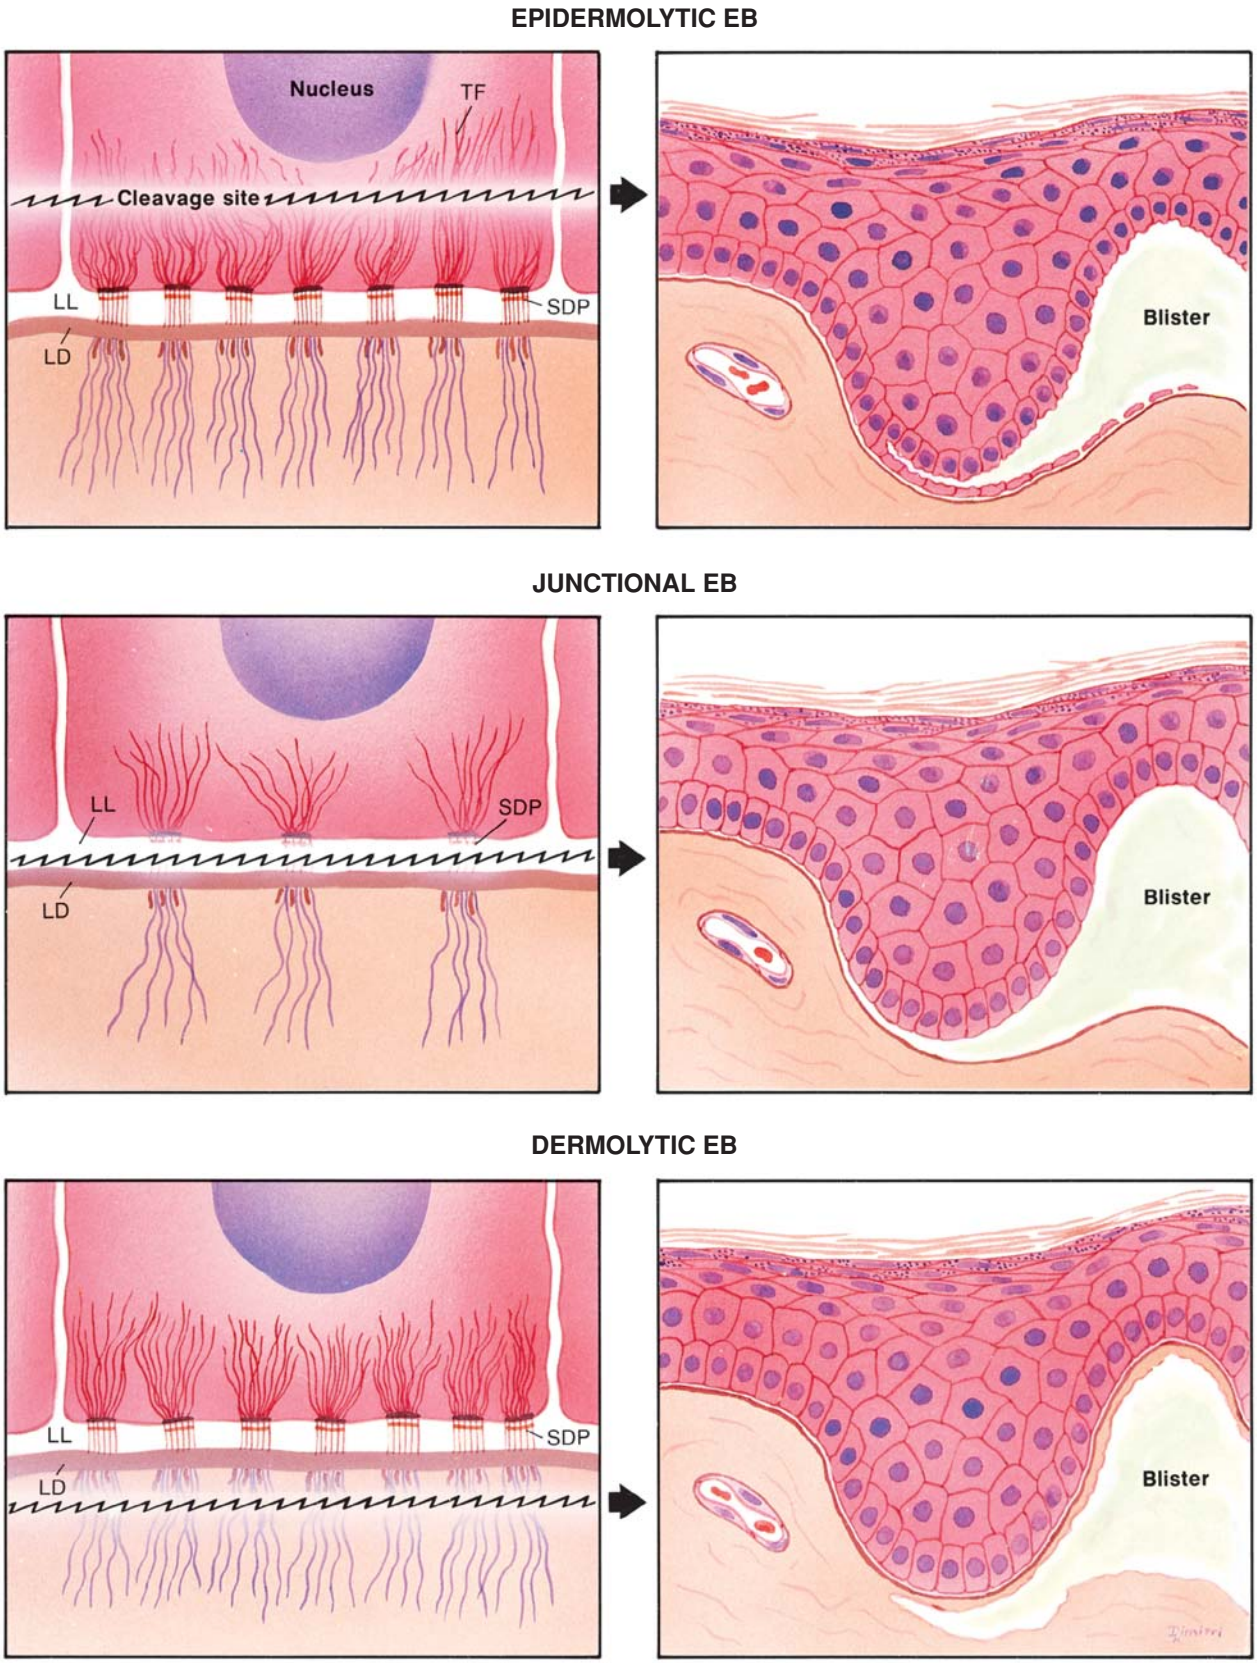

FIGURE 28-20. Epidermolysis bullosa (EB). Three distinct mechanisms of blister formation are shown. Electron microscopic images are diagrammed on the *left;* light microscopic images are on the *right.* **Epidermolytic EB** is caused by disintegration of the lowermost regions of the epidermal basal cells. The bottom portions of the basal cells cleave, and the remainder of the epidermis lifts away. Small fragments of basal cells remain attached to the basement membrane zone. **Junctional EB** is characterized by cleavage in the lamina lucida. **Dermolytic EB** is associated with rudimentary and fragmented anchoring fibrils. The entire basement membrane zone and epidermis split away from the dermis in relationship to these flawed anchoring fibrils. *LL* = lamina lucida; *LD* = lamina densa; *SDP* = subdesmosomal dense plate.

1q3, 18q11). The benign form reflects mutations in the gene for type XVII collagen (1q32, 10q23). Both types heal without scarring but may cause residual atrophy of the skin.

PATHOLOGY: An intact epidermis forms the roof of the vesicle in junctional EB. Plasma membranes of basal keratinocytes are unchanged. The vesicle floor is an intact lamina densa, as in epidermolytic EB, but there are no attached fragments of basal cell cytoplasm. The blister is thus within the lamina lucida. Both lesional and uninvolved skin shows fewer basal hemidesmosomes, which have poorly developed attachment plaques and subbasal dense plates.

Dermolytic Epidermolysis Bullosa

Also known as **dystrophic EB,** dermolytic EB is a group of autosomal dominant and autosomal recessive diseases in which blisters are immediately deep to the lamina densa. The recessive variant is more severe. In both types, healed blisters show atrophic ("dystrophic") scarring. Nails and teeth may be involved.

MOLECULAR PATHOGENESIS: Dermolytic EB is attributed to a defect in anchoring fibrils. These fibrils are abnormally arranged and reduced in number in apparently normal skin of affected newborns. The basic defect is a mutation in the gene for collagen type VII (3p21). Anchoring fibrils make up a net in the upper dermis, through which collagen types I and III fibers course. This structure anchors the epidermis to the underlying dermis. Its disruption results in subepidermal bullae arising in the sublamina densa zone.

PATHOLOGY: The vesicle roof is normal epidermis with an attached, intact lamina lucida and lamina densa. The base of the vesicle is the outer part of the papillary dermis. Ultrastructurally, there are fewer anchoring fibrils in the dominant type and virtually none in the recessive form. A corresponding decrease in anchoring fibril proteins AF-1 and AF-2 occurs in the two variants.

Kindler Syndrome

This type of EB shows autosomal recessive transmission and blisters with mixed cleavage planes. Distinctive clinical findings that differentiate it from other inherited EB types include poikiloderma (mottled pigmentation of the skin) and photosensitivity.

MOLECULAR PATHOGENESIS: This entity results from a mutation in FERMT1 (20p12), which encodes kindlin-1, a protein involved in adhesion between basal keratinocytes.

Bullous Pemphigoid Is a Subepidermal Blistering Disease Caused by Autoantibodies against Basement Membrane Proteins

BP is a common, autoimmune, blistering disease, which has clinical similarities to PV (hence the term "pemphigoid"), but which lacks acantholysis. The disease is most common in the later decades of life and affects all races and both genders.

MOLECULAR PATHOGENESIS: Like PV, BP is an autoimmune disease, but here complement-fixing IgG antibodies are against BPAG1 and BPAG2 basement membrane proteins. BPAG1 is a 230-kd protein in the intracellular portion of the basal cell hemidesmosome. BPAG2 is a 180-kd protein that traverses the plasma membrane and extends into the upper lamina lucida. The antigen–antibody complex may injure the basal cell plasma membrane via the C5b–C9 membrane attack complex (see Chapter 4). This damage may in turn interfere with elaboration of adherence factors by basal keratinocytes. More importantly, anaphylatoxins C3a and C5a are released in complement activation. They trigger mast cell degranulation and release of factors chemotactic for eosinophils, neutrophils and lymphocytes. Levels of IL-5 and eotaxin, which play significant roles in recruitment and function of eosinophils, are elevated in the blister fluid of patients with BP. Eosinophil granules contain tissue-damaging substances, including eosinophil peroxidase and major basic protein. These molecules, together with neutrophil and mast cell proteases, cause dermal–epidermal separation within the lamina lucida (Fig. 28-21).

PATHOLOGY: The blisters of BP are subepidermal; the roof is intact epidermis and the base is the lamina densa of the BMZ (Fig. 28-22). The blisters contain many eosinophils, plus fibrin, lymphocytes and neutrophils. In BP, apparently normal skin shows migration of mast cells from the venule toward the epidermis. With the onset of erythema, eosinophils appear in the upper dermis and may be arrayed along the epidermal BMZ. Ultrastructurally, dermal–epidermal separation begins with disruption of anchoring filaments of the lamina lucida. Immunofluorescence shows linear deposition of C3 and IgG at the epidermal BMZ and serum antibodies against BPAG1 and BPAG2 (Fig. 28-23).

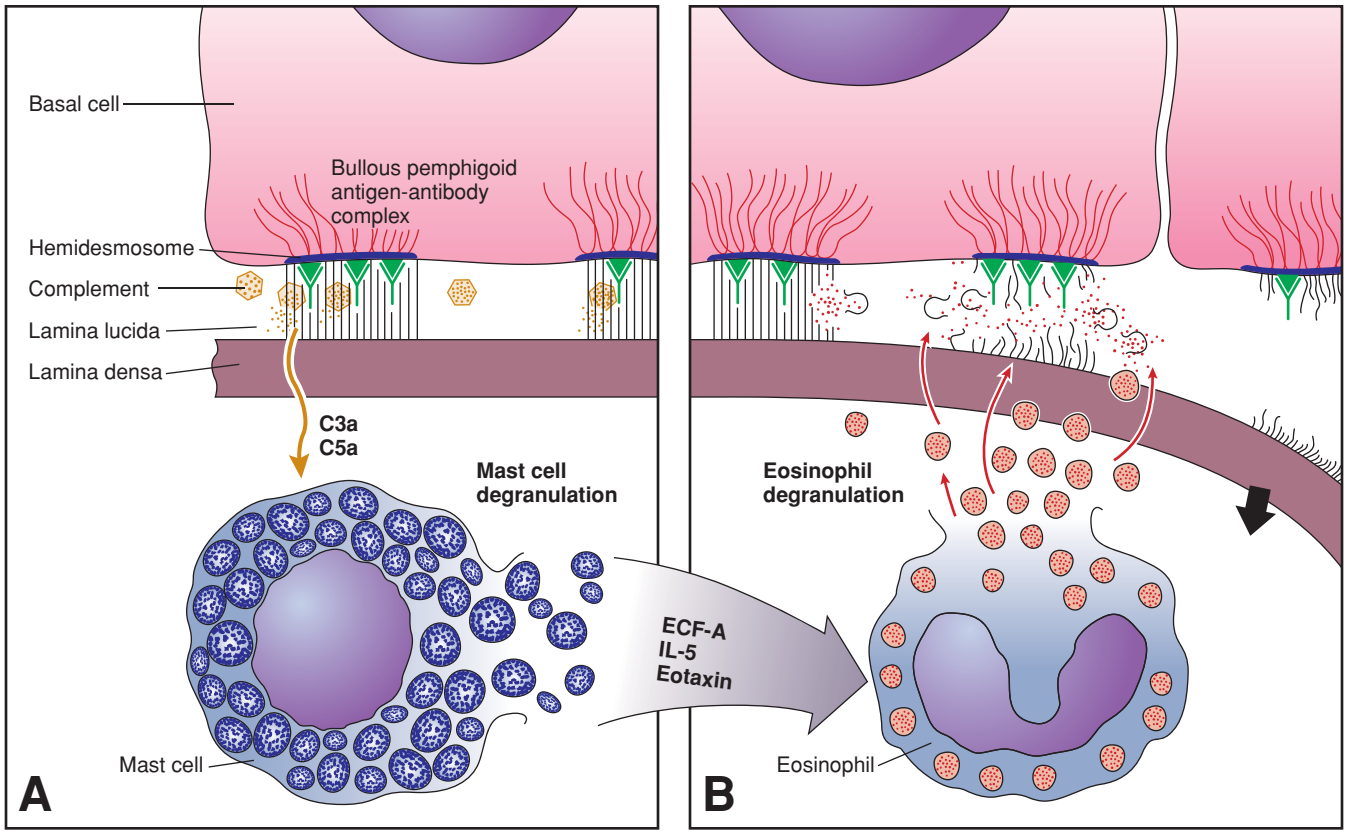
CLINICAL FEATURES: The blisters of BP are large and tense and may appear on normal-appearing skin or on an erythematous base (Fig. 28-22). The medial thighs and flexor aspects of the forearms are commonly affected, but the groin, axillae and other cutaneous sites may also develop blisters. The disease is self-limited but chronic, and the patient's general health is usually unaffected. Systemic glucocorticoid treatment greatly shortens the course of the disease.

Table 28-1 summarizes the molecular pathogenesis of the discussed immunobullous disorders as well acantholytic disorders.

Dermatitis Herpetiformis Reflects Gluten Sensitivity and Immune Complex Deposition

Dermatitis herpetiformis (DH) is an intensely pruritic eruption with urticaria-like plaques and small subepidermal vesicles over the extensor surfaces of the body.

MOLECULAR PATHOGENESIS: It accompanies gluten sensitivity in patients with HLA-B8, HLA-DR3 and HLA-DQw2 haplotypes. Although gluten-sensitive enteropathy may be subclinical, most patients will show features of celiac disease on small intestinal biopsy. Gluten is a protein in wheat, barley, rye and oats. DH cutaneous lesions reflect granular deposits of IgA, mainly



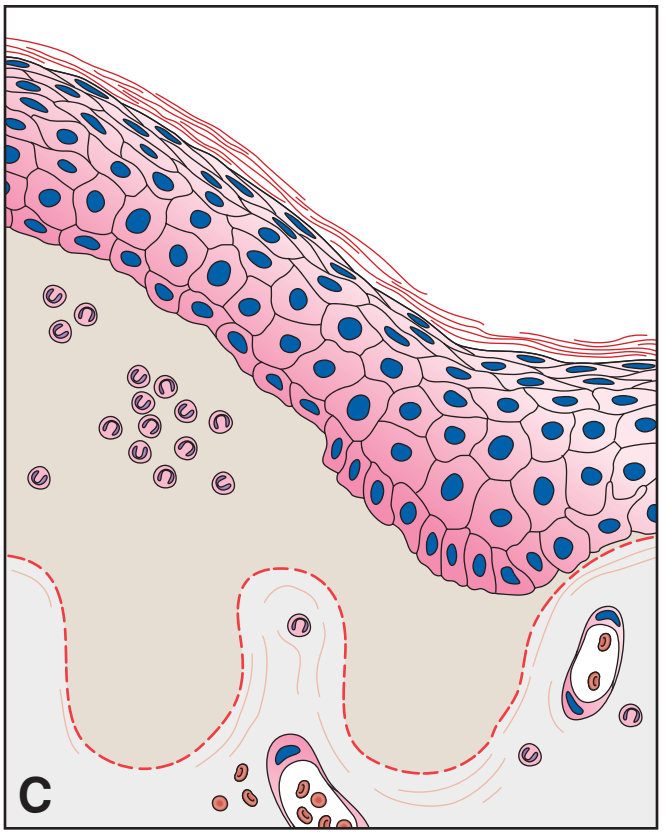


FIGURE 28-21. Bullous pemphigoid (BP). Pathogenetic mechanisms of blister formation are outlined. A circulating antibody to an apparently normal glycoprotein—BP antigen—in the lamina lucida precipitates the pathogenetic events in bullous pemphigoid. **A.** Antigen–antibody union activates complement, and the anaphylatoxins C3a and C5a are produced. These degranulate mast cells, resulting in the release of eosinophilic chemotactic factors. **B, C.** The tissue-damaging substances of eosinophilic granules cause vesicle formation at the lamina lucida, with some breakdown of the lamina densa. *ECF-A* = eosinophil chemotactic factor-A.

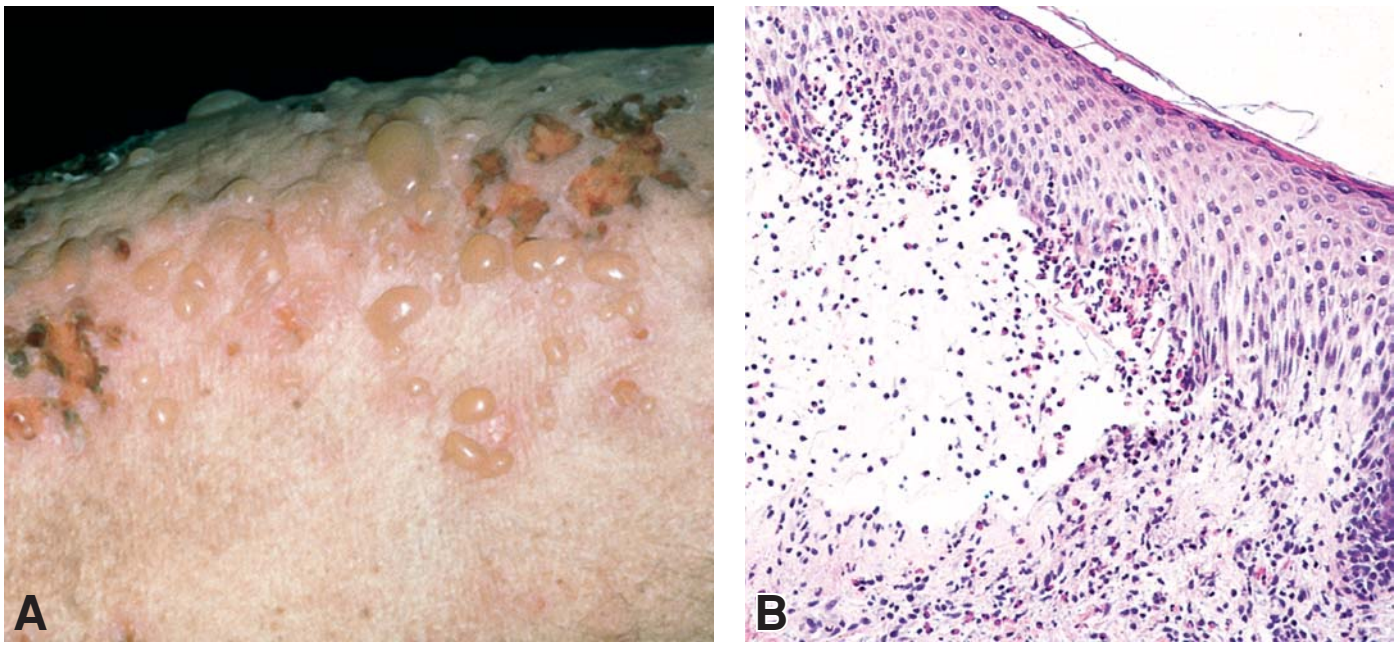

FIGURE 28-22. Bullous pemphigoid. A. The skin shows multiple tense bullae on an erythematous base and erosions, distributed primarily on the medial thighs and trunk. **B.** A subepidermal blister has an edematous papillary dermis as its base. The roof of the blister consists of the intact, entire epidermis, including the stratum basalis. Inflammatory cells, fibrin and fluid fill the blister.

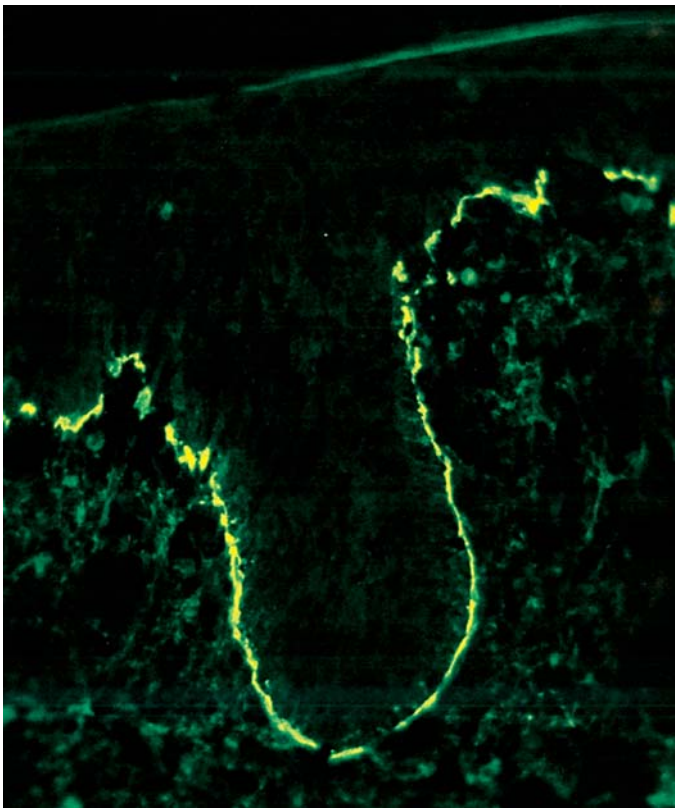

FIGURE 28-23. Bullous pemphigoid. Direct immunofluorescence study discloses linear deposition of immunoglobulin G (IgG) (and C3) along the dermal–epidermal junction. Ultrastructurally, these antibodies and complement are present in the lamina lucida.

at the tips of dermal papillae (Fig. 28-24). Such IgA immune complexes are more prominent in perilesional skin than in normal-appearing skin. Gluten-free diets control the disease; reintroduction of gluten provokes new lesions.

Genetically predisposed patients may develop IgA antibodies to components of gluten in the intestines. Resulting IgA complexes then gain access to the circulation and deposit in the dermal papillae (Fig. 28-24). Patients with DH have increased levels of IgA autoantibodies to tissue transglutaminase, suggesting that there is a dermal autoantigen related to tissue transglutaminase. Antibodies to smooth muscle endomysium are also increased in many patients with DH.

IgA immune complexes do not activate complement efficiently (alternate pathway), and few neutrophils are attracted to the site. However, those neutrophils that do accumulate elaborate leukotrienes, which attract more neutrophils. The neutrophils release lysosomal enzymes that degrade laminin and type IV collagen, cleaving the epidermis from the dermis and eventually causing blisters (Fig. 28-24).

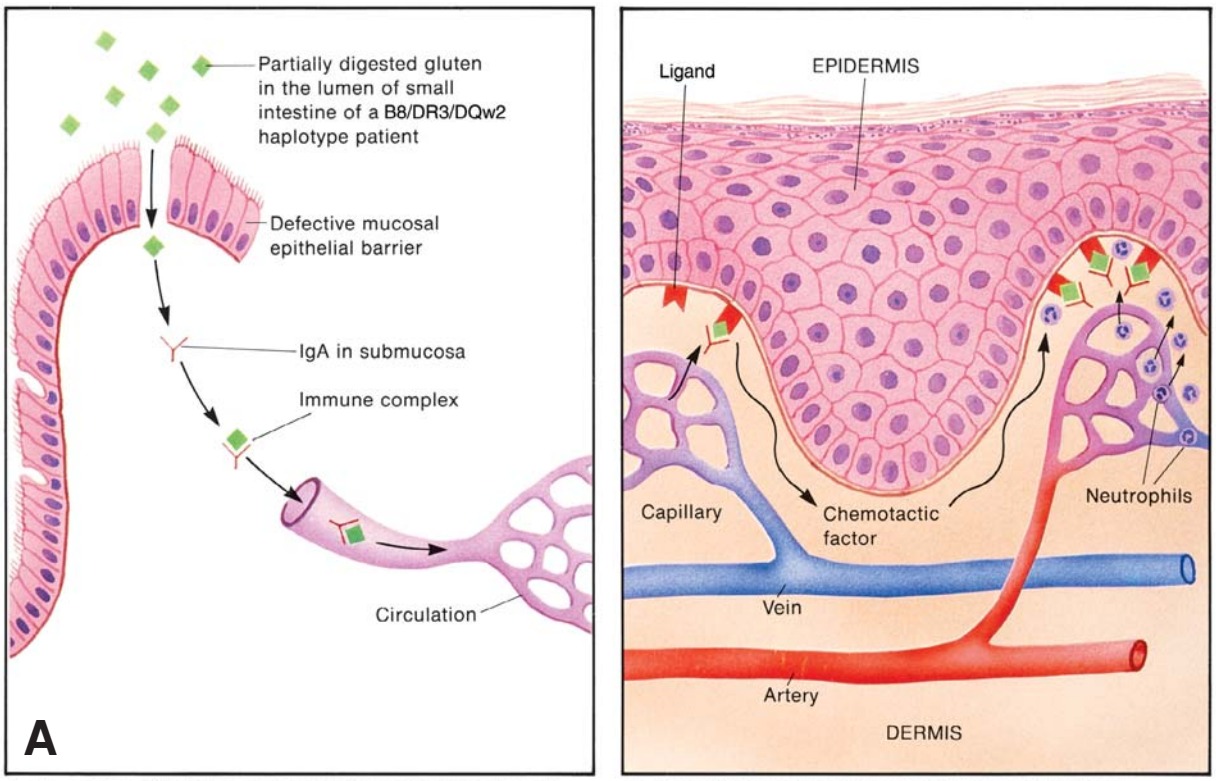
CLINICAL FEATURES: The lesions of DH are especially prominent over the elbows, knees and buttocks (Fig. 28-25A). These intensely pruritic vesicles may become grouped similarly to those of herpes simplex infections (hence, "herpetiformis") and are almost invariably rubbed until broken. Thus, patients may present with only crusted lesions and no intact vesicles. DH is of varying severity and characterized by remissions, but it is disturbingly chronic. Healing lesions often leave scars. Besides a gluten-free diet, dapsone or sulfapyridine may control the signs and symptoms of DH by an unknown mechanism. An increased risk of lymphoproliferative disorders and systemic lupus erythematosus has been reported.

TABLE 28-1
PATHOGENESIS OF IMMUNOBULLOUS AND ACANTHOLYTIC DISORDERS

Condition	Pathogenetic Mechanism	Gene Target	Result
Bullous pemphigoid	Autoantibody against basal cell hemidesmosome	BPAG1, BPAG2	Subepidermal blister
Pemphigus vulgaris	Autoantibody against desmosomal proteins	Desmoglein 1, 3	Intraepidermal blister
Pemphigus foliaceous	Autoantibody against desmosomal proteins	Desmoglein 1	Intraepidermal blister
Epidermolysis bullosa (EB) simplex	Molecular defect in cytokeratin intermediate filaments	KRT5 KRT14	Intraepidermal blister
Junctional EB	Molecular defect in laminin, integrins, collagen	LAMA3, LAMB3, LAMC2, ITGB4, COL17A1	Blister within lamina densa
Dermolytic EB	Molecular defect in anchoring fibrils	COL7A1	Blister below lamina densa
Kindler syndrome	Molecular defect in basal keratinocyte adhesion	KIND1	Blistering, photosensitivity
Darier disease	Molecular defect in keratinocyte adhesion	ATP2A2	Acantholysis, dyskeratosis
Hailey-Hailey disease	Molecular defect in keratinocyte adhesion	ATP2C1	Acantholysis, dyskeratosis

PATHOGENESIS: A delicate perivenular lymphocytic infiltrate appears first, together with a row of neutrophils just deep to the lamina densa in the dermal papillae. During the next 12 hours, neutrophils aggregate in clusters of 10–25 at the tips of the dermal papillae to create a diagnostic histologic appearance.

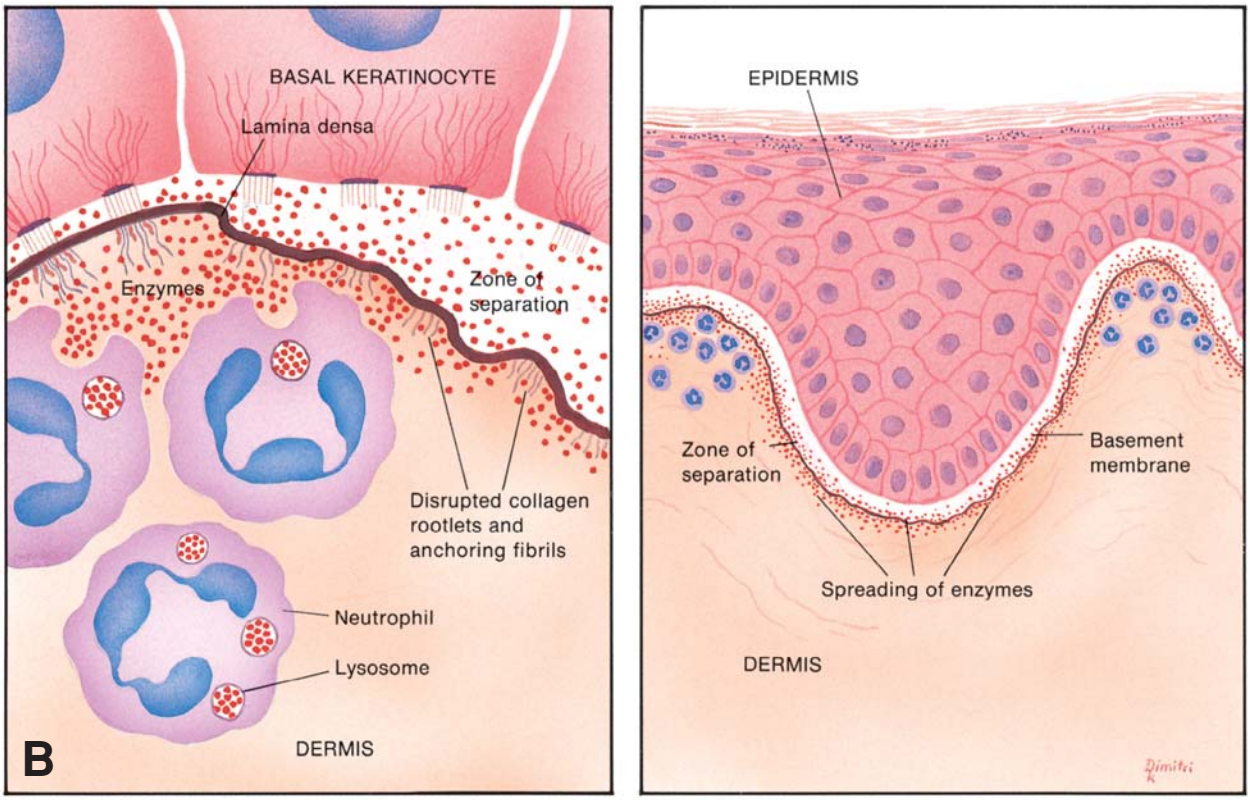
There are two related mechanisms of dermal–epidermal separation. One is associated with the sheet-like spread of a layer or two of neutrophils at the dermal–epidermal interface. In this case, the whole epidermis detaches from the papillary dermis (Fig. 28-25B). The vesicle roof contains the epidermis; the floor is composed of the lamina densa and



1. Formation of immune complexes in submucosa of small intestine. Passage of immune complexes into the circulation.

2. Ligand–immune complex union releases neutrophil chemotactic factor. Neutrophils migrate to the tips of the papillae.

FIGURE 28-24. Dermatitis herpetiformis. Proposed pathogenesis for cutaneous lesions. The disease is initiated in the small intestine and is likely expressed in the skin because of the presence of a ligand immediately deep to the lamina densa. *IgA* = immunoglobulin A.



3. Dissolution of basal rootlets and anchoring fibrils by enzymes released by neutrophils. Early dermo-epidermal separation.

4. Concentration of neutrophils at the tips of the papillae. Spreading of enzymes along basement membrane. Lifting away of lamina densa.

FIGURE 28-24. (*Continued*)

the papillary dermis. Unlike BP, eosinophils are uncommon early in the course of DH. In the second route of vesicle formation, many neutrophils accumulate rapidly in the tips of the dermal papillae. Release of their lysosomal enzymes into the superficial portion of the dermal papillae uncouples the epidermis from the dermis at the tips of dermal papillae, disrupts the BMZ in the lamina lucida and superficial part of the papillae and tears the epidermis across the adjacent rete ridges. Roofs of resulting vesicles have alternating tears across their epidermal covering, and their floors show residual epidermal pegs alternating with the basal half of dermal papillae. In both cases, granular IgA is deposited at the dermoepidermal junction (Fig. 28-25C).

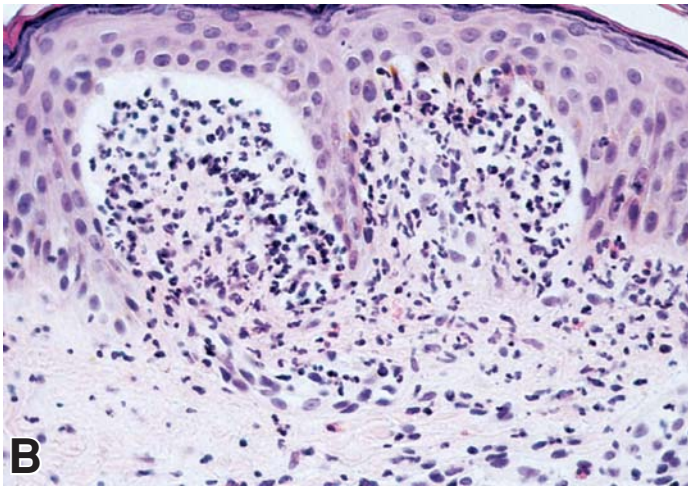
Erythema Multiforme Is Often a Reaction to a Drug or Infection

Erythema multiforme (EM) is an acute, self-limited disorder that varies from a few annular or ring-like and targetoid erythematous macules and blisters (EM minor) to a life-threatening, widespread ulceration of the skin and mucous membranes (EM major; Stevens-Johnson syndrome). ***It is usually a reaction to a drug or an infectious agent, in particular, herpes simplex virus infection.***

ETIOLOGIC FACTORS: A long list of agents may provoke EM, including herpesvirus, *Mycoplasma* and sulfonamides, but precipitating factors are identified in only half of cases. In postherpetic EM, viral antigens, IgM and C3 deposit perivascularly, and at the epidermal BMZ. The combination of infiltrating lymphocytes and antigen–antibody complexes within the lesions suggests that humoral and cellular hypersensitivity are both involved.

PATHOLOGY: The dermis in EM shows a sparse lymphocyte infiltrate about the superficial vascular bed and at the dermal–epidermal interface. The characteristic morphologic feature in the epidermis is apoptotic ("dyskeratotic") keratinocytes, with pyknotic nuclei and eosinophilic cytoplasm. Apoptosis may be extensive and associated with a subepidermal vesicle, whose roof is an almost completely necrotic epidermis. Because of the acute onset of the disease, in most cases there is little or no change in the stratum corneum. The dermis shows perivascular lymphocytic infiltrate, without eosinophils.

CLINICAL FEATURES: The characteristic "target" or "iris" lesions of EM have a central, dark red zone, occasionally with a blister, surrounded by a paler area (Fig. 28-26). In turn, the latter is encompassed by a peripheral red rim. Urticarial plaques are common. The presence of vesicles and bullae usually predicts a more severe course. EM is a common condition, with a peak incidence in the second and third decades of life. It is occasionally encountered in association with other presumably immunologic cutaneous disorders, including erythema nodosum, toxic epidermal necrolysis and necrotizing vasculitis. **Stevens-Johnson syndrome** and **toxic epidermal necrolysis** (TEN) refer to unusually severe forms of EM that involve mucosal surfaces and internal organs and are frequently fatal.



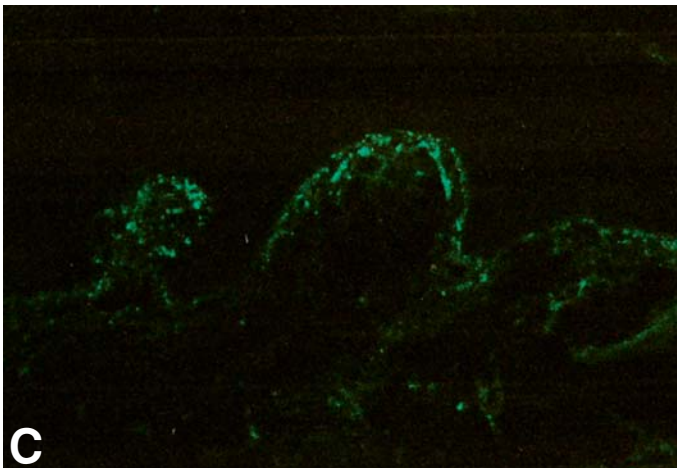


FIGURE 28-25. Dermatitis herpetiformis. A. Pruritic, symmetric, grouped vesicles on an erythematous base are seen on the elbows and knees. **B.** Dermal papillary abscesses of neutrophils with vesicle formation at the dermal–epidermal junction are characteristic. **C.** Direct immunofluorescence reveals immunoglobulin A (IgA) deposited in dermal papillae in association with (but not necessarily directly upon) anchoring fibrils and elastic tissue fibers. This is the site of neutrophil infiltration and subepidermal vesicle formation.

Systemic Lupus Erythematosus Is Characterized by Autoantibodies and Immune Complexes That Deposit in the Skin

Cutaneous involvement in systemic lupus erythematosus (SLE; see Chapter 11) may be severe and cosmetically devastating but is not life-threatening. However, the nature and pattern of immune reactants in the skin are an excellent guide to the likelihood of systemic disease.

FIGURE 28-26. Erythema multiforme. Steroid-responsive "target" papules, characterized by central bullae with surrounding erythema, appeared after antibiotic therapy.

PATHOPHYSIOLOGY: Immune complexes are present in both lesional and normal-appearing skin in SLE. Deposition of immune reactants along the epidermal BMZ of normal-appearing skin is important in making the diagnosis. Epidermal injury seems to be initiated by exogenous agents such as UV light and perpetuated by cell-mediated immune reactions, similar to those in graft-versus-host disease. The manifestations of epidermal injury include vacuolization of basal keratinocytes, hyperkeratosis and diminished epidermal thickness, release of DNA and other nuclear and cytoplasmic antigens to the circulation and deposition of DNA and other antigens in the epidermal BMZ (lamina densa and immediately subjacent dermis) (Fig. 28-27). Thus, epidermal injury, local immune complex formation, deposition of circulating immune complexes and lymphocyte-induced cellular injury all seem to act in concert.

The various forms of cutaneous lupus are classified according to their chronicity, but considerable overlap in features is possible. There is an inverse relationship between the prominence of skin lesions and the extent of systemic disease.

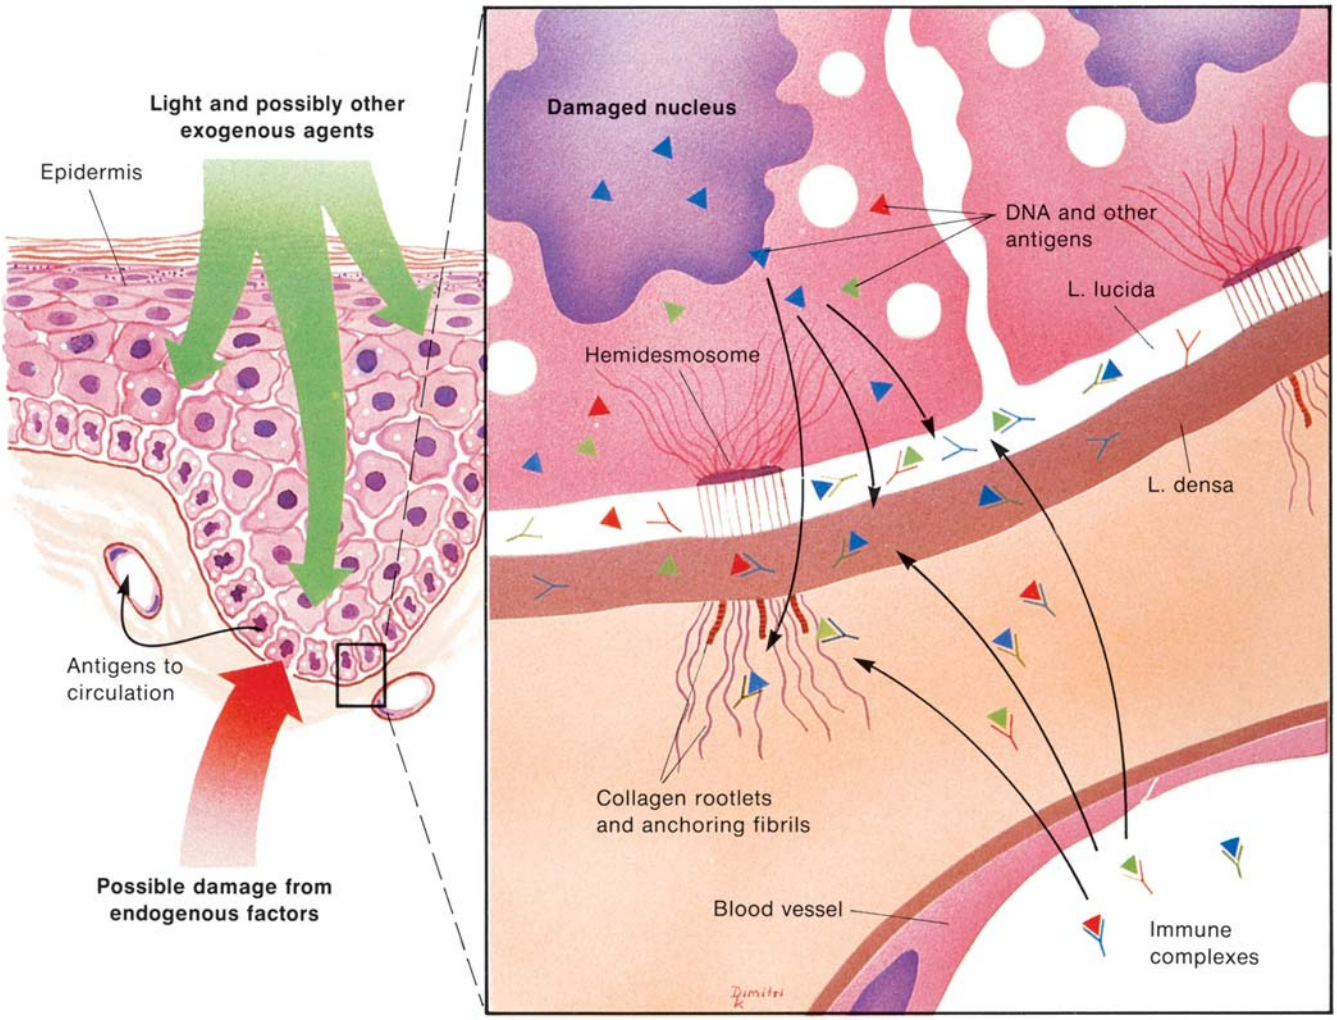

FIGURE 28-27. Lupus erythematosus. A cell-mediated immune reaction leads to epidermal cellular damage when initiated by light or other exogenous agents as well as endogenous ones. Such injury releases a large number of antigens, some of which may return to the skin in the form of immune complexes. Immune complexes are also formed in the skin by a reaction of local DNA with antibody that may also be deposited beneath the epidermal basement membrane zone. *L* = lamina.

CHRONIC CUTANEOUS (DISCOID) LUPUS ERYTHEMATOSUS: This form of lupus is usually limited to the skin. It generally affects skin above the neck, on the face (especially the malar area), scalp and ears. Lesions begin as slightly elevated violaceous papules with a rough scale of keratin. They enlarge to assume a disc shape, with a hyperkeratotic margin and a depigmented center. The cutaneous lesions may culminate in disfiguring scars. Elevated circulating antinuclear antibody (ANA) levels are seen in under 10% of patients.

PATHOLOGY: In discoid lupus, nucleated epidermal layers are modestly thickened or somewhat thin. Hyperkeratosis, without prominent parakeratosis, and plugging of hair follicles are prominent. The rete–papillae pattern of the dermal–epidermal interface is partially effaced. Basal keratinocytes are vacuolated, and eosinophilic apoptotic bodies are noted. The lamina densa is greatly thickened and reduplicated. On periodic acid–Schiff (PAS) staining, multiple layers of lamina densa extend into the subjacent dermis. The excessive quantity of lamina densa, a product of the basal keratinocytes, reflects a response of basal cells to damage. These changes all suggest that injury to basal keratinocytes is an essential pathogenetic characteristic of skin disease associated with lupus (Figs. 28-28, 28-29 and 28-30).

The basal keratinocytes and BMZ contain a diffuse lymphocytic infiltrate that penetrates the basal layer focally. Deeper in the dermis, dense patches of helper and cytotoxic/suppressor T lymphocytes, often with plasma cells, are commonly found around skin appendages. Immune complexes are mainly deep to the lamina densa but also occur as granular deposits on the lamina densa and within the lamina lucida. This pattern contrasts with that of BP in which there are only two antigens, both in the lamina lucida and characterized by a linear staining pattern.

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS: This disorder primarily afflicts young and middle-aged white women. Unlike discoid lupus, subacute cutaneous lupus may also involve the musculoskeletal system and kidneys. Initially, scaly erythematous papules develop and then enlarge into psoriasiform or annular lesions, which may fuse. Skin changes occur in the upper chest, upper back and extensor surfaces of the arms, suggesting that light exposure plays a role in the pathogenesis of the disorder. Significant scarring does not occur. About 70% of patients

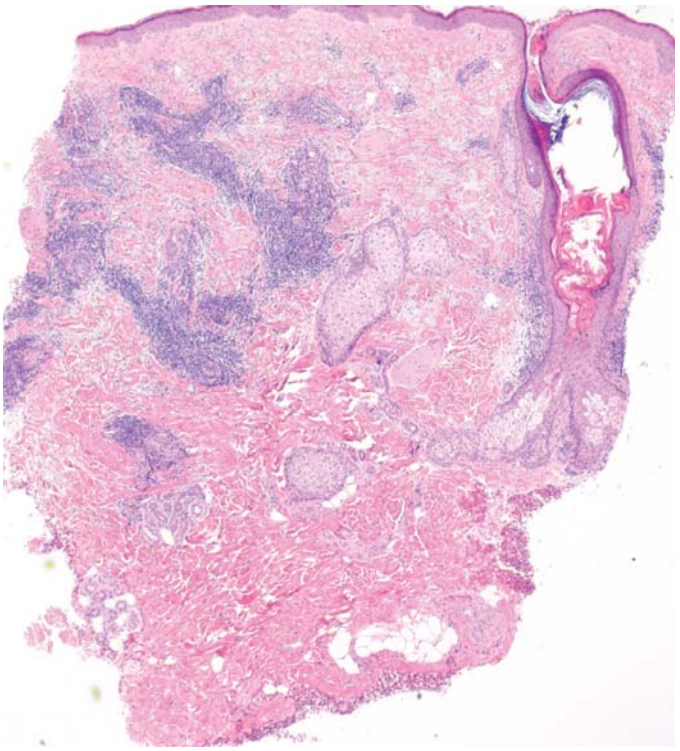

FIGURE 28-28. Lupus erythematosus. Perivascular and periappendageal lymphocytic inflammation is present in the superficial and deep dermis. A hair follicle plugged with keratin is present near the right edge.

have circulating anti-Ro (SS-A) antibodies. ANA levels are elevated in 70%.

PATHOLOGY: Subacute cutaneous lupus features edema of the papillary dermis, thickening of the lamina densa and prominent vacuolar degeneration of basilar keratinocytes. Although there is some lymphocytic infiltration of the BMZ, deeper patches of lymphocytes are not observed.

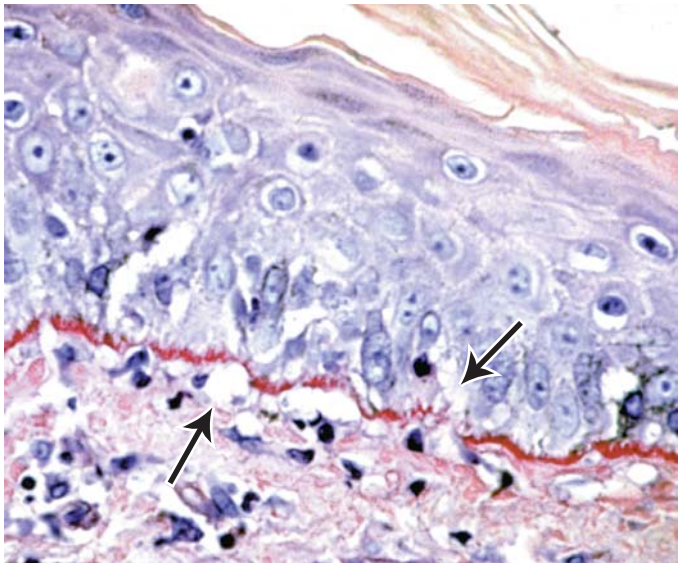

FIGURE 28-29. Lupus erythematosus. Basal cell necrosis with resultant basal keratinocytic migration and synthesis of new basement membrane zone leads to thickening of the epidermal basement membrane zone (BMZ), as evident in this periodic acid–Schiff (PAS) stain. Notice the vacuoles (*arrows*) on either side of the BMZ, an indicator of cellular injury.

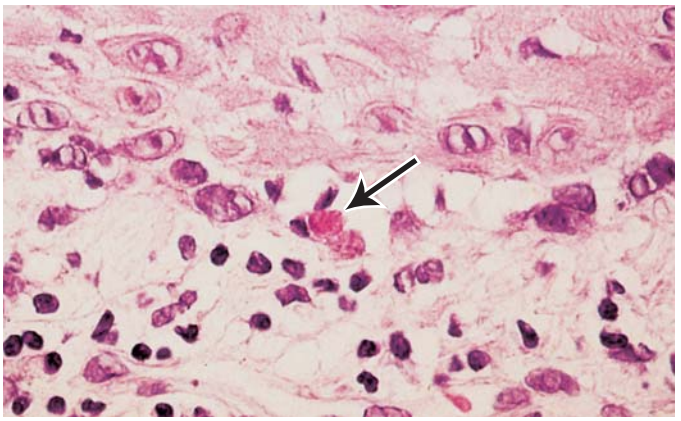

FIGURE 28-30. Lupus erythematosus. An active lesion shows striking basal vacuolization, with keratinocyte necrosis (*arrow*) forming a dense eosinophilic body (apoptotic/fibrillary/colloid body) that is surrounded by lymphocytes (satellitosis).

ACUTE SYSTEMIC LUPUS ERYTHEMATOSUS: Over 80% of patients with SLE have acute skin disease during their illness, in association with disease of the kidneys and joints. The rash is often the first manifestation of the disease and may precede the onset of systemic symptoms by a few months. The typical "butterfly" rash of SLE is a delicate erythema of the malar area of the face, which may pass in a few hours or a few days. Many patients have a maculopapular eruption of the chest and extremities, often following sun exposure. Both rashes heal without scarring. Lesions indistinguishable from discoid lupus may occur. ANA levels are elevated in more than 90% of patients.

PATHOLOGY: The earliest malar blush of acute cutaneous lupus may show only edema of the papillary dermis. More often, changes are like those in the subacute form of lupus. The histopathologic picture of lupus can be indistinguishable from other connective tissue diseases such as dermatomyositis. In **bullous SLE,** blisters may occur subepidermally and beneath the lamina densa. An autoantibody against type VII collagen in this location, which is a component of anchoring fibrils, is deposited and is associated with an infiltrate of neutrophils at the junction.

Lichen Planus Is a Cell-Mediated Immune Reaction at the Dermal–Epidermal Junction

"Lichenoid" tissue reactions are so named because the clinical lesions resemble certain lichens that form scaly growths on rocks or tree trunks. Lichenoid infiltrates are characterized by a band-like congregation of lymphocytes that obscures the dermal–epidermal junction. Epidermal turnover is decreased, leading to hyperkeratosis without parakeratosis. Lichen planus (LP) is the prototypic disorder of this group, which includes entities such as lichen nitidus and lichenoid drug eruptions.

ETIOLOGIC FACTORS: The etiology of LP is unknown. It is occasionally familial and may also accompany autoimmune disorders, such as SLE

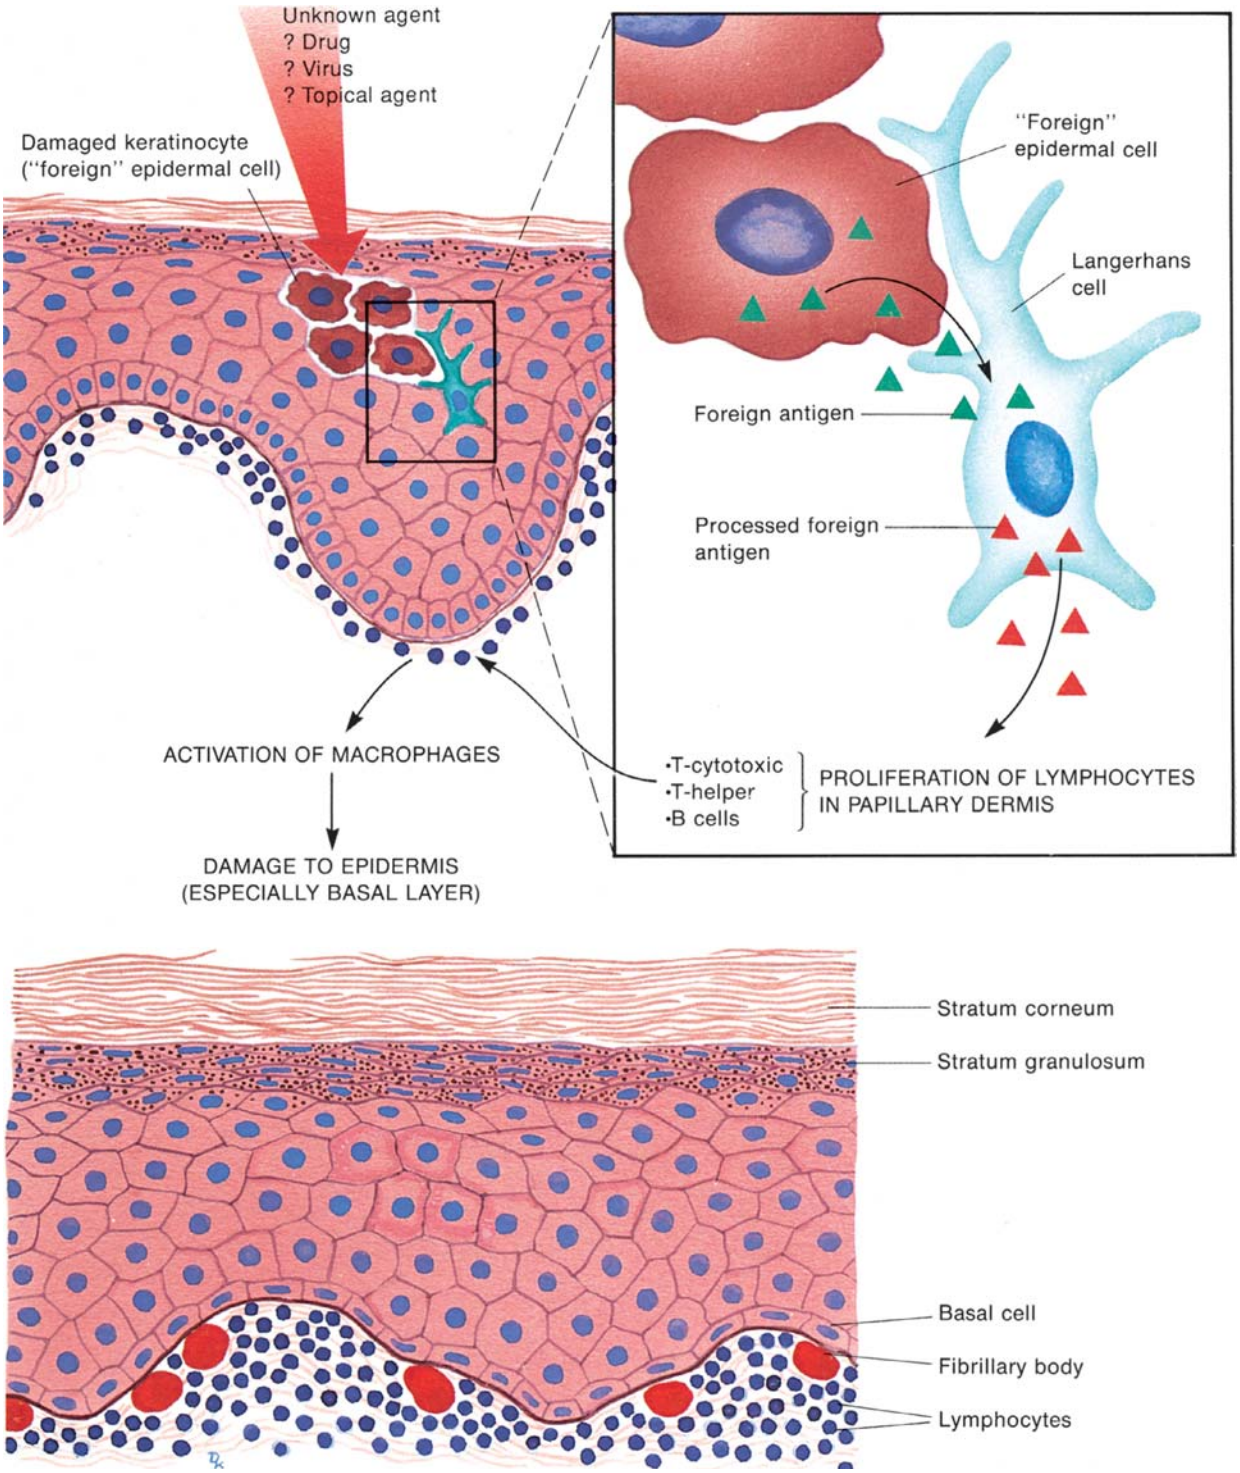

FIGURE 28-31. Lichen planus. Pathogenetic mechanisms are outlined. The disease is apparently initiated by epidermal injury. This injury causes some epidermal cells to be treated as "foreign." The antigens of such cells are processed by Langerhans cells. The processed antigen induces lymphocytic proliferation and macrophage activation. Macrophages, along with T lymphocytes, kill the epidermal basal cells, resulting in a reactive epidermal proliferation and the formation of fibrillary bodies.

and myasthenia gravis. LP is more common in patients with ulcerative colitis. Some drugs—gold, chlorothiazide and chloroquine—may induce lichenoid reactions. External agents such as photographic chemicals may evoke a lichenoid response. LP-like lesions often occur in later stages of chronic graft-versus-host disease. Thus, it seems that immunologic mechanisms play a role in the pathogenesis of LP (Fig. 28-31). The presence of apoptotic bodies and reduced epidermal cell turnover suggest that the lesions of LP result from basal layer cell destruction, creating reduced

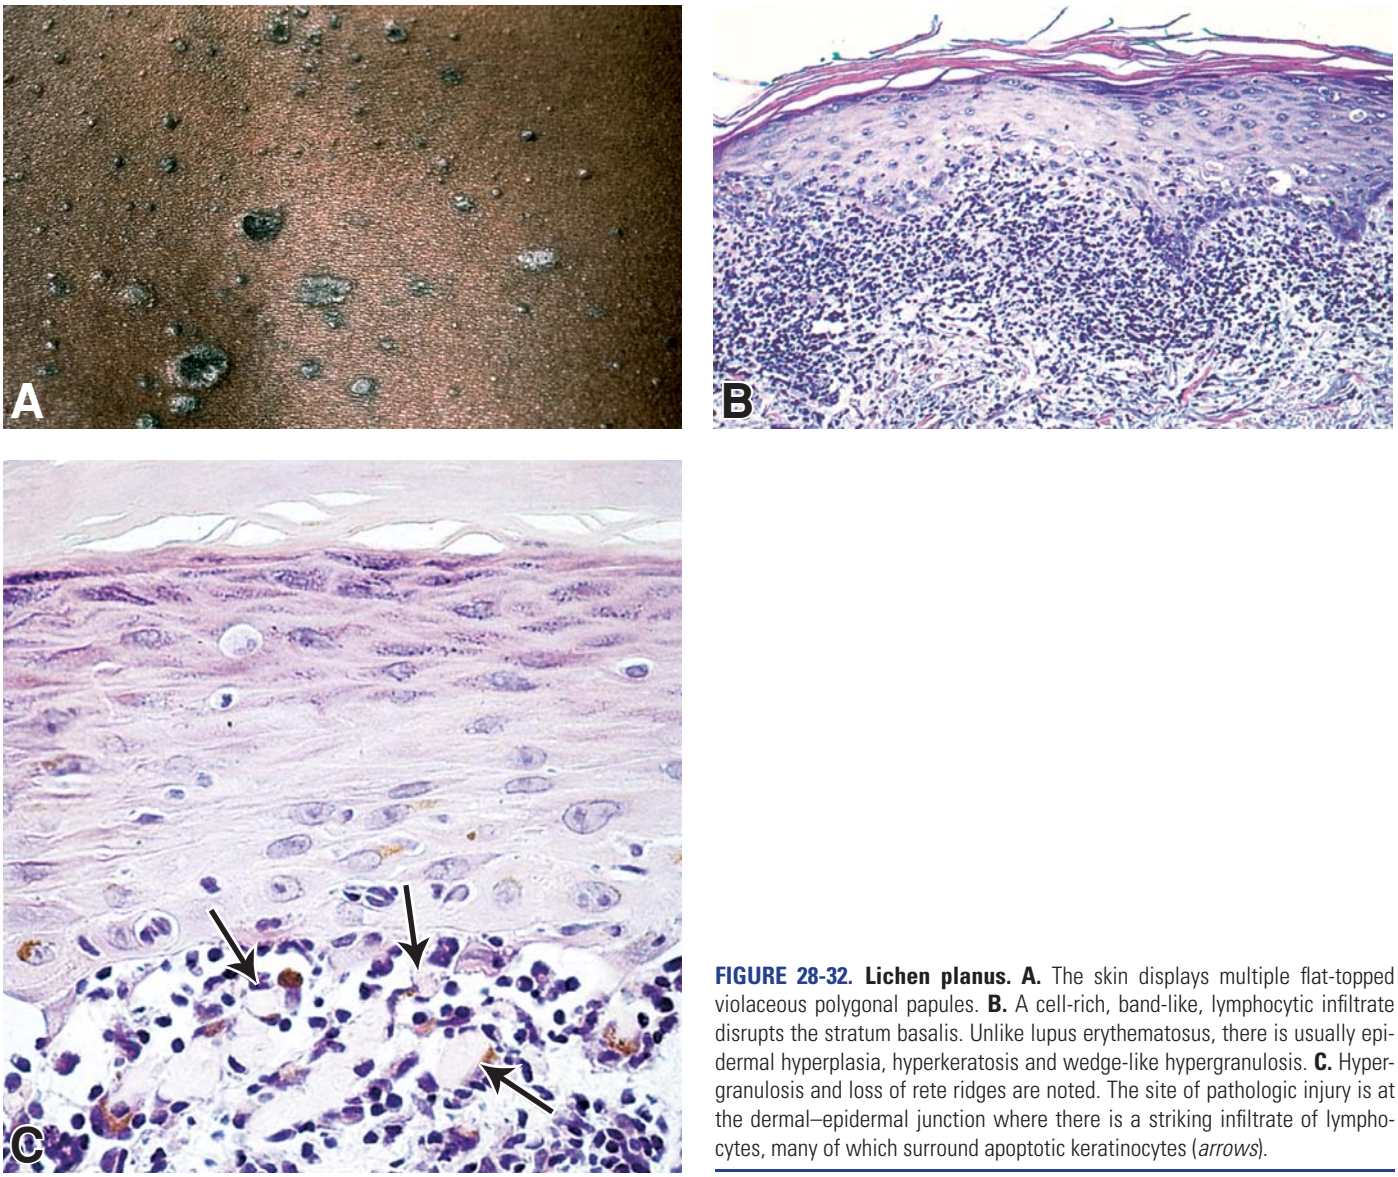

FIGURE 28-32. Lichen planus. A. The skin displays multiple flat-topped violaceous polygonal papules. **B.** A cell-rich, band-like, lymphocytic infiltrate disrupts the stratum basalis. Unlike lupus erythematosus, there is usually epidermal hyperplasia, hyperkeratosis and wedge-like hypergranulosis. **C.** Hypergranulosis and loss of rete ridges are noted. The site of pathologic injury is at the dermal–epidermal junction where there is a striking infiltrate of lymphocytes, many of which surround apoptotic keratinocytes (*arrows*).

and subsequent reactive epidermal proliferation. Evidence suggests that LP is a delayed type of hypersensitivity reaction (see Chapter 4), initiated and amplified by cytokines such as IFN-γ and IL-6, produced both by infiltrating lymphocytes and by stimulated keratinocytes. LP may coexist with hepatitis C infection.

PATHOLOGY: The epidermis in LP features compact hyperkeratosis with little or no parakeratosis, the lack of which correlates with reduced epidermal turnover associated with damage to basal keratinocytes. The stratum granulosum is thickened, frequently in a distinctive, focal, wedge-shaped pattern, with the base of the wedge abutting the stratum corneum. The stratum spinosum is variably thickened.

The distinctive pathology of LP is at the dermal–epidermal interface. The basal row of cuboidal cells is replaced by flattened or polygonal keratinocytes. The undulating interface between the dermal papillae and the rounded profiles of the rete ridges is obscured by a dense infiltrate of helper/inducer lymphocytes and macrophages, many of the latter containing melanin pigment **(melanophages)** (Fig. 28-32). Plasma cells are absent; their presence in association with basal keratinocyte atypia would suggest a lichenoid actinic keratosis, a form of epidermal dysplasia. Sharply pointed ("saw-toothed") rete ridges of keratinocytes project into the inflammatory infiltrate.

Commonly admixed with the infiltrate (in the epidermis or dermis) are globular, fibrillary, eosinophilic bodies, 15–20 μm (Fig. 28-32), which represent apoptotic keratinocytes. These structures are variably called *apoptotic*, *colloid*, *Civatte* or *fibrillary bodies*, *or dyskeratotic cells*. The fibrils within the apoptotic bodies are keratin filaments. Epidermal Langerhans cells are increased early in LP.

CLINICAL FEATURES: LP is a chronic eruption with violaceous, flat-topped papules, usually on the flexor surfaces of the wrists (Fig. 28-32A). White patches or streaks may also be present on oral mucous membranes (Wickham striae). The pruritic lesions usually resolve in less than a year but may occasionally persist longer.

INFLAMMATORY DISEASES OF THE SUPERFICIAL AND DEEP VASCULAR BED

Urticaria and Angioedema Are IgE-Dependent Hypersensitivity Reactions

These reactions are initiated by degranulation of mast cells sensitized to a specific antigen. **Urticaria** ("hives") are raised, pale, well-demarcated pruritic papules and plaques that appear and disappear within a few hours. The lesions represent edema of the superficial dermis. **Angioedema** is a condition in which the edema involves the deeper dermis or subcutis, resulting in an egg-like swelling. Both entities have a rapid onset and range in severity from simply annoying lesions to life-threatening anaphylactic reactions. The mainstays of treatment are avoiding the offending agent and prompt administration of antihistamines.

Dermatographism is a linear hive with a rich pink flare produced by briskly stroking the skin. It occurs in 4% of the population. It represents an exaggerated IgE-dependent response. One may write on the skin of such individuals and create a hive in the form of a legible word.

ETIOLOGIC FACTORS: Most cases of urticaria are IgE dependent and reflect exaggerated venule permeability due to mast cell degranulation. An almost endless list of materials may react with IgE antibodies on the surface of the mast cell. Urticaria may occur in both atopic and nonatopic people. Atopic patients have intensely pruritic skin eruptions, a family history of similar eruptions and a personal or family history of allergies. They commonly have elevated circulating IgE.

When mast cells degranulate and release their vasoactive mediators, cutaneous venules respond initially by becoming more permeable. This leads to rapidly forming edema. If the reaction persists, inflammatory cells are attracted to the area, causing an urticarial plaque (lasting more than a day).

Hereditary angioedema is a serious autosomal dominant disorder caused by mutation of the C1-esterase inhibitor.

PATHOLOGY: In urticaria, collagen fibers and fibrils are splayed apart by excess fluid. Lymphatic vessels are dilated; venules show margination of neutrophils and eosinophils. Vessels are cuffed by a few lymphocytes. In persistent urticaria, lymphocytes and eosinophils are increased, but neutrophils are sparse.

Cutaneous Necrotizing Vasculitis Is an Immune Reaction with Neutrophil Inflammation of Vessel Walls

Cutaneous necrotizing vasculitis (CNV) presents as **"palpable purpura"** and has also been called **allergic cutaneous vasculitis, leukocytoclastic vasculitis** and **hypersensitivity angiitis**.

ETIOLOGIC FACTORS: In CNV, circulating immune complexes deposit in vessel walls at sites of injuries, at branch points where turbulence is increased or where venous circulation is slowed, as in the lower extremities. Elaborated C5a complement component attracts neutrophils, which degranulate and release lysosomal enzymes, causing endothelial damage and fibrin deposition (Fig. 28-33).

CNV may be primary, without a known precipitating event in about half of the cases, or associated with a specific infectious agent (e.g., hepatitis B or C viruses [HBV, HCV]). It may also be a secondary process in a variety of chronic diseases, such as rheumatoid arthritis, SLE and ulcerative colitis. CNV may also be associated with (1) underlying malignancies such as lymphoma, (2) a drug or some other

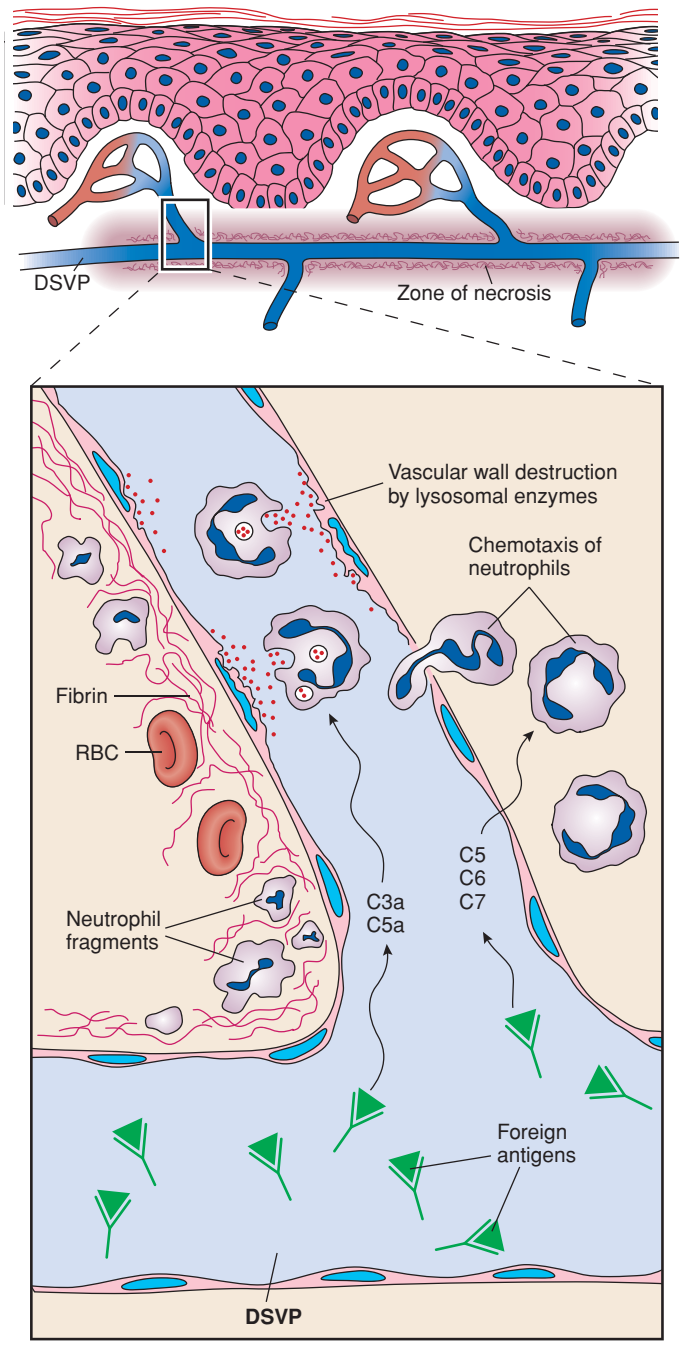

FIGURE 28-33. Cutaneous necrotizing vasculitis. The pathogenesis of vessel damage is depicted. The site of the vascular pathology is indicated in the *upper diagram*. Circulating immune complexes activate complement. There is neutrophilic chemotaxis (*C5a*) and neutrophilic destruction. Vascular damage occurs, with extravasation of erythrocytes, fibrin deposition and leukocytoclasia. *DSVP* = deep superficial venular plexus; *RBC* = red blood cell.

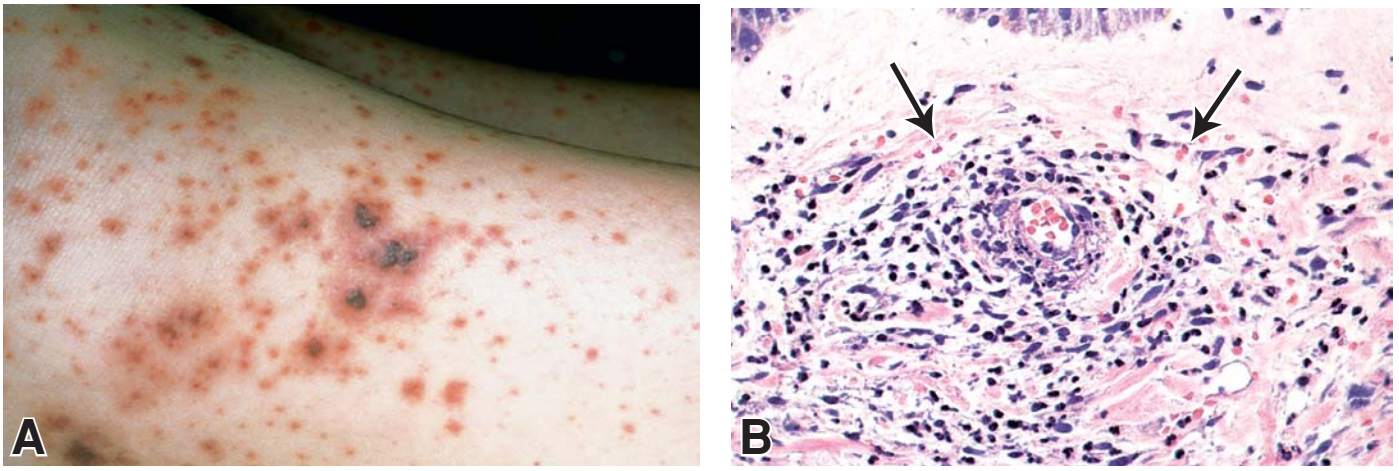

FIGURE 28-34. Cutaneous necrotizing vasculitis. A. Palpable purpuric tender papules on the legs of a 25-year-old woman. The condition resolved after therapy for streptococcal pharyngitis. **B.** The vessel is surrounded by pink fibrin and neutrophils, many of which have disintegrated (leukocytoclasis). Extravasated red blood cells (*arrows*) and inflammation give the classic clinical appearance of "palpable purpura."

allergy or (3) a postinfectious process such as Henoch-Schönlein purpura.

PATHOLOGY: Lesions of CNV show vessel walls obliterated by a neutrophilic infiltrate. Endothelial cells are difficult to visualize and vessel damage is manifested by fibrin deposition and erythrocyte extravasation (Fig. 28-34). Many of the neutrophils are also damaged, resulting in dust-like nuclear remnants, a process known as "leukocytoclasia." The collagen fibers between affected vessels are separated by neutrophils, eosinophils and leukocytoclastic cellular remnants, as well as the extravasated erythrocytes that account for the characteristic palpable purpura.

CLINICAL FEATURES: CNV is distinguished by 2–4-mm red, palpable lesions that do not blanch under pressure ("palpable purpura") (Fig. 28-34). Multiple lesions characteristically appear in crops on the legs or at sites of pressure. Lesions may be confined to the skin in an otherwise healthy person or may involve small blood vessels in the joints, gastrointestinal tract or kidneys. Individual lesions persist for up to a month, then resolve, leaving hyperpigmentation or atrophic scars. Despite removal of the offending agent, episodes of CNV may recur.

Allergic Contact Dermatitis Is Cell-Mediated Hypersensitivity to Exogenous Sensitizing Agents

Members of the *Rhus* genus of plants are common sensitizing agents, so that 90% of the population of the United States is sensitive to the common offenders: *Rhus radicans* (poison ivy), *Rhus diversiloba* (poison oak) and *Rhus vernix* (poison sumac). These plant dermatitides are so well known that the resultant disease is commonly labeled according to the offending plant. Patients state, "I have poison ivy" and go to physicians for relief rather than for diagnosis.

ETIOLOGIC FACTORS: The offending plant contains low–molecular-weight **haptens** (see Chapter 4), in particular, oleoresins. They are active in sensitization only when they combine with a carrier protein. This likely happens at the cell membrane of the Langerhans cell in the **sensitization phase,** a process that has been studied as a prototype of antigenic sensitization in delayed-type hypersensitivity (DTH). Formation of a **hapten–carrier complex** requires about 1 hour, after which it is processed as an antigen by Langerhans cells. These cells carry the antigen through the lymphatics to regional lymph nodes and present it to $CD4^+$ T cells (Fig. 28-35). After 5–7 days, some of these T lymphocytes recognize the antigen, become activated, multiply and circulate in the blood as memory cells. Some migrate to the skin, ready to react with the antigen if they encounter it. IL-1, made by Langerhans cells, supports proliferation of $CD4^+$ T_H1 cells, the effectors of DTH.

In the **elicitation phase,** specifically sensitized T lymphocytes in the circulation enter the skin. At the site of antigen challenge, Langerhans cells, endothelial cells, perivascular dendritic cells and monocytes process the antigen and present it to the specifically sensitized T cells, which then migrate into the epidermis. Cytokine production causes accumulation of more T cells and macrophages, which are responsible for epidermal cell injury.

PATHOLOGY: Allergic contact dermatitis is a type of **spongiotic dermatitis**. In the 24 hours after reexposure to the offending plant (elicitation phase), lymphocytes and macrophages congregate about superficial venules and extend into the epidermis. Epidermal keratinocytes are partially separated by the edema fluid, creating a sponge-like appearance **(spongiosis)** (Fig. 28-36). The stratum corneum contains coagulated eosinophilic fluid and plasma proteins. Later, many mononuclear inflammatory cells and eosinophils accumulate. Vesicles containing lymphocytes and macrophages are present, and abundant eosinophilic coagulated fluid accrues in the stratum corneum.

CLINICAL FEATURES: At first contact with poison ivy, for example, there is no immediate reaction. Five to 7 days after a reexposure, the site of contact becomes intensely pruritic. Then, erythema and small vesicles rapidly develop (Fig. 28-36). Over the next few

5. Sensitized lymphocytes transported to regional lymph nodes, where T cell hyperplasia is induced

FIGURE 28-35. Allergic contact dermatitis. Pathogenetic mechanisms are shown.

days, the area enlarges, becomes fiery red, develops vesicles and exudes a large amount of clear proteinaceous fluid. Pruritus is intense. The entire process lasts about 3 weeks. Exudation gradually subsides and the area is covered by an irregular crust that eventually falls off. Pruritus diminishes and healing occurs without scarring.

When a sensitized patient again comes into contact with poison ivy, the process is faster. Lesions appear within 1–2 days, spread rapidly and produce the same clinical appearance. However, the reaction is usually more intense. Lesions again clear in about 3 weeks. Allergic contact dermatitis responds to topical or systemic corticosteroids.

Granulomatous Dermatitis Is a Response to Indigestible Antigens

Granulomas, generally defined as localized collections of epithelioid macrophages (see Chapter 1), form in response to insoluble or slowly released antigens that produce either a focal nonallergic response or an allergic response in sensitized people. Implicated antigens include foreign substances implanted accidentally into the skin (e.g., silicone in breast implants) or endogenous antigens such as keratin. Other common causes include mycobacterial and other infections and granuloma annulare. Often, for example, in sarcoidosis and granuloma annulare, an inciting antigen may not be known. Phagocytosis of the foreign particulate matter, or processing of protein antigens, is central to activation of tissue macrophages, as they become the characteristic granulomatous epithelioid cells.

Sarcoidosis Is a Systemic Disease That May Lead to Skin Lesions

Sarcoidosis is a granulomatous disorder of unknown etiology that mainly affects the lungs but may also involve the skin, lymph nodes, spleen, eyes and other organs. Sarcoidal granulomas are the classic epithelioid cell type, without

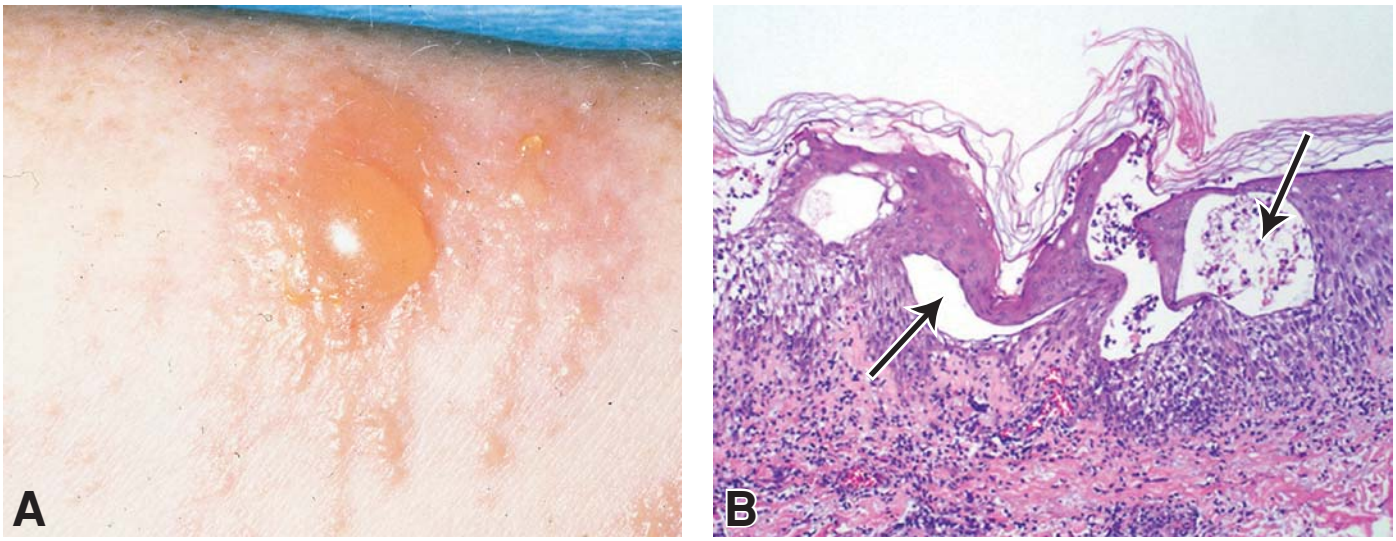

FIGURE 28-36. Allergic contact dermatitis. A. Vesicles and bullae developed on the volar forearm after application of perfume. **B.** Epidermal spongiosis and spongiotic vesicles (*arrows*) are present in this biopsy of "poison ivy." Infiltrating lymphocytes are apparent in the epidermis, where they effect the cell-mediated delayed hypersensitivity reaction.

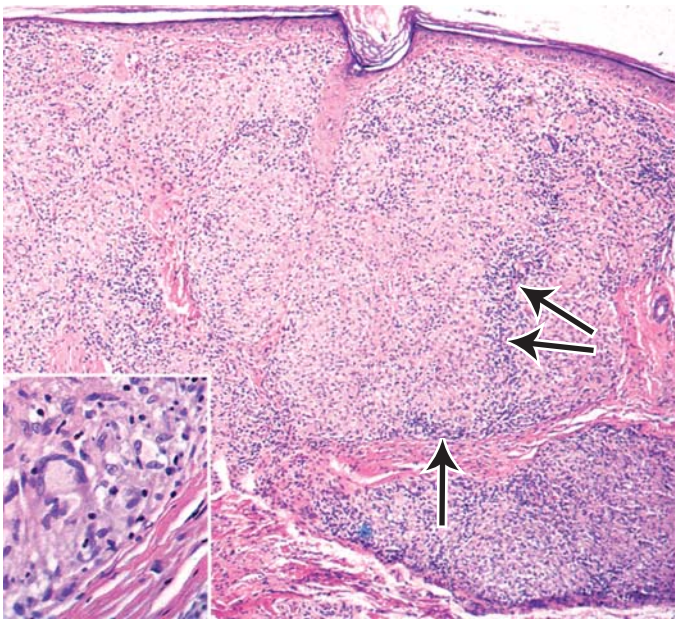

FIGURE 28-37. Sarcoidosis. Numerous large granulomas fill the reticular dermis. Around some of the granulomas are small cuffs of lymphocytes (*arrows*). The granulomas are composed of epithelioid macrophages, some of which are multinucleated (*inset*).

necrosis (Fig. 28-37). Cutaneous manifestations of sarcoidosis are asymptomatic papules, plaques and nodules in the dermis and subcutis. Some dermal plaques may be annular, and those that involve the subcutis appear as irregular nodules. In severe cases, cutaneous lesions may be so prominent that they simulate a diffusely infiltrative neoplasm.

Granuloma Annulare Is a Reaction to an Unknown Antigen

Granuloma annulare is a benign, self-limited disorder of unknown etiology, characterized by palisading "necrobiotic" granulomas in the skin.

ETIOLOGIC FACTORS: Granuloma annulare may be an immune reaction to an unknown antigen(s). It can occur after insect bites, sun exposure and viral infections. Offending antigens are thought to include viral antigens, altered dermal collagen or elastic fibers, or proteins in the saliva of biting arthropods. The precise type of immune reaction is unclear, but both circulating immune complexes and cell-mediated immunity may participate. The activated macrophages may also contribute to the process by releasing lysosomal enzymes and cytokines, which in turn cause the characteristic focal collagen degeneration ("necrobiosis").

PATHOLOGY: Well-developed lesions contain a central area of acellular degenerated collagen and mucin in the superficial to midreticular dermis (Fig. 28-38). This central area is surrounded by palisaded macrophages, each with the long axis of the nucleus radiating outward.

CLINICAL FEATURES: The most common type of granuloma annulare occurs on the dorsum of the hands and feet, primarily in children and young adults (Fig. 28-38A). The disease features asymptomatic, skin-colored or erythematous annular plaques. About 15% of patients have disseminated granuloma annulare, with 10 or more lesions involving the trunk and neck. Granuloma annulare rarely requires treatment and usually has no medical consequences. In patients with significant cosmetic disfigurement, lesional injection of steroids is usually effective.

SCLERODERMA: A DISORDER OF THE DERMAL CONNECTIVE TISSUE

Scleroderma (Greek, *skleros*, "hard") also displays variable structural and functional involvement of internal organs, including the kidneys, lungs, heart, esophagus and small intestine. **Morphea** is similar to scleroderma but involves only patchy, circumscribed areas of the skin. The pathogenesis and systemic manifestations of scleroderma are discussed elsewhere (see Chapters 4 and 12).

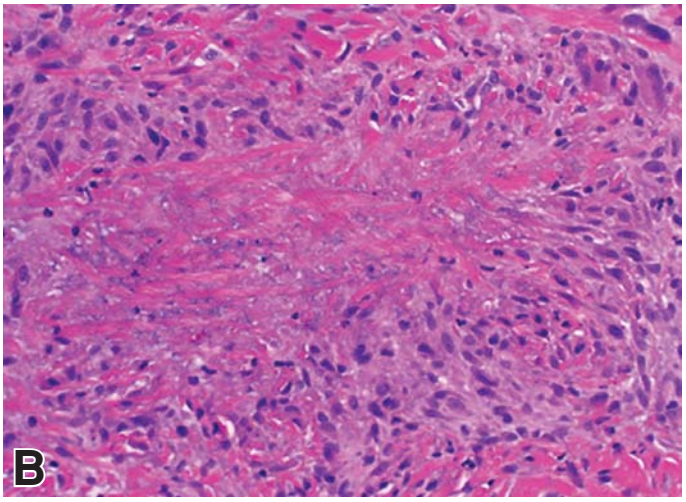

FIGURE 28-38. Granuloma annulare. A. The skin exhibits a typical annular plaque on the dorsal right hand. **B.** A central area of acellular degenerated collagen is surrounded by palisaded macrophages with the long axes of their nuclei radiating outward.

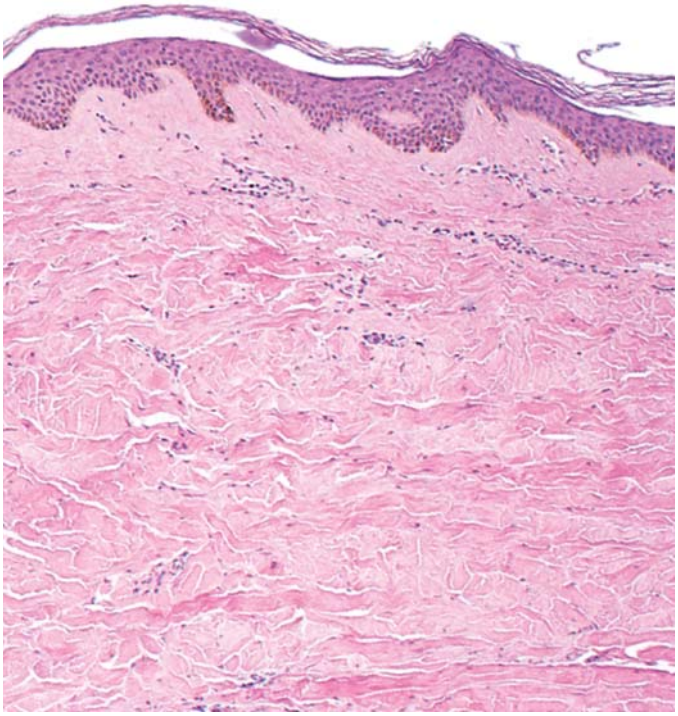

FIGURE 28-39. Scleroderma. The dermis is characterized by large, reticular collagen bundles that are oriented parallel to the epidermis. The large size and loss of basket-weave pattern of these collagen bundles are abnormal. No appendages are apparent because these structures have been destroyed.

PATHOLOGY: The initial cutaneous lesions of scleroderma are in the lower reticular dermis, but eventually the entire reticular dermis and even the papillary dermis are involved. There is diminished space among collagen bundles in the reticular dermis and a tendency for the collagen bundles to be enlarged, hypocellular and parallel to each other. A patchy lymphocytic infiltrate containing a few plasma cells is common and may also be present in the underlying subcutaneous tissue. Sweat ducts are entrapped in the thickened fibrous tissue, and the fat that is usually around them is lost. Hair follicles are completely obliterated (Fig. 28-39). In late stages of the disease, large areas of subcutaneous fat are replaced by newly formed collagen.

CLINICAL FEATURES: Scleroderma shows a peak incidence in people 30–50 years old. Women are afflicted 4 times as often as men. Patients with early scleroderma usually present with Raynaud phenomenon or nonpitting edema of the hands or fingers. Affected areas become hard and tense. The skin of the face becomes mask-like and expressionless, and the skin around the mouth exhibits radial furrows. In late stages of the disease, the skin over large parts of the body is thickened, densely fibrotic and fixed to the underlying tissue. Prognosis is related to the extent of disease in visceral organs, particularly the lung and kidney.

INFLAMMATORY DISORDERS OF THE PANNICULUS

Panniculitis denotes a diverse group of diseases characterized by inflammation, mainly in the subcutis (panniculus). The disorders gathered under the umbrella of panniculitis are classified according to the location of the inflammation. **Septal panniculitis** is inflammation in connective tissue septa, while **lobular panniculitis** entails involvement of fat lobules. These two entities may occur with or without accompanying vasculitis.

Erythema Nodosum Is Related to Toxic and Infectious Agents

Erythema nodosum (EN) is a cutaneous disorder that manifests as nonsuppurative, self-limited, tender nodules over extensor surfaces of the legs. It has a peak incidence in the third decade of life and is 3 times more common in women than in men.

ETIOLOGIC FACTORS: EN is triggered by a variety of agents, such as drugs and microorganisms, and accompanies a number of benign and malignant systemic diseases. Common infections complicated by EN include streptococcal diseases (especially in children), tuberculosis and *Yersinia* infection. In endemic areas, deep fungal infections (blastomycosis, histoplasmosis, coccidioidomycosis) are common causes. EN also frequently occurs after acute respiratory tract infections of unknown etiology, but which are likely viral. The agents most commonly implicated in drug-induced EN are sulfonamides and oral contraceptives. Finally, people with Crohn disease and ulcerative colitis may develop EN.

It is thought that EN represents an immunologic response to foreign antigens, although the evidence is indirect. For example, patients with tuberculosis or coccidioidomycosis do not develop EN until skin tests for reactions to antigens of those infectious agents become positive, and testing with Frei antigen for lymphogranuloma venereum may itself induce EN. The early acute inflammation suggests that EN may be a response to complement activation, with resulting neutrophil chemotaxis. Subsequent chronic inflammation, foreign body giant cells and fibrosis are due to adipose tissue necrosis at the interface of septa and lobules.

PATHOLOGY: Early EN lesions are in the fibrous septa of the subcutaneous tissue, where neutrophilic inflammation is associated with extravasation of erythrocytes. In chronic lesions, the septa are widened, with focal collections of giant cell macrophages around small areas of altered collagen and an ill-defined lymphocytic infiltrate (Fig. 28-40). Giant cells and inflammatory cells extend into the lobule from the interface between the septum and the fat lobule.

CLINICAL FEATURES: EN typically manifests acutely on the anterior aspects of the legs as dome-shaped, exquisitely tender, erythematous nodules. These eventually become firm and less tender and disappear in 3–6 weeks. As some nodules heal, others may arise, but all lesions resolve without residual scarring within 6 weeks.

Erythema Induratum Is Often Associated with *Mycobacterium tuberculosis*

Erythema induratum (EI) refers to chronic, recurrent subcutaneous nodules or plaques on the legs, predominantly in

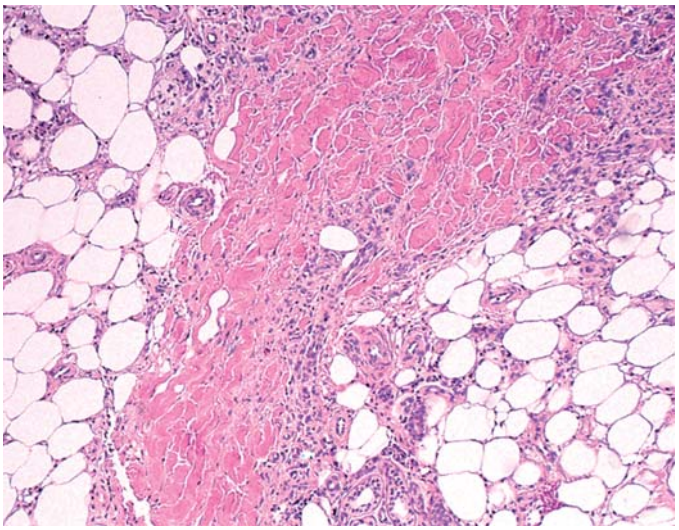

FIGURE 28-40. Erythema nodosum. The reticular dermis is present in the *upper right*. Within the panniculus is a widened septum (*extending through the middle of the field*). Lymphocytes and macrophages are present at its interface with the adipose tissue lobules. The vessels palisading along the interface of the septum are infiltrated by lymphocytes.

women. EI was traditionally considered a "tuberculid" (i.e., a hypersensitivity reaction to mycobacteria or associated antigens, but at a distant site). Although lesional tissue does not yield mycobacteria in culture or in laboratory animals, specific *Mycobacterium tuberculosis* DNA is present in greater than 75% of skin biopsies with EI.

PATHOLOGY: In contrast to EN, which is a septal panniculitis, EI is a lobular panniculitis initially, secondary to a vasculitis that produces ischemic necrosis of the fat lobule. The panniculus exhibits a dense, chronic inflammation within lobules, which can form prominent tuberculoid granulomas or areas of coagulative necrosis. Septa around the lobules are relatively spared. Vascular changes are usually extensive and include (1) prominent infiltration of small and medium-sized arteries and veins by a dense lymphoid or granulomatous infiltrate; (2) endothelial swelling, which may progress to thrombosis; and (3) fibrous thickening of the intima. Thus, sometimes this condition is called "nodular vasculitis." Extensive ischemic necrosis provokes subsequent ulceration of the overlying epidermis. Eventually, lesions heal by fibrosis.

CLINICAL FEATURES: Patients with EI present with recurrent, tender, erythematous, subcutaneous nodules on the legs, particularly the calves (as opposed to the shins, which are the usual location of EN). Lesions tend to ulcerate and heal with an atrophic scar. The course may last many years. Systemic steroids are usually necessary to control the disease.

Acne Vulgaris Is a Disorder of the Pilosebaceous Unit

Acne vulgaris is a self-limited, inflammatory disorder of sebaceous follicles that typically afflicts adolescents, results in intermittent formation of discrete papular or pustular lesions and may lead to scarring. It is cosmetically disfiguring and often psychologically debilitating. Acne is so common that many regard it as a "rite of passage" through adolescence. In some cases, acne extends to the third decade.

ETIOLOGIC FACTORS AND PATHOLOGY: The development of acne is related to (1) excessive hormonally induced production of sebum, (2) abnormal cornification of portions of the follicular epithelium, (3) a response to the anaerobic diphtheroid *Propionibacterium acnes* and (4) follicle rupture and subsequent inflammation. The sebaceous follicle contains a vellus hair and prominent sebaceous glands. Changes in hormonal status at puberty generate sebum production in the follicle and altered cornification in the neck of the sebaceous follicle (infundibulum). These effects lead to dilation of the follicular canal. Another round of excessive sebum production is associated with desquamation of squamous cells and accretion of keratinous debris, providing a rich environment for *P. acnes* proliferation. These combined changes produce a distended, plugged follicle: a **comedone**. Neutrophils attracted to the area by chemotactic factors released by *P. acnes* release hydrolytic enzymes to form a follicular abscess **(pustule)**. They also attack the follicle wall, thus permitting escape of sebum, keratin and bacteria into perifollicular tissue, where they stimulate further acute inflammation and a perifollicular abscess (Fig. 28-41). The development of allergy to *P. acnes* intensifies the inflammatory response. Fully evolved lesions show intense neutrophilic inflammation surrounding a ruptured sebaceous follicle. In addition, abundant macrophages, lymphocytes and foreign body giant cells accumulate in response to sebaceous follicle rupture.

CLINICAL FEATURES: Acne vulgaris features a variety of skin lesions in different stages of development, including comedones, papules, pustules, nodules, cysts and pitted scars. Comedones, the primary noninflammatory lesions of acne, are either open **(blackheads)** or closed **(whiteheads)**. More advanced inflammatory lesions vary from small, erythematous papules to large, tender, purulent nodules and cysts.

Acne vulgaris is treated with topical cleansing and keratolytic and antibacterial agents. Severe cases are managed with topical vitamin A, systemic antibiotics or synthetic oral retinoids (isotretinoin).

INFECTIONS AND INFESTATIONS

The skin is under constant assault from countless marauders and is an effective but imperfect barrier against them; bacteria, fungi, viruses, parasites and insects sometimes penetrate this first line of defense.

Impetigo Is a Cutaneous Infection by Staphylococci or Streptococci

Superficial bacterial infections of the skin, known as **impetigo,** occur mostly in children, who are often infected through minor breaks in the skin. Adults tend to contract impetigo after an underlying disease process compromises the barrier function of the skin. Honey-colored crusted erosions or

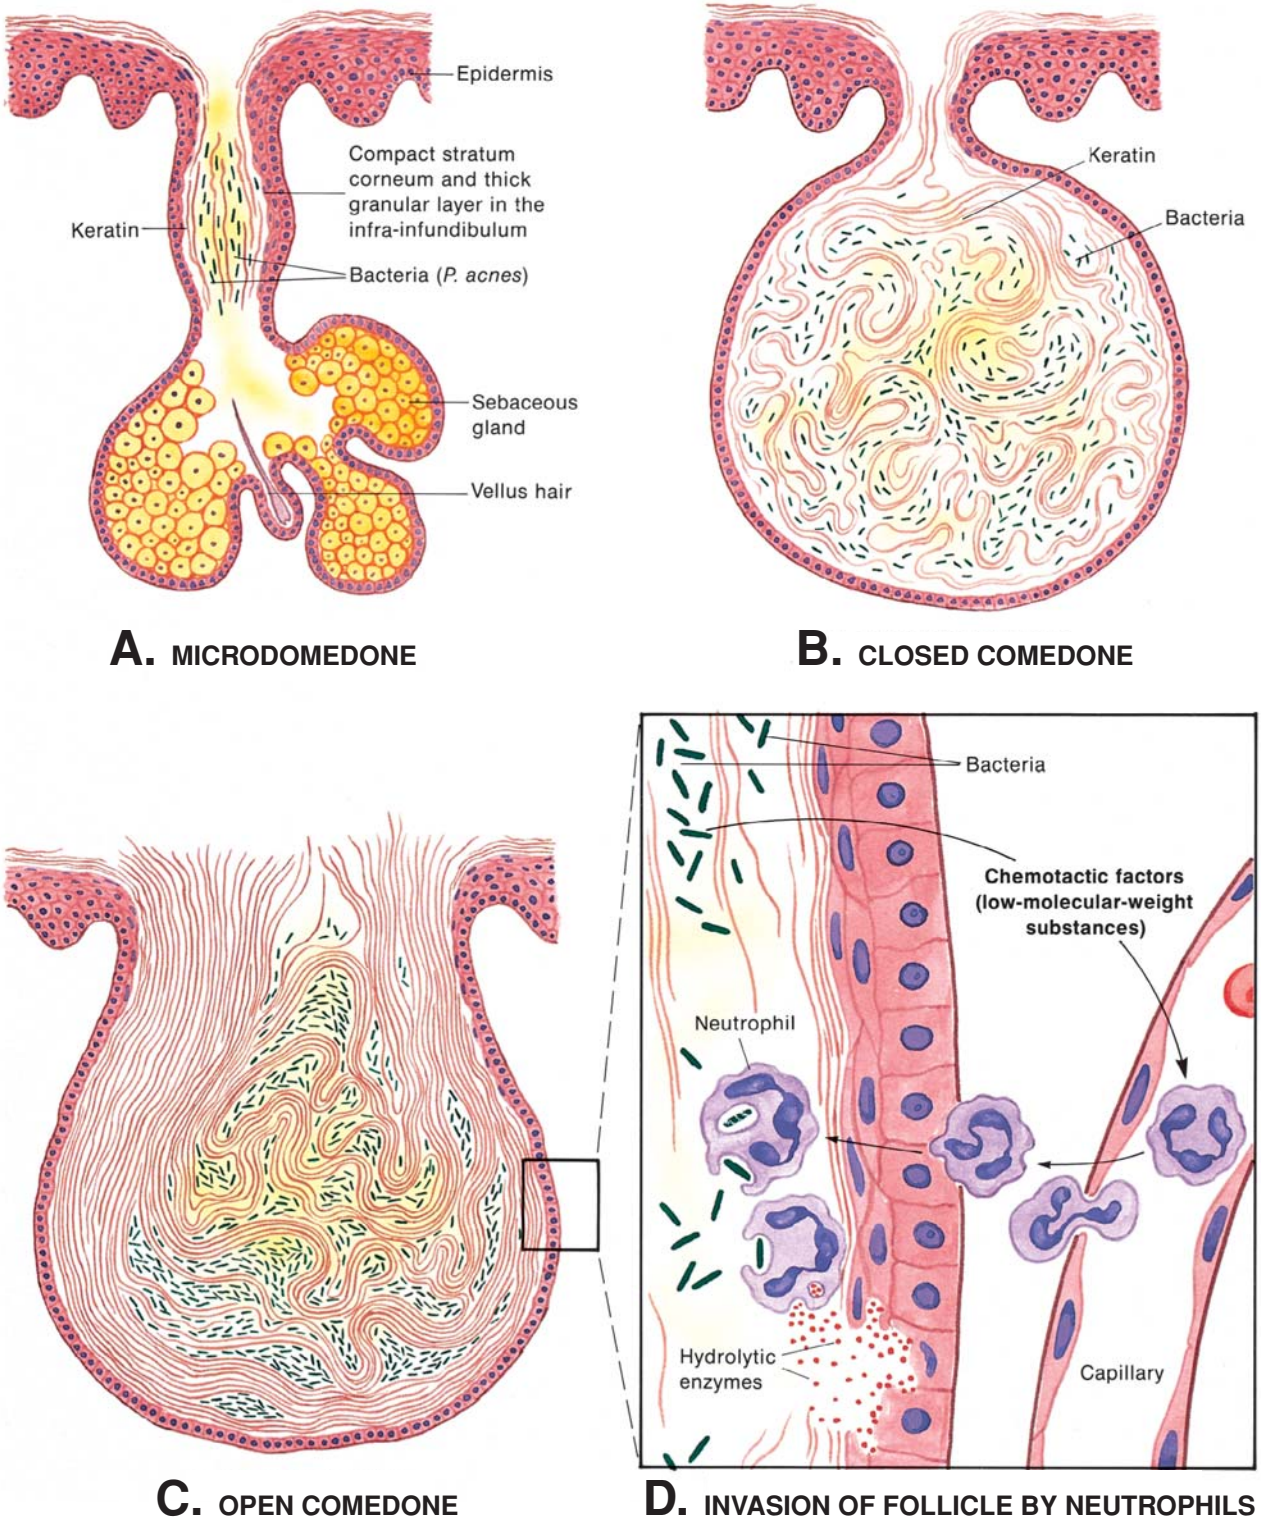

FIGURE 28-41. Acne vulgaris. The pathogenesis of follicular distention, rupture and inflammation is depicted. Acne is a disease of the follicular canal of a sebaceous follicle. A compact stratum corneum and a thickened granular layer in the infrainfundibulum are the beginning of the formation of a comedone. Microcomedones **(A)** and closed **(B)** and open **(C)** comedones form. Excessive sebum secretion occurs, and the bacterium *Propionibacterium acnes* proliferates. The organism produces chemotactic factors, leading to neutrophil migration into the intact comedone. Neutrophilic enzymes are released, and the comedone ruptures, inducing a cycle of chemotaxis and intense neutrophilic inflammation **(D, E)**. (*continued*)

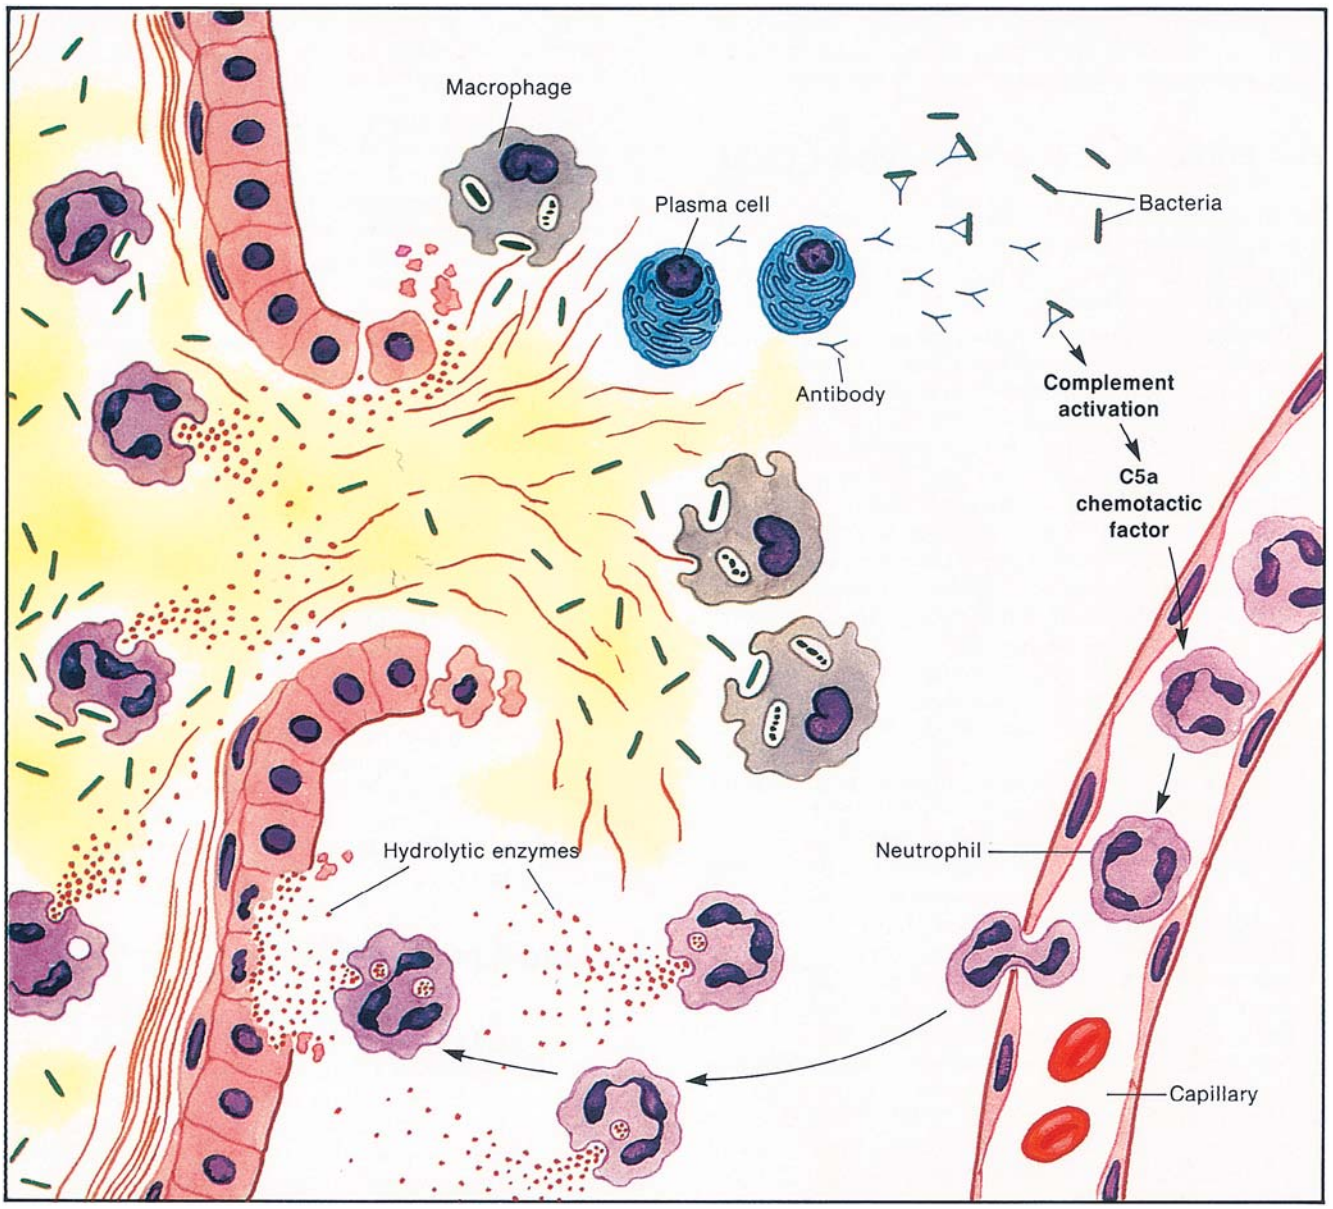

E. INFLAMMATION AND RUPTURE OF SEBACEOUS FOLLICLE

FIGURE 28-41. (*Continued*)

ulcers, often with central healing, occur most commonly on exposed areas such as the face, hands and extremities (Fig. 28-42). A combination of topical and systemic antimicrobial agents against staphylococci or streptococci is the mainstay of therapy.

PATHOLOGY: Neutrophils accumulate beneath the stratum corneum. Bacteria may be visualized with special stains. Vesicles or bullae form and eventually rupture, allowing a thin, seropurulent discharge to appear. This discharge dries and forms the characteristic layers of exudate containing neutrophils and cell debris. Reactive epidermal changes (spongiosis, elongation of rete ridges) and superficial dermal inflammation are usually present. **Ecthyma** is more typically caused by *Pseudomonas aeruginosa* (ecthyma gangrenosum) and several other organisms. It occurs when the organisms enter the superficial aspects of the skin from the bloodstream to form a necrotizing ulcerated lesion. Neutrophils are present in the floor of the ulcer and in the dermis, and bacteria are often seen migrating through vessel walls.

Superficial Fungal Infections Are Caused by Dermatophytes

Dermatophytes are fungi that can infect nonviable keratinized epithelium, including stratum corneum, nails and hair. They synthesize keratinases that digest keratin and provide themselves with sustenance. Superficial fungal infections are often caused by a change in the skin microenvironment, which allows overgrowth of transient or resident flora. For example, use of immunosuppressive agents such as topical or

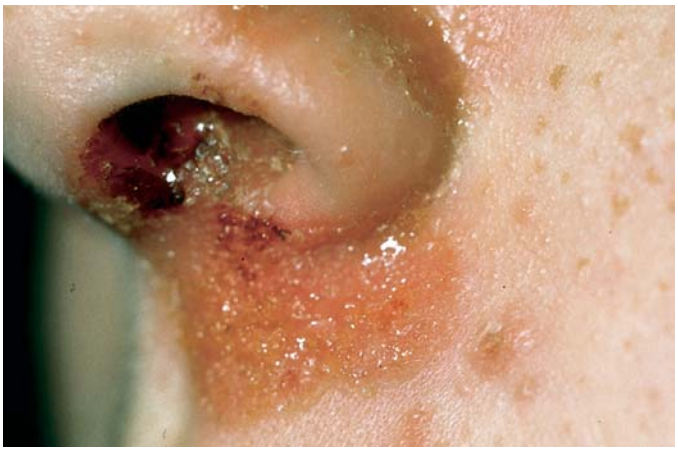

FIGURE 28-42. Impetigo contagiosa. Honey-colored crusts secondary to rupture of vesicopustules are seen in the nasal area of a child, an area commonly colonized by *Staphylococcus aureus.*

systemic glucocorticoids may impair cell-mediated immune responses that normally eliminate dermatophytes. Excessive sweating or occlusion of a body part may provide an environment that "tips the balance" between fungal proliferation and elimination in favor of proliferation.

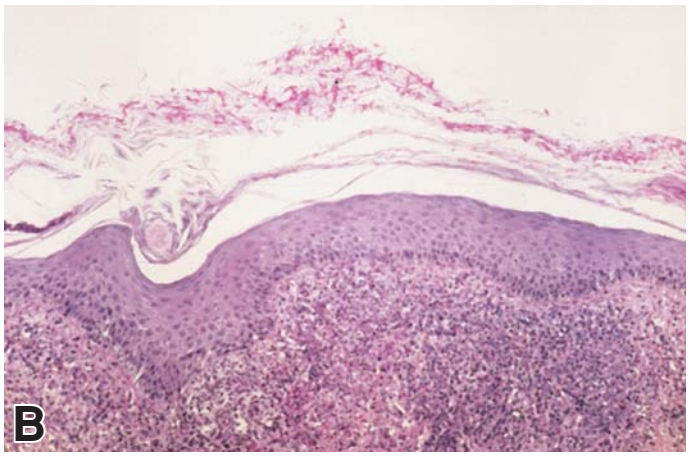
Of the 10 or so dermatophyte species that often cause human cutaneous infection, *Trichophyton rubrum* is the most common. A superficial dermatophyte infection is called a **dermatophytosis, tinea** or **ringworm**. The tineas have distinctive clinical features depending on the site of infection. They are divided as follows: (1) **tinea capitis** (scalp; "ringworm"), (2) **tinea barbae** (beard), (3) **tinea faciei** (face), (4) **tinea corporis** (trunk, legs, arms or neck, excluding the feet, hands and groin), (5) **tinea manus** (hands), (6) **tinea pedis** (feet; "athlete's foot"; Fig. 28-43A), (7) **tinea cruris** (groin, pubic area and thigh; "jock itch") and (8) **tinea unguium** (nails; "onychomycosis").

Other causes of superficial fungal infections are *Candida* sp. and *Malassezia furfur. Candida* sp. require a warm, moist environment in which to flourish, such as that found when a baby's bottom is encased in a wet diaper. *M. furfur* needs a moist, lipid-rich environment. **Tinea versicolor,** caused by *M. furfur,* is more common in young adults when sebum production is greatest. Variably sized, pigmented, sharply demarcated, round or oval macules with fine scales are present, predominantly on the upper trunk.

Special stains such as PAS show budding yeast and hyphal forms in the most superficial layers of the stratum corneum. Hyperkeratosis, epidermal hyperplasia and chronic perivascular inflammation are noted in the dermis (Fig. 28-43B, C).

Deep Fungal Infections May Reflect Dissemination of Pulmonary Infections

Most invasive or systemic fungal infections arise from inhalation of aerosolized material contaminated with organisms such as *Histoplasma* or *Blastomyces.* A primary pulmonary



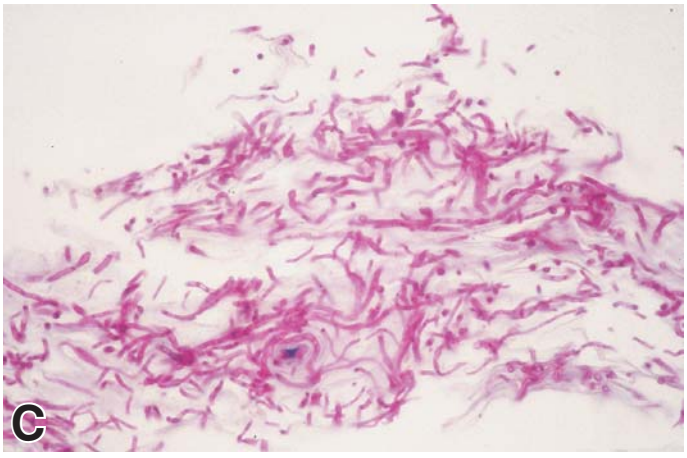


FIGURE 28-43. Dermatophytosis. A. Tinea pedis. A leading edge of scale and erythema in a moccasin distribution characterizes this infection, most commonly caused by *Trichophyton rubrum.* **B.** A dense inflammatory infiltrate is present in the epidermis and dermis and is associated with the presence of fungal hyphae in the stratum corneum. **C.** A higher-power view of the fungal hyphae in the stratum corneum.

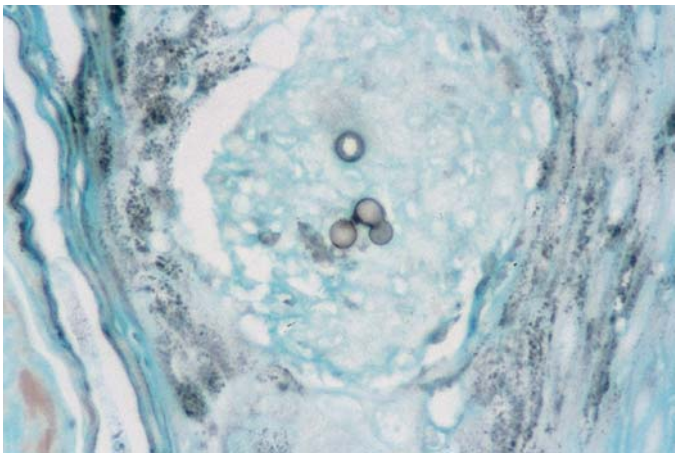

FIGURE 28-44. Blastomycosis. A Gomori methenamine silver stain highlights the organisms, which are thick-walled spores 8–15 microns in diameter. One of the organisms demonstrates broad-based budding.

infection may then spread to the skin or mucosa. Locally invasive fungal infections of the skin are rare and usually arise from traumatic implantation of organisms such as *Sporothrix* or *Fonsecaea.* An underlying immunocompromised state increases the likelihood of dissemination of fungal organisms.

Deep extension of a local cutaneous infection often causes a chancre-like lesion at the site of implantation. Intervening lymphatic vessels may be indurated and thickened. Nodules and ulcers, especially if bilateral, suggest an internal source of infection.

The presence of certain morphologic features or staining patterns may provide clues to the identity of the organism. For example, the yeast form of *Blastomyces dermatitidis* has notably refractile walls and a broad-based budding pattern, but the yeast form of *Histoplasma capsulatum* is much smaller, is often found within macrophages and shows a narrow-based budding pattern. Staining a smear with India ink, or a tissue biopsy with mucicarmine, may show the thick capsule characteristic of the yeast *Cryptococcus neoformans.* Marked epidermal hyperplasia, intraepidermal microabscesses and suppurative granulomatous inflammation in the dermis is often associated with these deep-seated fungal infections (Fig. 28-44).

Viral Skin Infections Cause Diverse Clinical Manifestations

Some viruses (see Chapter 9), such as the poxvirus **molluscum contagiosum** or **human papillomaviruses** (HPVs), cause transient benign epithelial proliferations that resolve spontaneously. Others (e.g., measles or *parvovirus* [**erythema infectiosum**]) produce febrile illnesses with self-limited cutaneous eruptions **(exanthems)**. Primary infection by most **human herpesviruses** is often asymptomatic but results in a state of latent infection. Upon reactivation, the virus causes a painful, vesicular eruption.

Molluscum contagiosum is a common infection among children and sexually active adults. It is self-limited and is easily spread by direct contact. Firm, dome-shaped, smooth-surfaced papules with a characteristic central umbilication are usually found on the face, trunk and anogenital area. Epidermal cells contain large intracytoplasmic inclusion bodies ("molluscum bodies") within cup-shaped areas that also exhibit verrucous (papillomatous) epidermal hyperplasia. Numerous viral particles are present within these inclusion bodies (Fig. 28-45).

Arthropod Infestations Produce Pruritic Skin Lesions

Mites and lice, other insects and spiders cause local lesions that may be very pruritic.

- ***Scabies*** is a severely pruritic, eczematous dermatitis caused by the mite *Sarcoptes scabei.* The female mite burrows beneath the stratum corneum on the fingers, wrists, trunk and genital skin (Fig. 28-46). Intense lymphocytic and eosinophilic dermatitis is induced as a hypersensitivity reaction to the mite and its eggs and feces.
- ***Pediculosis,*** another pruritic dermatosis, may be caused by a variety of human lice. Eggs ("nits") of the lice may be found attached to hair shafts.

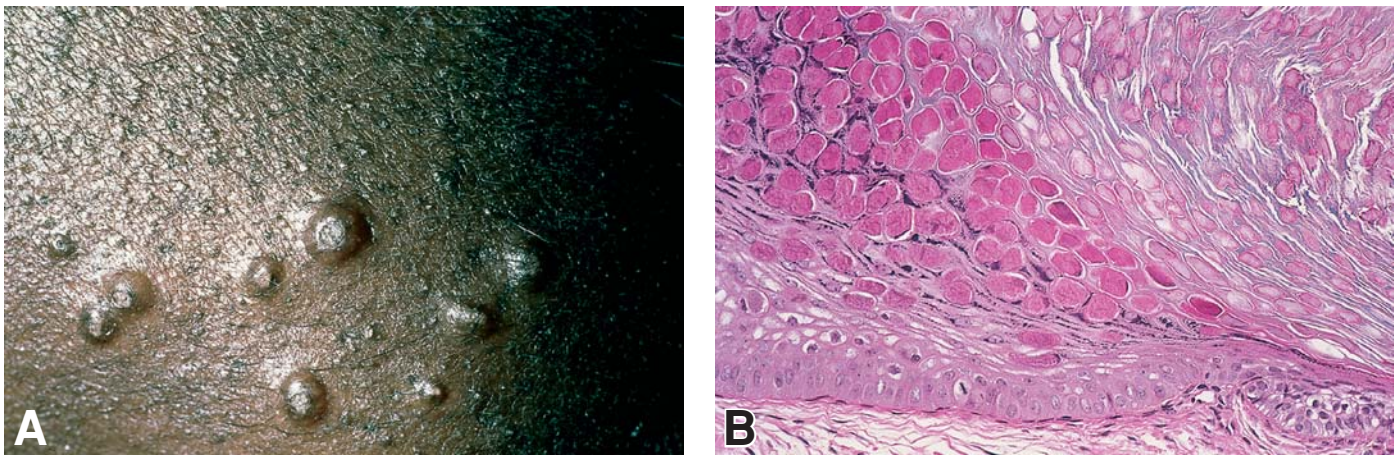

FIGURE 28-45. Molluscum contagiosum. A. Multiple umbilicated papules in an HIV-positive patient. **B.** The keratinocytes that are infected with this poxvirus show large eosinophilic cytoplasmic inclusions called "molluscum bodies."

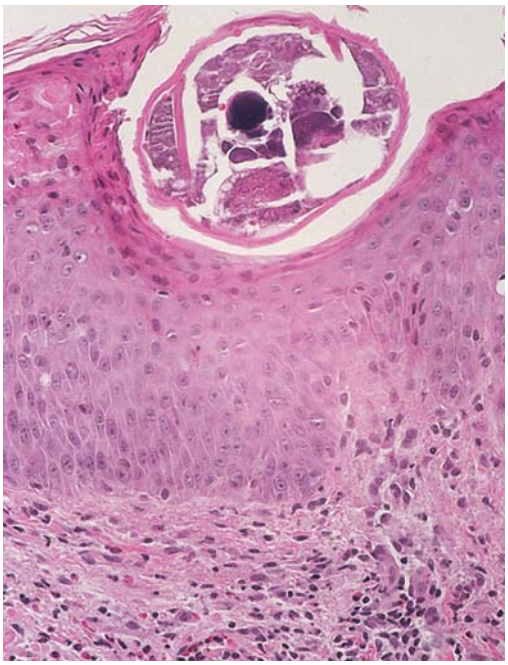

FIGURE 28-46. Scabetic nodule. A scabies mite is present in the stratum corneum.

- **Biting insects** produce lesions that vary from small, pruritic papules to large, weeping nodules. The reaction varies with the arthropod species and host immune response. For example, tick bites tend to be large, with a striking lymphocytic and eosinophilic infiltrate. Lymphoid follicles may also form. Flea bites are usually urticarial, with a scant neutrophilic infiltrate. The venoms injected by arthropods such as the brown recluse spider may give rise to severe local tissue necrosis.

PRIMARY NEOPLASMS OF THE SKIN

Common Acquired Melanocytic Nevi (Moles) Are Localized Benign Neoplastic Proliferations of Melanocytes within the Epidermis or Dermis

ETIOLOGIC FACTORS: Most people, regardless of skin color, develop 10–50 nevi on their skin. The total number depends on light exposure and innate susceptibility. Except for occasional cosmetic significance, nevi are important mainly in relation to melanoma, as markers of individuals at increased risk of developing melanoma, as potential precursors of melanoma and as stimulants of melanoma. Even though 30% of melanomas arise in relation to a nevus, nevi are much more common than melanomas, and most are stable or undergo senescence over time. Thus, wholesale excision of nevi is not effective as a means of preventing melanoma.

Black skin can develop nevi, but less commonly. Those nevi that develop in the skin of darkly pigmented people are usually not associated with an increased risk of melanoma or progression to melanoma. However, the risk of melanoma on the palms of the hands, the soles of the feet or the genital skin is the same in all races. Nevi, like melanomas, do not ordinarily develop in areas protected from light by at least two layers of clothing, such as the buttocks. There is an unequivocal causal relationship between exposure to ultraviolet light and melanocytic nevi (and malignant melanoma), but the relationship is complex. Some people with fair skin form relatively few nevi, but those with dark skin occasionally develop numerous nevi. The ability to form nevi is partly under genetic control and has been correlated with polymorphic variants of the melanocortin receptor and with subsequent variation in the ratio of pheomelanin to eumelanin. These are the pigments associated with red and brown hair, respectively, and also with susceptibility to burning and tanning. There are at least two distinguishable profiles of individuals at risk for melanoma. One group prototypically has skin that may burn but can tan and has an increased number of nevi. The other group consists of red-haired, blue-eyed people with milk-white skin, who are exquisitely sensitive to light and do not tan well. However, they form freckles and do not develop a significant number of nevi. In addition, many patients with melanoma may have overlapping features.

MOLECULAR PATHOGENESIS: A majority of nevi have recently been found to have an activating mutation of the oncogene *BRAF,* which can lead to growth stimulation through the mitogen-activated protein kinase (MAPK) pathway. However, after an initial period of growth, nevi are stable lesions that may regress or senesce. Such senescence is mediated by increased activity of p16, which is encoded by the gene *CDKN2A* on chromosome 9p21 and is an inhibitor of cyclin-dependent kinase 4 (CDK4). The p16 protein suppresses cell proliferation and promotes end-stage differentiation of the nevus cells (see Chapter 5).

Epidemiologic studies have shown melanocytic nevi to be strong risk markers for development of melanomas. Someone with 100 or more nevi that are 2–5 mm has a 3-fold greater risk of developing melanoma than a person with fewer than 25 similar nevi. Patients with clinically atypical-appearing nevi or histologically proven dysplastic nevi are at even greater risk for melanoma. Only 10 or more such clinically atypical or dysplastic nevi may be associated with a 12-fold increased risk for melanoma. As nevi are very common and melanomas are not, the risk of progression of any one nevus is small.

Melanocytic nevi begin to appear between the first and second years of life and continue to emerge for the first two decades of life. A nevus first appears as a small tan dot no bigger than 1–2 mm. During the next 3–4 years, the dot enlarges to become a uniform tan to brown circular or oval area. The peripheral outline usually remains regular. When it reaches 4–5 mm in diameter, it is flat or slightly elevated, stops enlarging peripherally and is sharply demarcated from surrounding normal skin. Over the next 10 years, the lesion elevates and its color pales to the point of becoming a tan tag-like protrusion. For the next decade or two, it gradually flattens and the skin may approximate a normal appearance. In most people, the number of nevi gradually decreases over time. Notably, many melanoma patients tend to retain increased numbers of nevi, including atypical ones, in the later decades of life.

PATHOLOGY: At the inception of a melanocytic nevus, melanocytes are increased in the basal epidermis, with subsequent hyperpigmentation. They

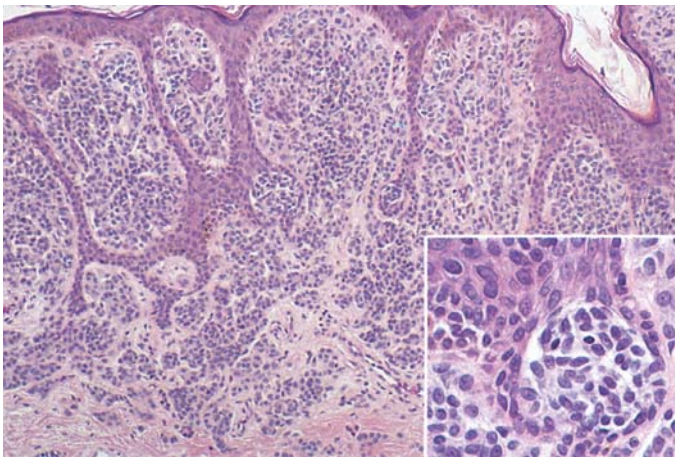

FIGURE 28-47. Compound melanocytic nevus. Melanocytes are present as nests within the epidermis and dermis. An intraepidermal nest of melanocytes is surrounded by keratinocytes (*inset*).

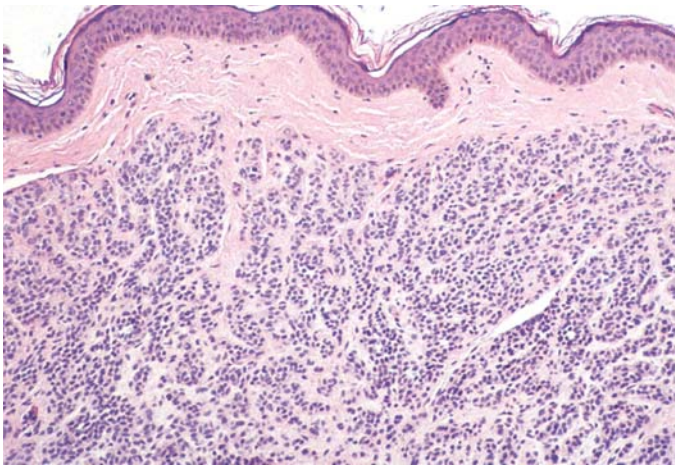

FIGURE 28-48. Dermal melanocytic nevus. The melanocytes are entirely confined to the dermis.

eventually form nests, frequently at tips of rete ridges, and then migrate into the dermis where they form small clusters. As the lesion becomes elevated, the dermal nevus cells begin to differentiate in a manner reminiscent of Schwann cells (melanocytes like Schwann cells are derived from embryonic neural crest), an evolution that gradually encompasses the entire dermal component, leaving a core of delicate neuromesenchyme. The nevus may eventually flatten and possibly even disappear. The histologic classification of melanocytic nevi reflects their evolution:

- **Junctional nevus:** Melanocytes form nests at the tips of epidermal rete ridges. They are then by definition known as "nevus cells," and they also tend to lose their dendritic morphology and retain pigment in their cytoplasm.
- **Compound nevus:** Nests of melanocytes are seen in the epidermis and some of the cells have migrated into the dermis (Fig. 28-47).
- **Dermal nevus:** Intraepidermal melanocytic growth has ceased and melanocytes are present only in the dermis (Fig. 28-48). Pigment tends to be lost at this stage, but the presence of a residual nested architecture is an important clue to the diagnosis of a nevus versus another tumor.

Dysplastic (Atypical) Nevi Are Risk Markers for Melanoma

An increased number of total nevi is a significant risk factor for melanoma, as is the presence of large nevi. Some common acquired nevi do not follow the pattern of growth, differentiation and disappearance described above and are called "dysplastic nevi." These are especially strong risk factors. Such lesions persist and are often larger than 5 mm. They may show foci of aberrant melanocytic growth and become larger and somewhat irregular peripherally (although less so than melanomas). The peripheral area is flat (macular) and extends symmetrically from the parent nevus. Some clinically dysplastic nevi are entirely macular.

Dysplastic nevi were first described in melanoma kindreds, families in which there is a greatly increased incidence of melanoma. In these families and in general population members, patients with dysplastic nevi are at increased risk of developing melanoma. Not all patients with dysplastic nevi will develop melanomas, and not all melanomas occur in patients with dysplastic nevi. The magnitude of this risk varies with the number of nevi and is especially high in patients with a prior melanoma or family history of melanoma. The genetics of dysplastic nevi are not completely understood, and contributions from multiple genes are likely.

Melanocytic Dysplasia Features Architectural Disorder and Cytologic Atypia

Dysplastic nevi are characterized by junctional proliferation of nevoid to epithelioid melanocytes arranged singly and in nests, with nests predominating. These lesions occur mainly near the dermal–epidermal junction and at the tips and sides of elongated rete ridges. A band of eosinophilic connective tissue ("concentric eosinophilic fibroplasia") is seen around the rete ridges. Horizontal nests of lesional cells extend from some rete to adjacent rete ("bridging"). As these architectural features become more prominent, melanocytes with large atypical nuclei that are reminiscent of malignant cells may also appear in the areas of architectural disorder, remaining a minority population and constituting "random cytologic atypia." The combination of architectural disorder and cytologic atypia together defines a dysplastic nevus (Figs. 28-49 and 28-50). Areas of dysplasia may also be associated with a subjacent lymphocytic infiltrate. More than 1/3 of malignant melanomas have precursor nevi, most of which show melanocytic dysplasia. However, most dysplastic nevi are stable and never progress to melanoma. In other words, dysplastic nevi are much more common in the population than melanomas. Between 7% and 20% of the population has at least one dysplastic nevus, depending on the diagnostic criteria applied. In this regard, controversy about the significance of dysplastic nevi largely reflects diagnostic variation. Moderate and severe histologic dysplasia, but not mild dysplasia, is associated with increased risk of developing melanoma. Mild histologic dysplasia may thus be considered, like prostatic intraepithelial neoplasia type I (PIN I) in the prostate or mild dysplasia in the uterine cervix, to be a common lesion of little or no prognostic or diagnostic significance.

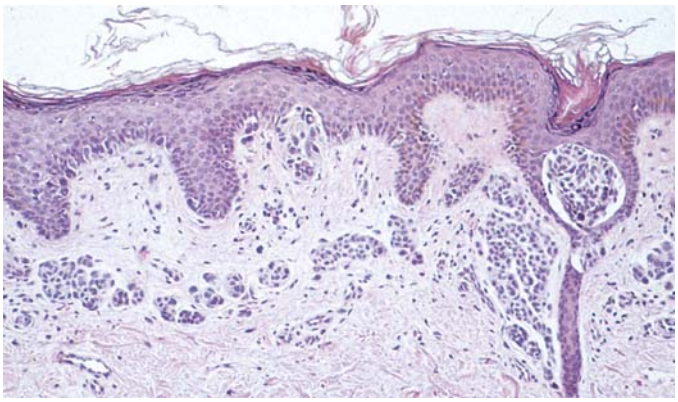

FIGURE 28-49. Compound nevus with melanocytic dysplasia. On the *right,* a compound nevus is apparent with both intraepidermal and dermal components. To the *left,* within the epidermis, are single, atypical melanocytes within the basal layer, as well as incipient lamellar fibroplasia. Dermal melanocytes are present *below.*

The Prognosis of Malignant Melanoma Reflects the Depth of Invasion

Malignant melanoma is a neoplasm of melanocytes. The term "melanoma" in current practice is synonymous with "malignant melanoma." Malignant melanoma, although not one of the most common cancers overall, is a leading cause of cancer mortality in young adults. It is rare in adolescence and exceedingly rare in childhood. Melanomas may progress through two major stages. In the "radial growth phase" (RGP), the lesion spreads (as viewed clinically) along the radii of an imperfect circle in the skin but remains superficial and thin (as measured by micrometer in the method originally described by Breslow). In the "vertical growth phase" (VGP), there is a focal area in which the lesion expands in a more or less spherical manner to form a tumor mass, with increasing Breslow thickness. Melanomas are dependent, to a greater or lesser extent, on an activated oncogene, *BRAF,* which is also mutated in benign nevi. The histopathologic subtypes of melanoma, discussed below, are related to the particular oncogenes involved in their pathogenesis. Loss of p16 (and in some cases other tumor suppressors) is common in melanomas and leads to unrestrained proliferation and the potential for future progression "from bad to worse."

The incidence of malignant melanoma is increasing rapidly. It is estimated that over 1% of children born today will develop malignant melanoma. The prognosis of most melanomas is excellent if lesions are recognized and excised before entering a vertical growth phase. However, a patient is at increased risk of dying from metastatic disease if the tumor exceeds a critical depth in the dermis.

Radial Growth Phase Melanoma

The most common type of melanoma is **superficial spreading melanoma,** which can present in the radial growth phase

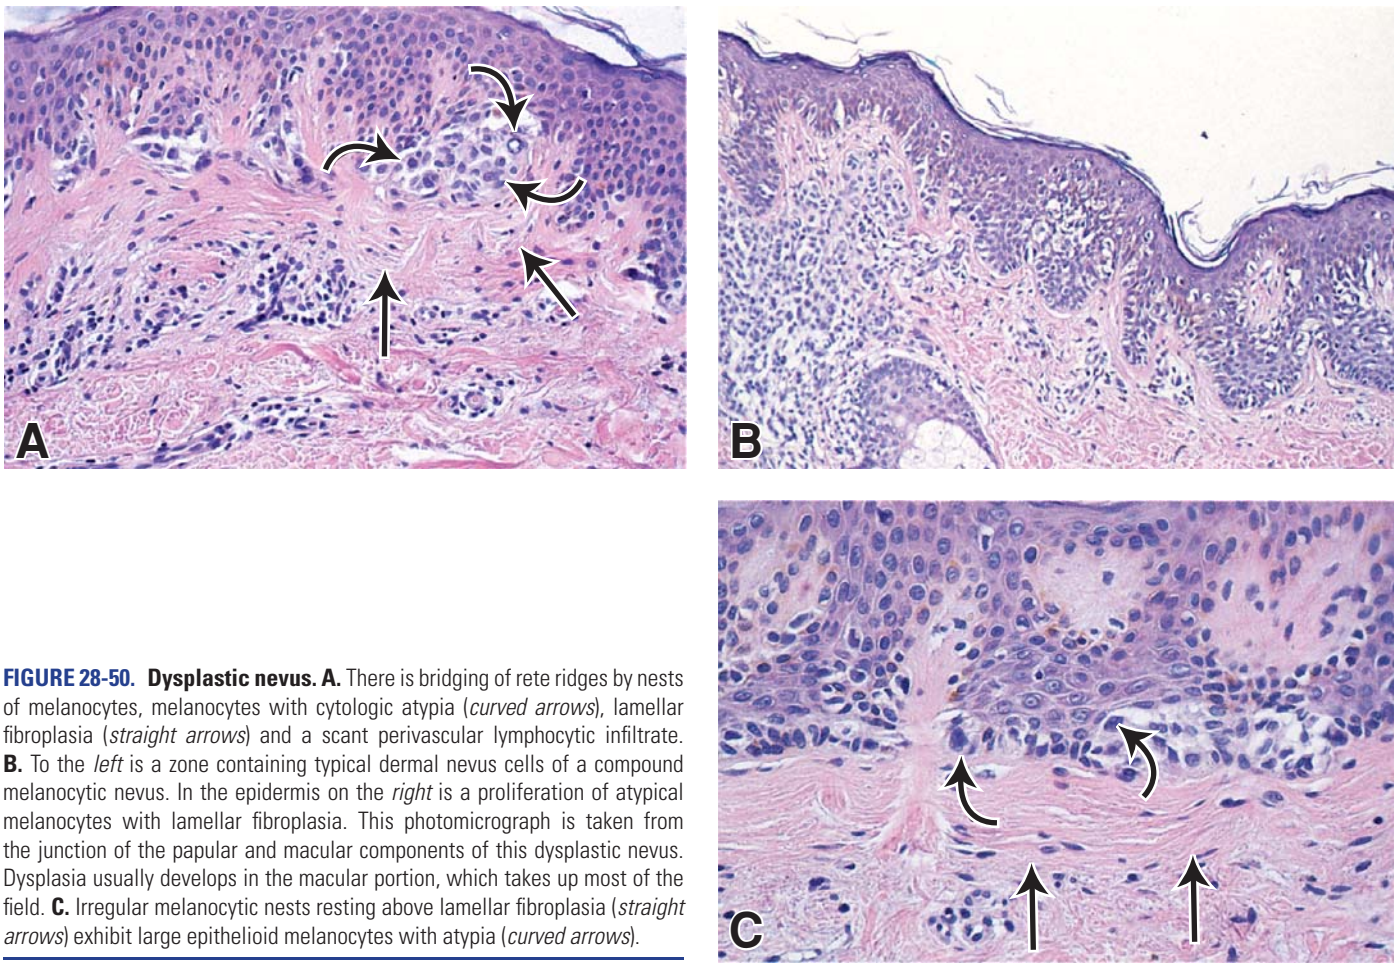

FIGURE 28-50. Dysplastic nevus. A. There is bridging of rete ridges by nests of melanocytes, melanocytes with cytologic atypia (*curved arrows*), lamellar fibroplasia (*straight arrows*) and a scant perivascular lymphocytic infiltrate. **B.** To the *left* is a zone containing typical dermal nevus cells of a compound melanocytic nevus. In the epidermis on the *right* is a proliferation of atypical melanocytes with lamellar fibroplasia. This photomicrograph is taken from the junction of the papular and macular components of this dysplastic nevus. Dysplasia usually develops in the macular portion, which takes up most of the field. **C.** Irregular melanocytic nests resting above lamellar fibroplasia (*straight arrows*) exhibit large epithelioid melanocytes with atypia (*curved arrows*).

FIGURE 28-51. The clinical appearance of the radial growth phase in malignant melanoma of the superficial spreading type. The larger diameter is 1.8 cm.

or vertical growth phase (Fig. 28-51). Excision for histologic examination is the gold standard for diagnosis of melanoma of any sort.

PATHOLOGY: In a superficial spreading melanoma, large, often pigmented epithelioid melanocytes are dispersed in nests and as individual cells through the entire thickness of the epidermis ("pagetoid scatter") and not just along the basal layer (as occurs in nevi and in lentiginous forms of melanoma described below). These melanocytes may be limited to the epidermis **(melanoma in situ)** or they may invade into the papillary dermis. In the radial growth phase, no nest has growth preference (larger size) over the other nests (Fig. 28-52), so cells grow evenly in all directions: upward in the epidermis, peripherally in the epidermis and downward into the dermis **(invasion)**. Mitoses are not seen in dermal melanocytes (except when the vertical growth phase is present) but may be present in the epidermal component. These lesions enlarge at the periphery, hence the term **radial**. A brisk lymphocytic infiltrate typically accompanies melanocytes in the radial growth phase. Such lesions rarely metastasize.

MOLECULAR PATHOGENESIS: Melanoma has several different genetic mutations implicated in its pathogenesis, involving many different molecular pathways. As with nevi, activating *BRAF* mutations are seen in 40%–50% of melanomas, and *NRAS* mutations are seen in 10%–20%. These kinases both utilize the MAPK pathway, which regulates cell proliferation. Upstream from both NRAS and BRAF is the receptor tyrosine kinase c-Kit, for which mutations account for only 1% of melanomas overall. However, it is the most common mutation seen in acral and mucosal subtypes, and often in lentigo maligna melanoma. Downstream from NRAS is the phosphatidylinositol-3-kinase (PI3K)/AKT pathway, which regulates cell survival and is suppressed by PTEN (see Chapter 5). In this context, PTEN mutations occur in 60% of cases. Mutations in *CDKN2A* are common in sporadic and familial melanomas and account for 30% of cases overall. CDKN2A encodes two tumor suppressors, including $p16^{INK4A}$, which inhibits

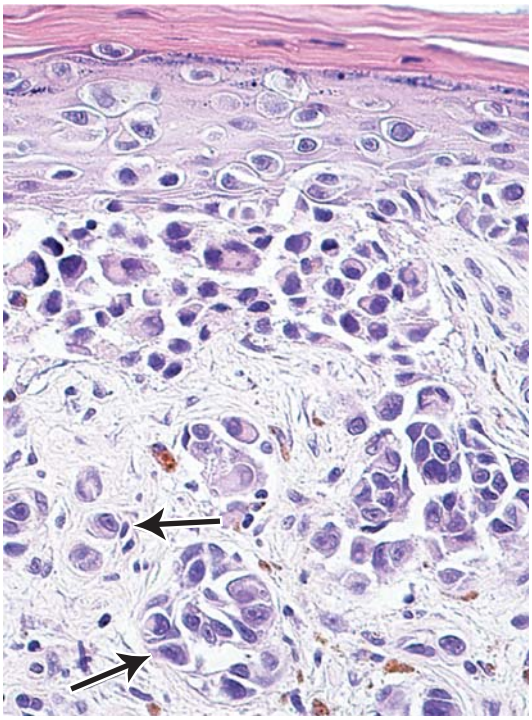

FIGURE 28-52. Malignant melanoma, superficial spreading type, radial growth phase. Melanocytes grow singly within the epidermis at all levels and as large, irregularly sized nests at the dermal–epidermal junction. Tumor cells are present in the papillary dermis (*arrows*), but no nest shows preferential growth over the others.

CDK4, and CDK6. p16 function may be impaired by other mechanisms, in addition to mutations of its gene. As many of the same activating mutations occur in both benign nevi and melanomas, malignancy most likely entails a combination of these mutations, inactivation of senescence genes (like p16) and other still unidentified alterations.

The increased understanding of melanoma molecular mechanisms has spurred the developments of targeted therapies aimed at inhibiting particular genetic pathways, including tyrosine kinase inhibitors of Kit and BRAF inhibitors, with many more in clinical development (Fig. 28-53).

CLINICAL FEATURES: Superficial spreading melanoma (SSM) usually follows a history of intermittent sun exposure and sunburn. Early melanomas in the radial growth phase have slightly elevated and palpable borders. The neoplasm is usually variably and haphazardly pigmented. Some parts are black or dark brown, while other areas may be lighter brown, possibly mixed with pink or light blue tints. The entire lesion is sometimes purely dark brown (Fig. 28-51). With regard to lesions that are eventually documented to be melanoma, patients often state that a change occurred in a nevus. Such alterations can include itching, increase in size, darkening or bleeding and oozing, though the latter signs tend to appear later. With or without such observations on the part of the patient, any lesion that prompts clinical suspicion of melanoma warrants an excisional biopsy. The "ABCDE rule" is a convenient mnemonic to help recognize changes in nevi that should prompt patients to seek medical attention: **a**symmetry of shape, **b**order irregularity, **c**olor variation and a **d**iameter more than

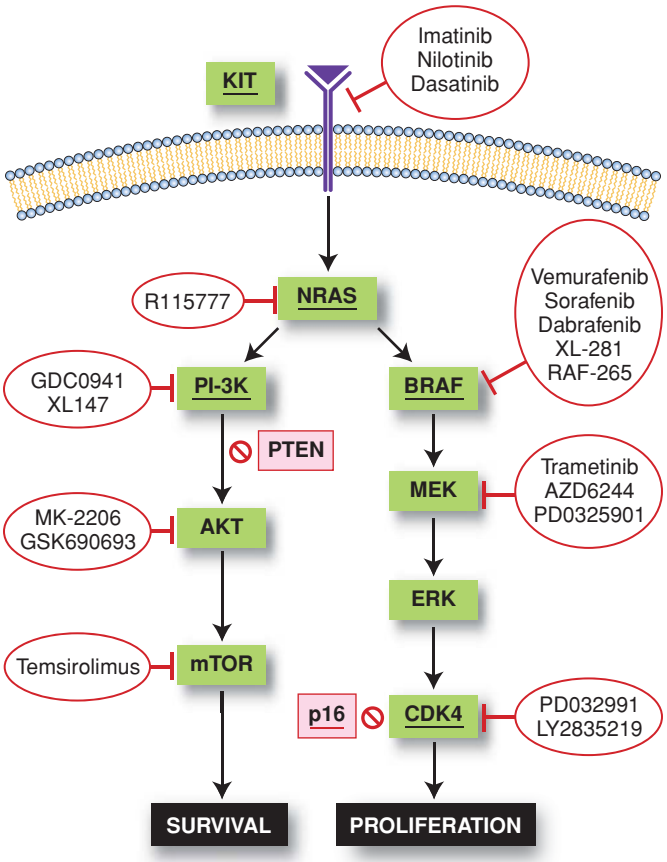

FIGURE 28-53. Simplified melanoma genetic pathway schema. Mitogen-activated protein kinase (MAPK) and phosphatidylinositol-3-kinase (PI3K)/AKT pathways are depicted, which regulate cell proliferation and cell survival, respectively. Red ovals contain examples of targeted therapeutic agents currently in use or in clinical trials. Underlined genes are ones with proven mutations in melanoma.

6 mm. The letter "E" can stand for "**e**levation" or more importantly "**e**volution." However, not all early melanomas exhibit these attributes, and any changing lesion should be evaluated for excisional biopsy.

Vertical Growth Phase Melanoma

After a variable time (usually 1–2 years), the character of growth begins to change. Melanocytes exhibit mitotic activity in both the epidermal and dermal components and grow as expanding spheroid nodules in the dermis (Fig. 28-54). The net direction of growth tends to be perpendicular to that of the radial growth phase, hence **vertical** (Figs. 28-54, 28-55 and 28-56).

PATHOLOGY: The vertical growth phase is usually characterized by:

- The cellular aggregate that characterizes the vertical growth phase is larger than the clusters of melanocytes that form the epidermal and dermal (invasive) components of the radial growth phase. Invasion can occur in both the radial growth phase and vertical growth phase, but the dominant direction of tumor growth shifts from the epidermis to the dermis in the vertical growth phase. This property of expansile growth in the dermis is called *tumorigenicity.*
- Mitotic figures are common in the vertical growth phase and, along with tumorigenicity, form one of its two defining attributes.
- Markers of cell cycle progression, such as Ki-67, and the phosphohistone mitosis markers increase in cells of the vertical growth phase.
- The melanocytes tend to look different from those of the radial growth phase. For example, they may contain little or no pigment, while the cells in the radial growth phase are melanotic.
- Tumors that involve the reticular dermis are usually considered to be in the vertical growth phase.

FIGURE 28-54. Malignant melanoma. The superficial spreading type is represented by the relatively flat, dark, brown–black portion of the tumor. Three areas in this lesion are characteristic of the vertical growth phase. All are nodular in configuration; two have a pink coloration, and the largest is a rich, ebony black.

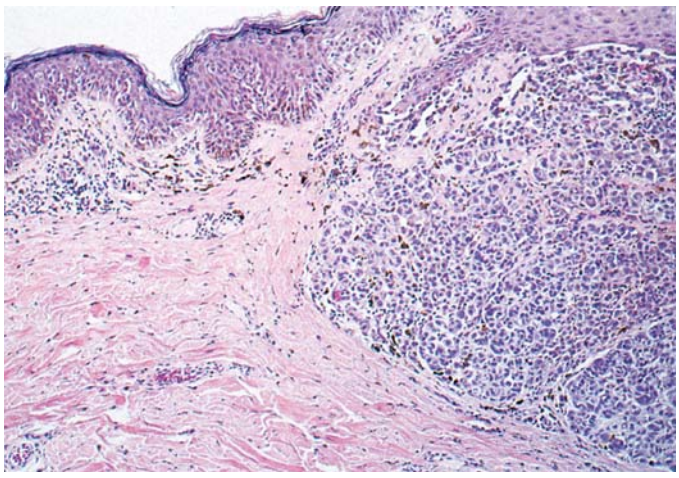

FIGURE 28-55. Malignant melanoma, superficial spreading type, vertical growth phase. Vertical growth is manifested by the distinct spheroid tumor nodule to the *right.* This focus of melanocytes clearly has a growth advantage (larger size of the aggregate) over nests in the adjacent radial growth phase (*left*).

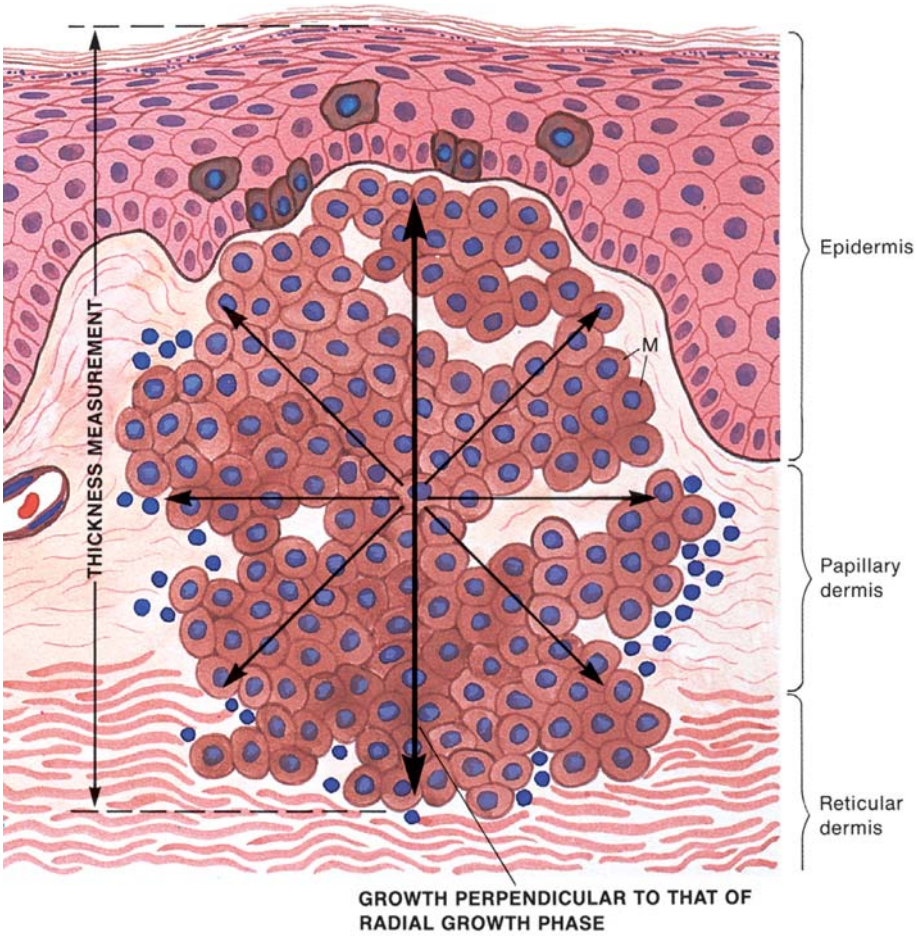

FIGURE 28-56. Malignant melanoma. The evolved vertical growth phase in malignant melanoma of the superficial spreading type is shown, with an indication of how thickness is measured. In this illustration, the vertical growth phase has extended into the reticular dermis. Small nodules of tumor cells that clearly have a growth preference over other tumor cells are a manifestation of the vertical growth phase. Thickness measurements (*arrows*) are taken from the most superficial aspect of the granular layer across the tumor at its thickest point (to its deepest point of invasion).

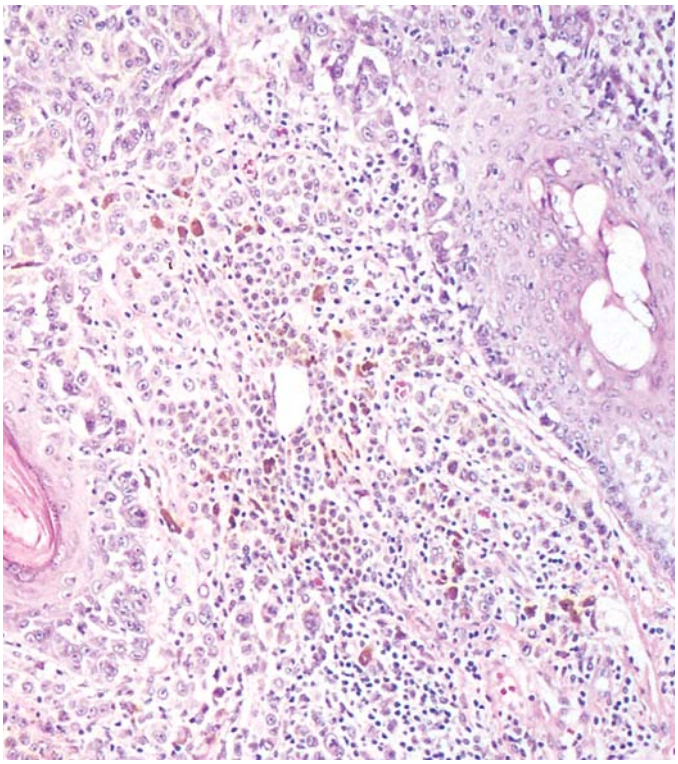

FIGURE 28-57. Malignant melanoma, vertical growth phase. The host response consists of lymphocytes infiltrating amid the melanocytes ("tumor-infiltrating lymphocytes").

- Host response (i.e., lymphocytic inflammation; Fig. 28-57) may be absent or reduced at the base of the vertical growth phase, compared to the radial growth phase.

Not all tumors in the vertical growth phase possess the propensity to metastasize. Thus, vertical growth phase melanomas less than 1 mm thick that lack mitoses rarely metastasize. The risk of metastasis can be predicted, albeit imperfectly, through the use of prognostic models.

Nodular Melanoma

Occasionally, a melanoma "bypasses" the stepwise tumor progression described above and manifests all of its malignant characteristics in the initial lesion. Nodular melanoma is an uncommon form of the tumor (10%), which appears as a circumscribed, elevated, spheroidal nodule. It does not develop through a radial growth phase but is in the vertical growth phase when initially observed (Fig. 28-58). Nodular melanoma is composed of one or more nodules of cells that grow in an expansile fashion in the dermis (Fig. 28-59). These lesions lack most of the ABCD criteria. They may be advanced in thickness, and thus at high risk of metastasis at the time of diagnosis, despite being often small in diameter, symmetric and homogeneous in color.

Lentigo Maligna Melanoma

Lentigo maligna melanoma, also known as **Hutchinson melanotic freckle,** is a large, pigmented macule that occurs

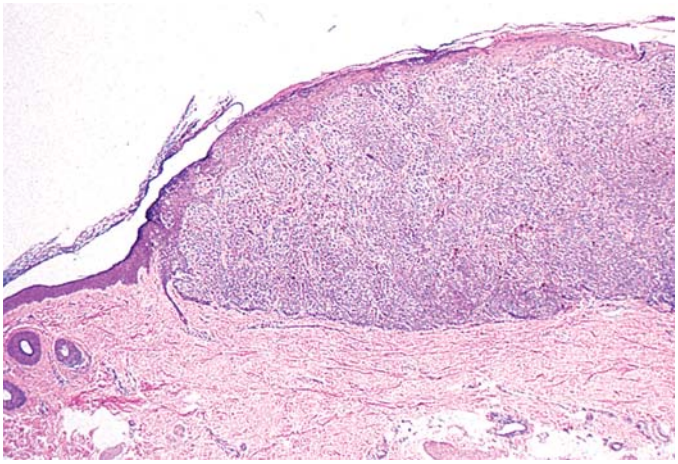

FIGURE 28-58. Malignant melanoma, nodular type. Intraepidermal growth is essentially absent. There is no radial growth lateral to the nodule. This tumor expands the papillary dermis and distorts the reticular dermal junction; it is therefore level III.

on sun-damaged skin. It develops almost exclusively in fair-skinned, usually elderly whites, often with a history of being outdoor workers. Because it occurs on exposed body surfaces, often without history of acute sunburn injury, it is probably related to chronic ultraviolet light exposure. Lentigo maligna melanoma, like acral and mucosal melanomas (see below), is less likely than superficial spreading melanoma to be associated with mutations of *B-RAF,* while *NRAS* mutations are more common. Some of these melanomas have activating mutations of the receptor tyrosine kinase c-Kit and may be responsive, at least for a time, to c-Kit inhibitors.

PATHOLOGY: In the radial growth phase, lentigo maligna melanoma (LMM) is a flat, irregular, brown to black patch that may cover a large part of the face or dorsal hands (Fig. 28-60). The cells of the radial growth phase are predominantly in the basal layer, often forming contiguous rows of atypical single melanocytes, but occasionally forming small nests that hang down into the papillary dermis (Fig. 28-61). Although cells of the radial growth phase of LMM vary in size, they tend to be smaller and less pigmented than those of SSM and are usually associated with effacement of rete ridges and thinning of the epidermis. The subjacent dermis often shows a modest lymphocytic infiltrate and, with only rare exceptions, solar degeneration of the connective tissue.

The clinical appearance of LMM in the vertical growth phase is shown in Fig. 28-62. Histologically, the cells in this phase tend to be spindle shaped. They occasionally provoke a connective tissue response to form a firm plaque **(desmoplastic melanoma),** which may mimic a scar or a neuroma and be difficult to diagnose histologically. Cells of the vertical growth phase, in any melanoma but especially in LMM and other lentiginous melanomas, may also grow along small nerves ("neurotropism").

FIGURE 28-59. Malignant melanoma of the nodular type. The primary focus of growth of this 0.5-cm lesion is in the dermis.

FIGURE 28-60. Malignant melanoma of the lentigo maligna type, radial growth phase.

Acral Lentiginous Melanoma

Acral lentiginous melanoma occurs with about equal frequency in all races. It is thus the most common form of

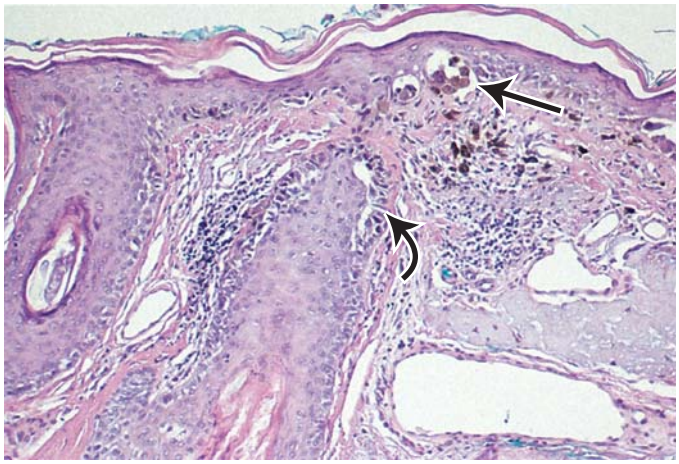

FIGURE 28-61. Lentigo maligna. Atypical melanocytes grow mostly at the dermal–epidermal interface (*straight arrow*), with extension down the external root sheath of follicles (*curved arrow*). Upward growth of melanocytes is much less prominent than in malignant melanoma of the superficial spreading type.

FIGURE 28-62. Lentigo maligna. The clinical appearance of the radial and vertical growth phase in malignant melanoma of the lentigo maligna type is shown. The lesion is 1 cm in diameter.

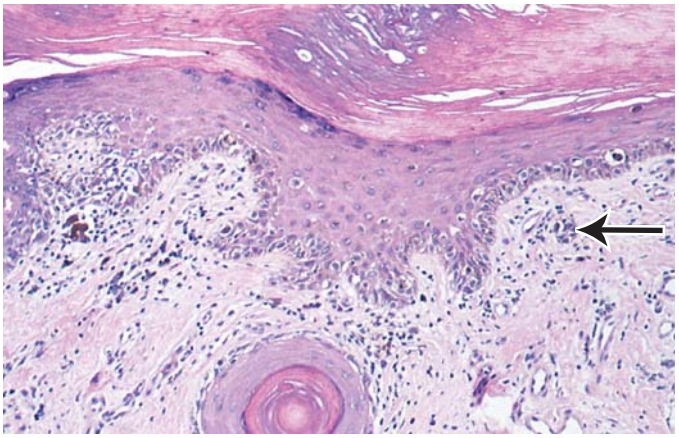

FIGURE 28-64. Malignant melanoma, acral lentiginous type, principally intraepidermal radial growth. Atypical melanocytes are present along the dermal–epidermal junction. A small dermal nest of atypical melanocytes is present (*arrow*).

melanoma in dark-skinned people. As the name implies, it is generally limited to palms, soles and subungual regions. The World Health Organization classifies "acral melanoma" to include not only lentiginous but all forms of melanoma in acral skin. Increased copy numbers and often mutations of the cell cycle marker cyclin D are common findings in these lesions.

PATHOLOGY: In the radial growth phase, acral lentiginous melanoma forms an irregular, brown to black patch that covers a part of the palm or sole or arises under a nail, usually on a thumb or great toe (Fig. 28-63). Tumor cells are confined mostly to the basal layer of the epidermis and tend to maintain long dendrites (Figs. 28-64 and 28-65). A brisk lichenoid lymphocytic infiltrate is often seen.

The vertical growth phase (Figs. 28-66 and 28-67) is like that of lentigo maligna melanoma, in that it commonly consists of spindle cells and occasionally includes desmoplasia and neurotropism.

Metastatic Melanoma

Metastatic melanoma arises from the melanocytes of the vertical growth phase of any of the various forms of melanoma. Initial metastases usually involve regional lymph nodes, although hematogenous spread to organs is also possible. When the latter occurs, metastases are unusually widespread in comparison with other neoplasms; virtually any organ may be involved. Metastatic melanomas may remain dormant and clinically undetectable for long periods after the apparently successful excision of a primary melanoma, only to reappear years later (see Chapter 5).

Staging and Prognosis of Melanoma

The prognosis of a patient with a melanoma is based on:

TUMOR THICKNESS: Tumor thickness, originally described by Breslow, is the strongest prognostic variable for melanomas that are apparently confined to their primary sites (stages 1 and 2 in the staging system of the American Joint Committee on Cancer [AJCC]). The "Breslow thickness" of a melanoma is measured from the most superficial aspect of the stratum granulosum to the point of maximal thickness (Fig. 28-56). Outcome may be predicted with some

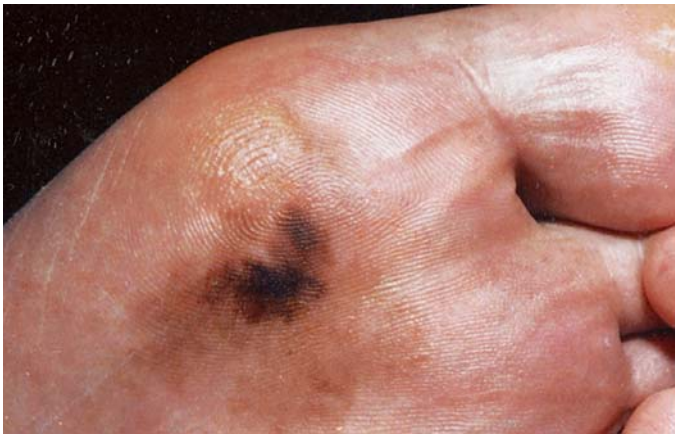

FIGURE 28-63. Malignant melanoma, acral lentiginous type (radial growth phase). The clinical appearance of the sole of the foot is depicted.

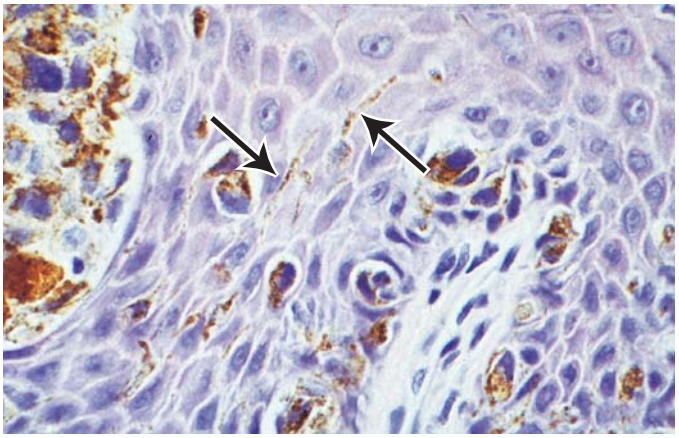

FIGURE 28-65. Malignant melanoma, acral lentiginous type. Large melanocytes with prominent dendrites (*arrows*) are present in the basilar region of the epidermis. The tumor cells contain numerous melanosomes, making the perinuclear and dendritic cytoplasms brown.

FIGURE 28-66. Malignant melanoma, acral lentiginous type. The lesion on the heel is the primary tumor. The flat portion represents the radial growth phase, while the elevated portion indicates the vertical growth phase. The dark nodule on the instep is a metastasis.

accuracy by dividing tumors based on thickness. Cutoffs occur at 1-mm intervals, although the 0.76-mm cutoff originally proposed by Breslow still has merit for optimal separation of the lowest-risk melanomas. Prognosis up to 10 years after removal of the primary lesion may then be estimated from Table 28-2.

ULCERATION: Ulceration in a primary melanoma is associated with decreased survival. In one study, survival rates were 66% and 92% for patients with and without ulceration, respectively. Ulceration is a stage modifier in the AJCC system; its presence raises a lesion to the next stage in each thickness group.

DERMAL MITOTIC RATE: For tumor cells in the vertical growth phase, the mitotic rate correlates well with survival. Survival becomes progressively worse as the mitotic rate increases. The 5-year survival is 99% for patients whose tumors show no mitoses, 85% if the mitotic rate is 0.1–6.0/mm^2 and 68% with greater than 6 mitoses/mm^2. Mitogenicity, or the presence of any mitoses in the dermis, is a risk factor for recurrence in otherwise early-stage ("thin") melanomas and is a modifier of stage 1 (melanomas of thickness <1 mm).

TABLE 28-2

TUMOR THICKNESS AS SOLE PREDICTOR OF OUTCOME 10 YEARS AFTER DEFINITIVE THERAPY OF PRIMARY MELANOMA

Thickness (mm)	Survival (%)
≤1	83–88
1.01–2	64–79
2.01–4	51–64
>4	32–54

LYMPHOCYTIC INFILTRATE: Interaction of lymphocytes with tumor cells in the vertical growth phase is an important prognostic indicator. Lymphocytes are said to be "infiltrative" when they actually penetrate and disrupt the tumor, frequently forming rosettes around tumor cells (Figs. 28-57 and 28-68). If tumor-infiltrating lymphocytes (TILs) are present throughout the vertical growth phase or are seen across the entire base of the vertical growth phase, the infiltrate is said to be "brisk." The more prevalent the TILs, the better is the prognosis. However, this and the other attributes listed below are not included in the AJCC staging system, which is the current standard of care.

LOCATION: Melanomas on the extremities have a better prognosis than those on the head, neck or trunk (axial).

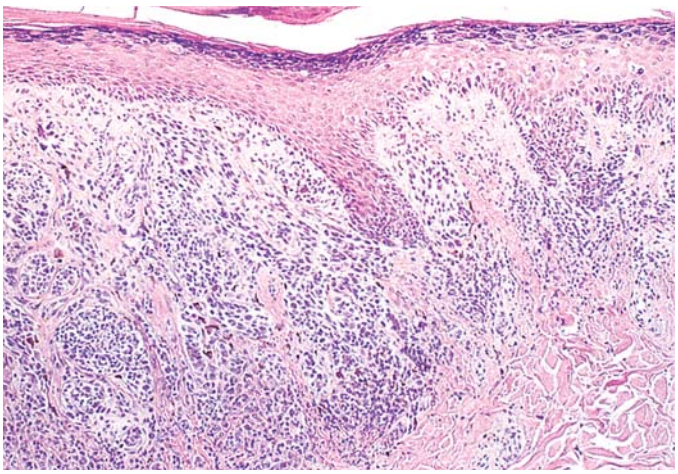

FIGURE 28-67. Malignant melanoma, acral lentiginous type, vertical growth phase. On the *left* is confluent growth of atypical dermal melanocytes filling and expanding the papillary dermis.

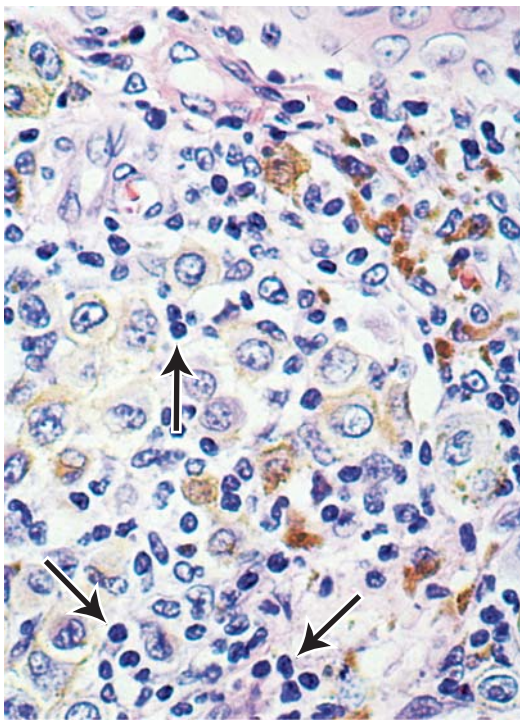

FIGURE 28-68. Malignant melanoma, vertical growth phase. Numerous tumor-infiltrating lymphocytes are arranged among individual tumor cells.

However, melanomas on the sole of the foot or the subungual region have a prognosis similar to, or worse than, axial lesions.

SEX: For every site and thickness, women have better prognoses than men. For example, women with axial melanomas 0.8–1.7 mm thick have almost 90% 10-year survival after excision of the lesion, while the comparable figure in men is 60%.

REGRESSION: Many primary melanomas show some spontaneous regression in the radial growth phase component, indicated clinically by a color change to blue-white or white. Such regression entails a widened papillary dermis, containing melanophages and a lymphocytic infiltrate, with no melanoma cells in the epidermis overlying these dermal changes. The prognostic significance of partial regression is unclear: many studies suggest that it reflects a worse prognosis, but the issue is not settled.

LEVELS OF INVASION: The Clark level system describes the degree of tumor penetration within the anatomic layers of the skin The Clark levels are not as accurate as tumor thickness in predicting risk of metastasis and are not included in the AJCC system. However, levels have prognostic significance in some subsets of cases.

- **Level I:** Tumor cells are entirely above the basement membrane (in situ).
- **Level II:** Invasive cells are present only in the papillary dermis without filling or expanding it (radial growth phase).
- **Level III:** The tumor has usually entered the vertical growth phase and impinges on the reticular dermis, forming small expansile nodules that expand and fill the papillary dermis.
- **Level IV:** Tumor cells invade between the collagen bundles of the reticular dermis.
- **Level V:** The tumor extends into the subcutaneous fat.

LYMPHATIC INVASION: Although intuitively important, this property has not been included in prognostic models because it is rarely seen in routine sections. There is recent evidence that lymphatic invasion may be more common than previously thought when enhanced detection techniques are used, and that it is prognostically significant.

STAGE: The stage of the disease is the most important single factor influencing a patient's survival. Metastasis to regional lymph nodes is now determined routinely by sentinel lymph node staging, which involves biopsy of a single node that lies first in the regional node drainage pattern. Lymph node involvement suggests an estimated 40% decrease in 5-year survival, compared with patients with clinically localized tumors. The number of involved lymph nodes is also highly predictive of prognosis. Patients with 1 positive node have a 10-year survival of 40%, compared with 25% with 2–4 positive nodes, and 15% with 5 or more nodes involved.

The tumor–node–metastasis (TNM) system of tumor staging incorporates features of the primary tumor, regional lymph nodes and soft tissues and distant metastases. The **T** (primary tumor) attributes of tumor thickness, presence or absence of ulceration and mitogenicity are classified histologically after excision of the melanoma. Numbers of lymph nodes with metastatic tumor and characterization of this tumor as micrometastasis or macrometastasis are a large part of the **N** (node) classification. **Micrometastases** are nodal metastases diagnosed after sentinel or elective lymphadenectomy; **macrometastasis** are clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy. The term "submicroscopic" metastasis has been proposed for sentinel node involvement below certain thresholds of size and penetration into the node. The **M (metastasis)** properties incorporate results of evaluation for distant metastases at various anatomic sites. TNM classification is based primarily on thickness and modified by ulceration and mitogenicity. For localized primary melanomas and for regional and systemic metastatic disease, it helps define the pathologic stage of disease, which in turn reflects the probability of survival.

Current recommendations regarding excision of confirmed melanomas state that a 5-mm margin of uninvolved tissue should be obtained with in situ melanoma, a 1-cm margin with a tumor thickness of 1 mm or less and a 2-cm margin with a tumor thickness greater than 1 mm or with Clark level IV or greater with any thickness. However, many clinicians would use a 1-cm margin, at least for tumors in the lower end of these ranges, and margins are typically adjusted so as to spare important structures, such as the eyes. Sentinel lymph node sampling is generally considered with tumor thickness greater than 1 mm or with other risk factors, including ulceration or mitogenicity (dermal mitotic activity), especially in tumors thicker than 0.75 mm. If metastatic disease ensues, targeted therapeutics, such as BRAF inhibitors, can be employed. Immunomodulatory drugs are also used, such as antibodies to CTLA-4 (cytotoxic T-lymphocyte antigen 4) and PD-1 (programmed cell death 1), to boost immune responses against malignancy.

Benign Tumors of Melanocytes May Mimic Melanoma

Congenital Melanocytic Nevus

About 1% of white children are born with some form of pigmented skin lesion, sometimes as inconspicuous as a small patch of pale tan hyperpigmentation. Much more rarely, the trunk or an extremity is covered by a large pigmented patch or plaque that is cosmetically deforming ("giant hairy" or "garment" nevus). Such areas display a striking increase in intraepidermal and dermal melanocytes, which may extend deep into the subcutaneous tissue. Malignant melanomas may develop in these large congenital melanocytic nevi, although not in the majority of cases. These melanomas may occur in childhood. Attempts are sometimes made to remove these large lesions, but their size may make surgical removal problematic.

Spitz Nevus/Tumor

Spitz tumors (also known as spindle and epithelioid cell nevi) occur in children or adolescents and, less often, in adults. They are elevated, spheroid, pink, smooth nodules, usually on the head or neck. Spitz tumors grow rapidly, reaching 3–5 mm in 6 months or less. Lesions are composed of large spindle or epithelioid melanocytes in the epidermis and dermis (Fig. 28-69). The cells, although to some extent stereotypic, are so atypical that an incorrect diagnosis of melanoma may be made, even though melanoma is rare in childhood. Most Spitz tumors are benign and are called Spitz nevi. A few have metastasized, although usually not beyond regional nodes. Therefore, the prognosis is to some extent uncertain,

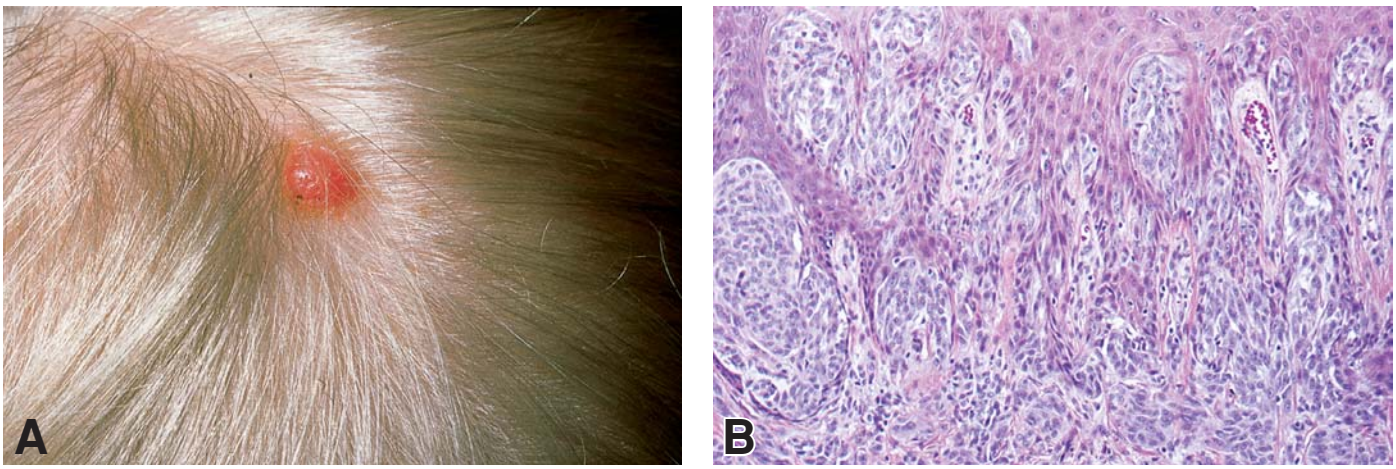

FIGURE 28-69. Spindle and epithelioid cell (Spitz) nevus. A. A symmetric pink nodule appeared suddenly in a child but then remained stable for several weeks until it was excised. **B.** Spitz tumors are composed of large melanocytes with prominent nuclei. Within a hyperplastic epidermis, the melanocytes are present in large nests. Even though the cells are large and, at first glance, suggest melanoma, they are much more uniform than the cells of most malignant melanomas.

especially in adults. Sometimes in these lesions, as in other rare categories of melanocytic tumors, a descriptive diagnosis, such as "melanocytic tumor of uncertain malignant potential" (MELTUMP), is all that can be rendered. Genomic studies that look for copy number variation in the tumor cell nuclei can provide additional information that may be of assistance in decision making regarding therapy. Most Spitz tumors have fusion gene rearrangements forming constitutively activated chimeric oncogenes, rather than the point mutations of oncogenes that are the rule in melanomas.

Blue Nevus

Blue nevi appear in childhood or late adolescence as dark blue, gray or black, firm, well-demarcated papules or nodules on the dorsal hands or feet or on the buttocks, scalp or face. Their clinical appearance may prompt an excisional biopsy to rule out nodular melanoma. Melanin-containing melanocytes with long, thin dendrites are present in the superficial to middermis, where they are often admixed with numerous melanin-containing macrophages (Fig. 28-70). There are also rare examples of "cellular blue nevi" and "malignant blue nevi."

Freckle and Lentigo

Freckles, or **ephelides,** are small, brown macules that occur on sun-exposed skin, especially in people with fair skin (Fig. 28-71). They usually appear at about age 5. The pigmentation of a freckle deepens with exposure to sunlight and fades when light exposure ceases. A **lentigo** is a discrete, brown macule that appears at any age and on any part of the body (though a **solar lentigo,** or "liver spot," appears at an older age after long-term sun exposure) (Fig. 28-72). Unlike ephelides, the pigmentation of a lentigo does not depend on sun exposure. Ephelides show hyperpigmentation of basal keratinocytes without concomitant increases in the number of melanocytes. Lentigines, on the other hand, display elongated rete ridges, increased melanin pigment in both basal keratinocytes and melanocytes and increased melanocytes. Larger lesions may need to be biopsied to rule out lentigo maligna melanoma.

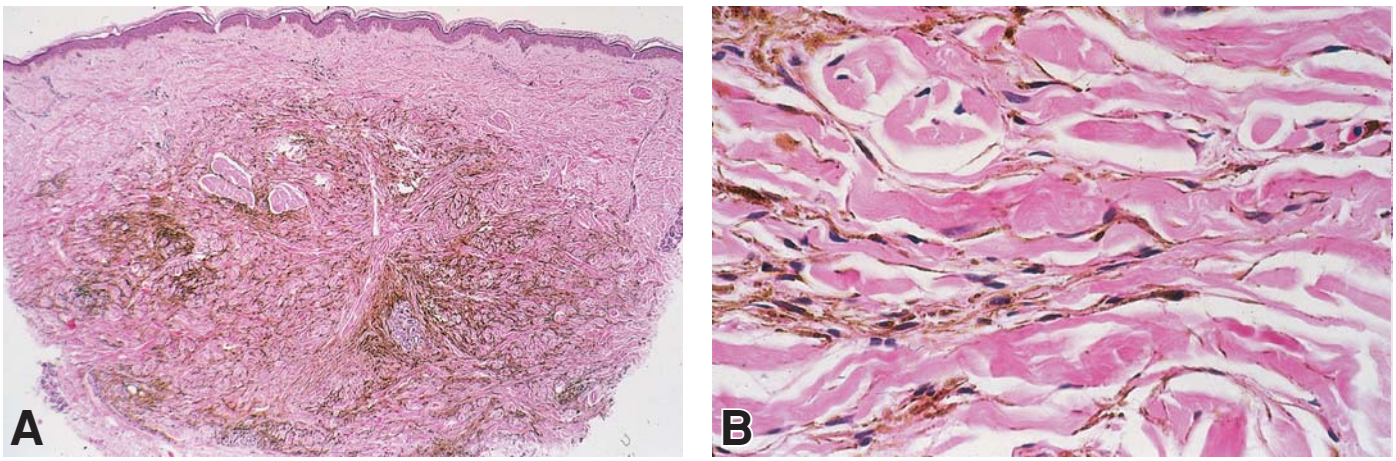

FIGURE 28-70. Blue nevus. A. Within the dermis there is a poorly defined but symmetric spindle cell proliferation that is dark brown. **B.** The lesion is composed of elongated cells with heavily pigmented dendrites and small bland nuclei.

FIGURE 28-71. Freckle. A fair-complexioned man has a prominent brown macule that darkens in sunlight.

Lentigines, often called freckles by the public and by clinicians, are strong risk factors for melanoma, acting synergistically with nevi, dysplastic nevi and other risk factors. Their prevalence is strongly related to polymorphisms of the melanocortin receptor gene (*MC1R,* which has been named the "freckle gene").

Verrucae Are Warts Caused by Human Papillomavirus

Verrucae are cutaneous tumors. They are elevated, circumscribed, symmetric, epidermal proliferations that often appear papillary. ***HPV is the cause of verrucae.***

PATHOLOGY:

- **Verruca vulgaris,** or the **common wart,** is an elevated papule with a verrucous (papillomatous) surface. A papilla, the defining feature of a papilloma, is a finger of connective tissue usually containing a vessel, covered by a glove of epithelium. Such lesions may be single or multiple and occur most on the dorsal surfaces of the hands or on the face.

FIGURE 28-72. Lentigo. A 1-cm irregular patch of slightly variegated hyperpigmentation is present with a background of chronic solar damage.

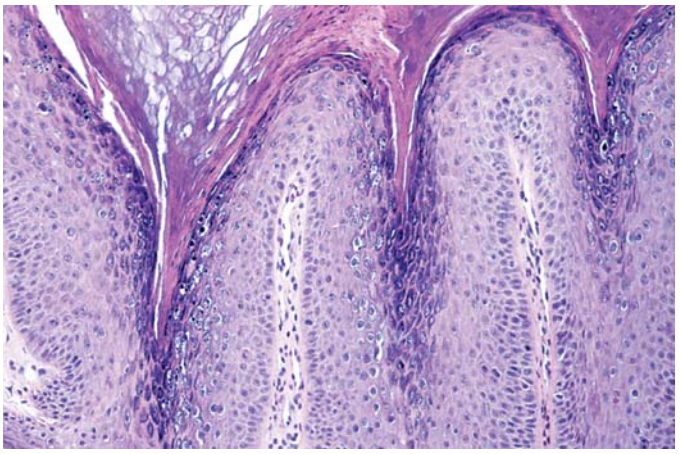

FIGURE 28-73. Verruca vulgaris. Verruca vulgaris is the prototype of papillary epidermal hyperplasia. Squamous epithelial-lined fronds have fibrovascular cores. The blood vessels within the cores extend close to the surface of verrucae, which makes them susceptible to traumatic hemorrhage and the resultant black "seeds" that patients observe.

Verruca vulgaris displays hyperkeratosis and papillary epidermal hyperplasia (Fig. 28-73). **Koilocytes** (i.e., enlarged keratinocytes with a pyknotic nucleus surrounded by a halo-like cleared area) are seen within the upper epidermis. Viral inclusions are difficult to identify (Fig. 28-74). HPV, especially serotypes 2 and 4, are commonly found in verruca vulgaris. There is no malignant potential.

- **Plantar warts** are benign, frequently painful, hyperkeratotic nodules on the soles of the feet. Occasionally, similar lesions appear on the palms of the hands **(palmar warts)**. Plantar warts are endophytic or exophytic, papillary, squamous epithelial proliferations. The cells contain abundant cytoplasmic inclusions that resemble the darker-staining keratohyaline granules. The nuclei of keratinocytes near the base of these warts also contain pink nuclear inclusions. HPV type 1 is the etiologic agent.
- **Verruca plana,** or "flat warts," are small flat papules that typically appear on the face. They display slight elongation

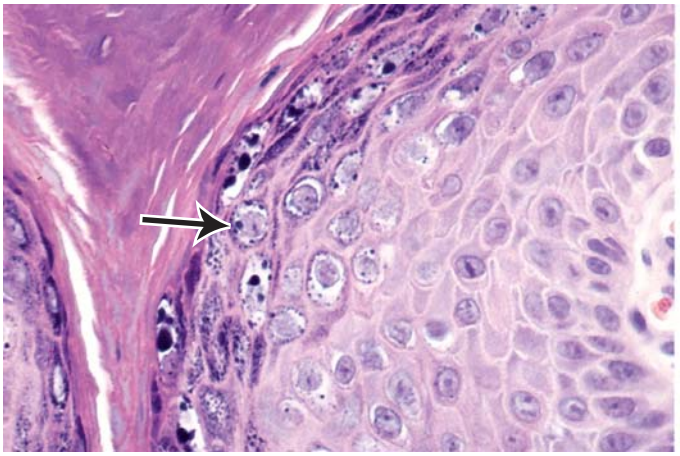

FIGURE 28-74. Verruca vulgaris. Characteristic cytopathic changes occur in the outer portion of the stratum spinosum and stratum granulosum, in which there is perinuclear vacuolization and prominent keratohyaline granules, with homogeneous blue inclusions (*arrow*).

of rete ridges (acanthosis), striking hypergranulosis and superficial koilocyte formation. HPV types 3 and 10 often elicit these lesions. The lesions do not progress to cancer.

- **Condyloma acuminatum** is a venereally transmitted wart usually caused by HPV serotypes 6 and 11 and occurring primarily around the genitalia. These are papillary squamous proliferations. Koilocytosis and an almost continuous cap of parakeratosis are usually present. Squamous carcinomas may develop, especially when HPV types 16 and 18 are involved.
- **Bowenoid papulosis,** also caused by HPV types 16 and 18, is characterized by multiple hyperpigmented papules on the genitalia. Lesions may be histologically identical to squamous cell carcinoma (SCC) in situ in that they display disordered epithelial maturation and scattered keratinocyte atypia. The lesions also exhibit parakeratosis and irregular acanthosis. Although Bowenoid papulosis often regresses, it may progress to dysplasia or malignancy.
- **Epidermodysplasia verruciformis** is a rare autosomal recessive disease characterized by impaired cell-mediated immunity and subsequent enhanced susceptibility to HPV infection. Warts similar to those of verruca plana, with confluence into patches, are widespread. It first appears in childhood, and squamous cell carcinoma develops in 30%–60% of patients. HPV types 5, 8, 9 and 47 are most common.

Keratosis Is a Benign Horny Growth Composed of Keratinocytes

Seborrheic Keratosis

Seborrheic keratoses are scaly, frequently pigmented, elevated papules or plaques with scales that are easily rubbed off. They are common later in life but their etiology is unknown. Seborrheic keratoses tend to be familial. Clinically and microscopically, they appear "pasted on" and contain broad anastomosing cords of mature stratified squamous epithelium, forming papillae and associated with small cysts of keratin (horn cysts) (Fig. 28-75). Seborrheic keratoses are innocuous but are a cosmetic nuisance. The sudden appearance of many seborrheic keratoses may be associated with internal malignancies ("sign of Leser-Trélat"), especially gastric adenocarcinoma.

Actinic Keratosis

Actinic keratoses ("from the sun's rays") are keratinocytic neoplasms that develop in sun-damaged skin as circumscribed keratotic patches or plaques, commonly on the backs of the hands or the face. The stratum corneum is no longer loose and basket-weaved but is replaced by a dense parakeratotic scale. The basal keratinocytes show significant atypia (Fig. 28-76). Actinic keratoses may evolve into squamous carcinomas in situ and finally into invasive cancers, but most are stable and many regress.

Keratoacanthoma

Keratoacanthomas are rapidly growing keratotic papules on sun-exposed skin that develop over 3–6 weeks into crater-like nodules. They reach a maximum size of 2–3 cm. Spontaneous regression usually follows within 6–12 months, leaving an atrophic scar. Some lesions may cause considerable damage before they regress, and some fail to regress. Keratoacanthomas are considered by some to be self-resolving variants of squamous cell carcinoma.

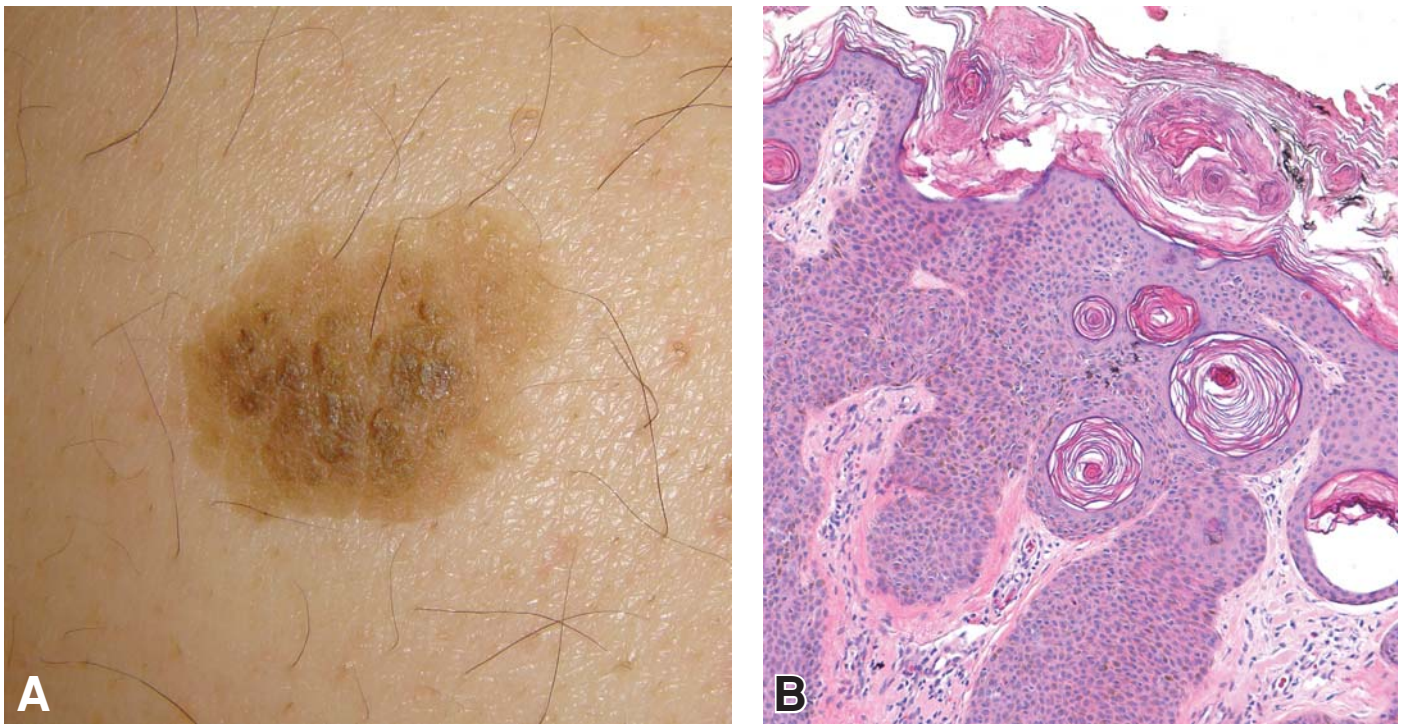

FIGURE 28-75. Seborrheic keratosis. A. Sharply defined, "stuck-on" brown lesions are a common presentation. **B.** Broad anastomosing cords of mature stratified squamous epithelium are associated with small keratin cysts.

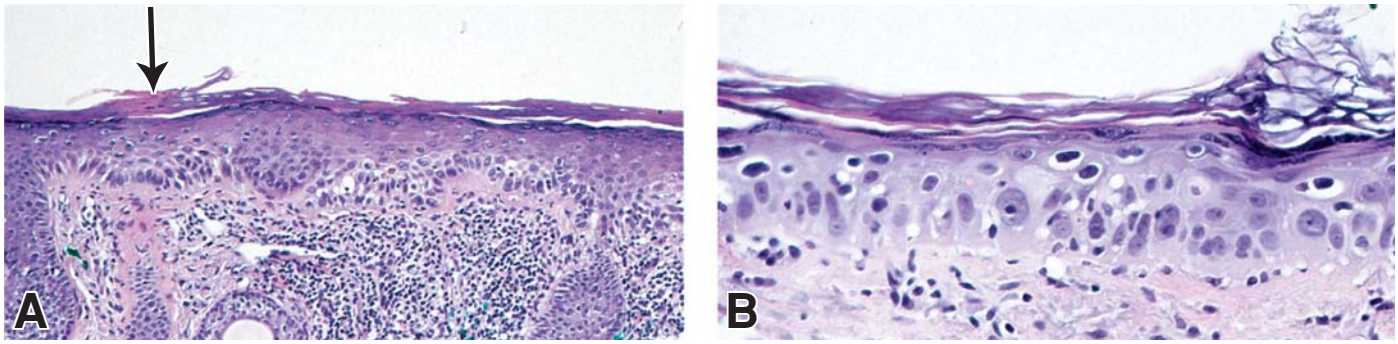

FIGURE 28-76. Actinic keratosis. A. A low-power view reveals cytologic atypia within the stratum basalis and lower stratum spinosum with loss of polarity. A lichenoid, band-like, lymphocytic infiltrate is frequently present. Parakeratosis is present here only in a small focus (*arrow*). **B.** High-power examination of an actinic keratosis reveals striking cytologic atypia of the basal keratinocytes, the hallmark of actinic keratoses.

PATHOLOGY: Histologically, keratoacanthomas are endophytic proliferations of keratinocytes. The lesion is cup shaped, with a central, keratin-filled umbilication and overhanging ("buttressing") epidermal edges (Fig. 28-77). At the base of the keratin, keratinocytes are large and have abundant homogeneous, eosinophilic ("glassy") cytoplasm. At the lower aspect of the lesion, irregular tongues of squamous epithelium infiltrate the collagen of the reticular dermis. Older lesions show active fibroplasia in the dermis around these tongues. There may be focal lichenoid inflammation, and the dermis may be markedly infiltrated with neutrophils, lymphocytes and eosinophils. Microabscesses of neutrophils and entrapped dermal elastic fibers are often present within the lesion.

Basal Cell Carcinoma Is a Locally Invasive Epidermal Neoplasm

Basal cell carcinoma (BCC) is the most common malignant tumor in people with pale skin. It may be locally aggressive, but metastases are exceedingly rare.

MOLECULAR PATHOGENESIS: ***BCC usually develops on sun-damaged skin of people with fair skin and freckles.*** However, unlike squamous lesions, BCC also arises on areas not exposed to intense sunlight. It is unusual to find BCC on the fingers and dorsal surfaces of the hands. The tumor is thought to derive from pluripotential cells in the basal layer of the epidermis, more specifically, in the bulge region of the hair follicle.

In several heritable syndromes, BCC originates on skin that has had little light exposure. In **nevoid BCC syndrome,** multiple tumors occur in the context of a complex multisystem disease. The syndrome also includes pits (dyskeratoses) on the palms and soles, mandibular cysts, hypertelorism and a predisposition to other neoplasms, including medulloblastoma. The BCCs of this syndrome appear at a young age and may number in the hundreds.

Germline mutations in the *PTCH* tumor suppressor gene on chromosome 9q22 cause nevoid BCC syndrome. Somatic mutations in *PTCH* have been implicated in up to 90% of sporadic BCCs and may be targeted in therapy of advanced lesions.

PATHOLOGY: BCCs contain nests of deeply basophilic epithelial cells with narrow rims of cytoplasm that are attached to the epidermis and protrude into the subjacent papillary dermis (Fig. 28-78). At least in early lesions, there is typically a specialized loose mucinous stroma containing fibroblasts and lymphocytes. Clefting artifact between the epithelial cells of the tumor and the stroma may sometimes help to distinguish BCC from

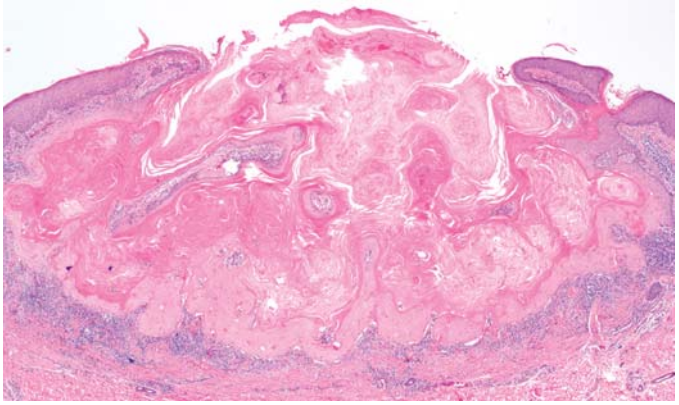

FIGURE 28-77. Keratoacanthoma. A keratin-filled crater (*center*) is lined by glassy proliferating keratinocytes.

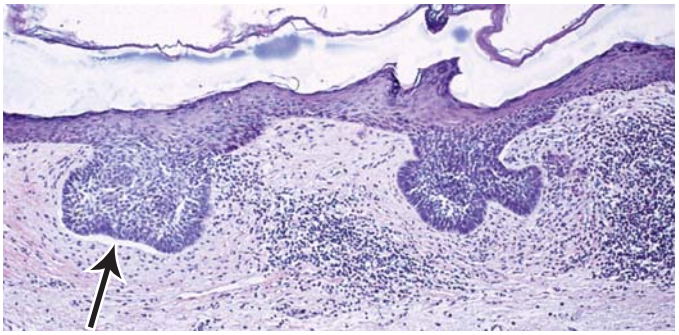

FIGURE 28-78. Basal cell carcinoma, superficial type. Buds of atypical basaloid keratinocytes extend from the overlying epidermis into the papillary dermis. The peripheral keratinocytes mimic the stratum basalis by palisading. The separation artifact (*arrow*) is present because of poorly formed basement membrane components and the hyaluronic acid-rich stroma that contains collagenase.

other adnexal neoplasms with basaloid cell proliferation. The central part of each nest contains closely packed keratinocytes that are slightly smaller than normal epidermal basal keratinocytes and show occasional apoptosis and mitoses. The periphery of each nest shows an organized layer of polarized, columnar keratinocytes, with the long axis of each cell perpendicular to the surrounding stroma ("peripheral palisading"). **Superficial, multicentric BCC** is composed of apparently isolated, but actually interconnected, nests that usually remain confined to the papillary dermis and manifest clinically as a spreading plaque. **Nodulocystic BCC** is also attached to the epidermis and exhibits the same cytologic and architectural features as the superficial type of BCC but grows more deeply into the dermis. Usually, tumor cells of the dermal islands are associated with a mucinous ground substance and are surrounded by an array of fibroblasts and lymphocytes. An important distinction is between BCCs with pushing borders and those with an infiltrative pattern, because the latter may be more likely to recur locally and to progress. Infiltrating BCCs with particularly dense sclerotic stroma are called **morpheaform BCCs** because of a clinical resemblance to lesions of localized scleroderma (also known as "morphea").

CLINICAL FEATURES: Common forms of BCC include:

- **Pearly papule** is the prototypic nodulocystic type of lesion, so named because it resembles a 2–3-mm pearl (Fig. 28-79). It is covered by tightly stretched epidermis and is laced with small, delicate, branching vessels (telangiectasia).
- **Rodent ulcer** is a small crater in the center of the pearl.
- **Superficial BCC** appears as a scaly, red, sharply demarcated plaque.
- **Morpheaform BCC** is a pale, firm, scar-like tumor that is ill-defined on and especially beneath the skin surface, making it particularly difficult to eradicate.
- **Pigmented BCC** may grossly resemble malignant melanoma. The pigment comes from reactive melanocytes that populate the tumor.

Treatment of BCC usually involves various excision or eradication procedures.

Cells of Squamous Cell Carcinomas May Resemble Differentiated Keratinocytes

SCCs are second only to BCCs in skin cancer incidence. SCCs are most common on sun-damaged skin of fair individuals with light hair and freckles, and often originate in actinic keratoses. They are exceedingly rare on normal black skin.

ETIOLOGIC FACTORS: SCCs have multiple causes, UV light being the most common, but also including ionizing radiation, chemical carcinogens and HPV. SCCs arising in sun-damaged skin metastasize rarely (<2%). They may also arise in chronic scarring processes, such as osteomyelitis sinus tracts, burn scars ("Marjolin ulcers") and areas of radiation dermatitis. In these settings, they metastasize more often. Over 90% of SCCs, and many actinic keratoses, have mutated *TP53* genes.

PATHOLOGY: SCC is composed of tumor cells that mimic epidermal stratum spinosum in varying degrees and extend into the subjacent dermis (Fig. 28-80). The edges of many tumors show changes typical of actinic keratosis, namely, a variably thickened epidermis with parakeratosis and significant atypia of basal keratinocytes.

CLINICAL FEATURES: SCCs characteristically arise in chronically sun-exposed areas such as the backs of the hands, face, lips and ears (Fig. 28-80A). Early lesions are small, scaly or ulcerated, erythematous papules, which may be pruritic. They are usually treated by excision, or sometimes by electrosurgery, topical chemotherapy or radiation therapy.

Merkel Cell Carcinomas Are Aggressive Tumors of Neurosecretory Cells That Show Epithelial Differentiation

These are typically solitary, dome-shaped, red to violaceous nodules or indurated plaques on the skin of the head and neck in elderly white patients. Merkel cell carcinomas

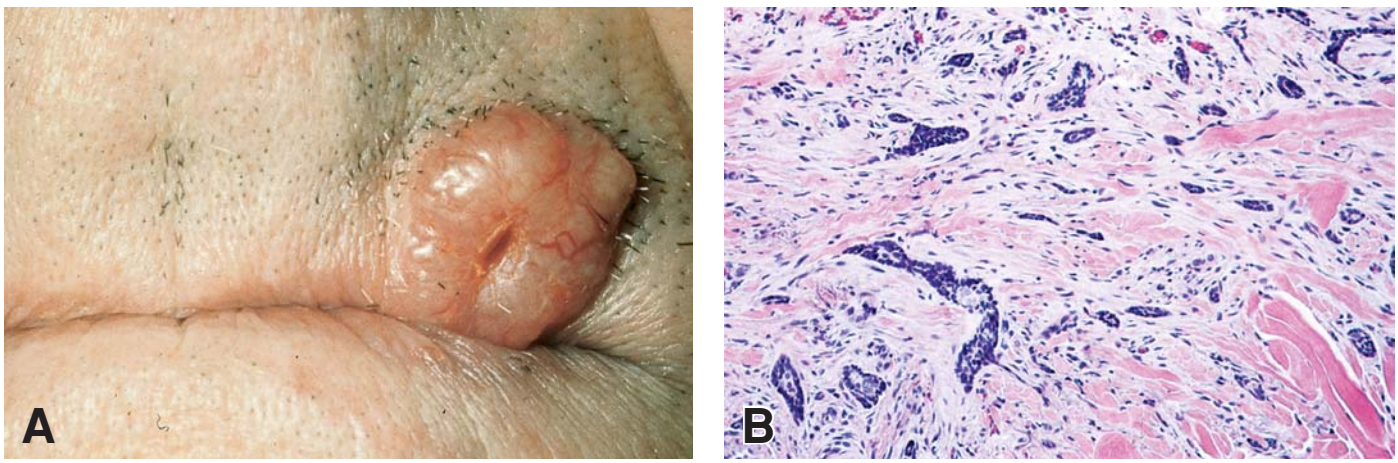

FIGURE 28-79. Basal cell carcinoma (BCC). A. Pearly papule: the tumor exhibits typical rolled pearly borders with telangiectases and central ulceration. **B.** Microscopic examination of morpheaform BCC shows a sclerosing and infiltrative lesion. Irregularly branching strands of tumor cells permeate the dermis, with induction of a cellular, fibroblastic, hyaluronic acid–rich stroma.

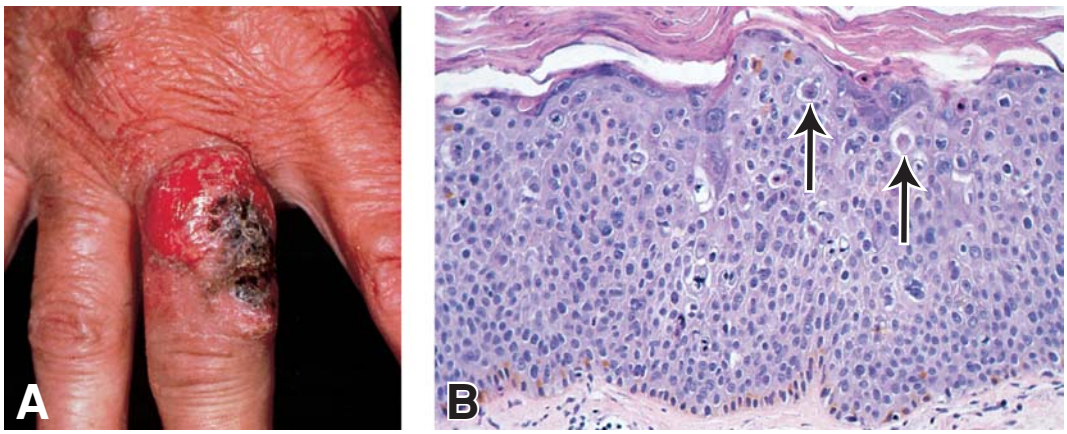

FIGURE 28-80. Squamous cell carcinoma. A. An ulcerated, encrusted and infiltrating lesion is seen on the sun-exposed dorsal aspect of a finger. **B.** A microscopic view of the periphery of the lesion shows squamous cell carcinoma in situ. The entire epidermis is replaced by atypical keratinocytes. Mitoses are apparent, as is apoptosis (*arrows*).

(MCCs) are aggressive tumors that are lethal in 25%–70% of patients within 5 years.

PATHOLOGY: Most MCCs have large nests of undifferentiated cells that resemble small cell carcinoma of the lung (Fig. 28-81). Peripherally, the tumors may show a trabecular pattern. Nuclear chromatin is dense and evenly distributed, cytoplasm is scant and mitotic figures and nuclear fragments are common. Cytokeratin 20 is distributed in a "perinuclear dot" cytoplasmic pattern. Tumor cells also express neuroendocrine markers such as chromogranin and synaptophysin.

MOLECULAR PATHOGENESIS: The genome of Merkel cell polyoma virus (MCV) is present in 75% of MCCs and may play a role in tumorigenesis. However, MCV is a common virus and association with MCCs is still speculative (see Chapter 5). Tumorigenicity is associated with a truncating mutation of the MCV *Tag* gene.

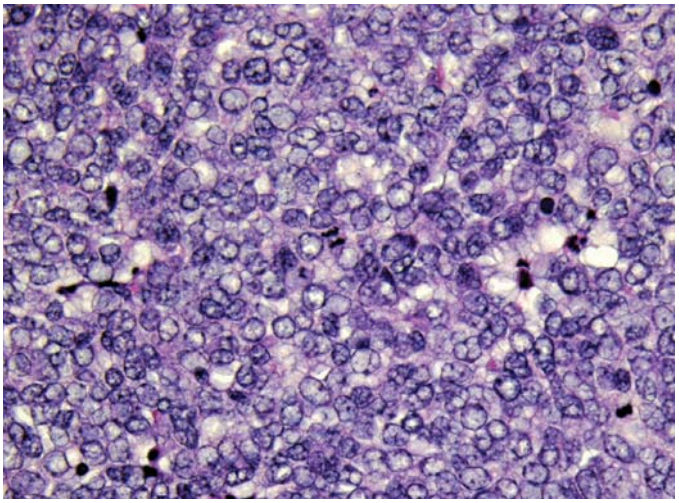

FIGURE 28-81. Merkel cell carcinoma. The tumor is composed of solid nests of undifferentiated cells that resemble small cell carcinoma of the lung.

Adnexal Tumors Differentiate toward Skin Appendages

Adnexal tumors appear as elevated small skin nodules that often occur in people with family histories of similar tumors. The lesions often appear at puberty. Although most are benign, malignant behavior is sometimes observed.

Sebaceous Neoplasms

Sebaceous neoplasms, including sebaceous adenomas, sebaceous epitheliomas (sebaceomas) and sebaceous carcinomas, are all tumors of sebaceous gland derivation. Clinically, sebaceous adenomas and epitheliomas are small, slow-growing papules or nodules commonly on the head and neck. Sebaceous carcinomas, however, often present larger than 1 cm and have a predilection for periocular sites. Histopathologically, sebaceous adenomas show a well-circumscribed proliferation of sebaceous lobules, primarily composed of mature sebocytes with some germinative basaloid cells. Sebaceous epitheliomas have a preponderance of germinative cells. Sebaceous carcinomas show histologic signs of malignancy, such as severe cytologic atypia, high mitotic activity and infiltrative growth.

MOLECULAR PATHOGENESIS: Patients with Muir-Torre syndrome, a variant of hereditary nonpolyposis colorectal carcinoma (HNPCC), present with sebaceous neoplasms. HNPCC (or Lynch syndrome) is associated with inherited germline defects in mismatch repair genes such MLH1, MSH2 and MSH6 (Fig. 28-82). See Chapters 5 and 19 for more about HNPCC.

Cylindroma

Cylindromas are adnexal neoplasms with features of sweat gland differentiation. They may be solitary or multiple elevated nodules around the scalp. An autosomal dominant, heritable variant features multiple tumors. Occasionally, they become large and cluster about the head ("turban tumors"). Cylindromas show sharply circumscribed nests of deeply basophilic cells surrounded by a hyalinized, thickened BMZ (Fig. 28-83).

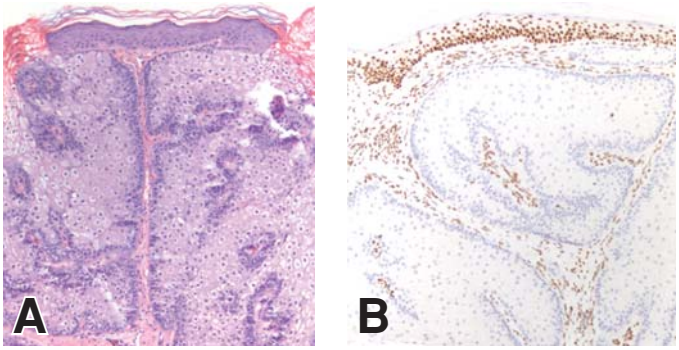

FIGURE 28-82. Sebaceous Adenoma. A. Microscopic view of sebaceous adenoma showing large sebaceous lobules composed primarily of clear sebocytes lined by basaloid germinative cells. **B.** Immunohistochemical staining for mismatch repair protein MSH6 shows loss of nuclear staining in the neoplastic sebaceous cells with intact staining in the benign surface epithelium and in intermixed dermal fibroblasts, indicating this patient may have Muir-Torre syndrome.

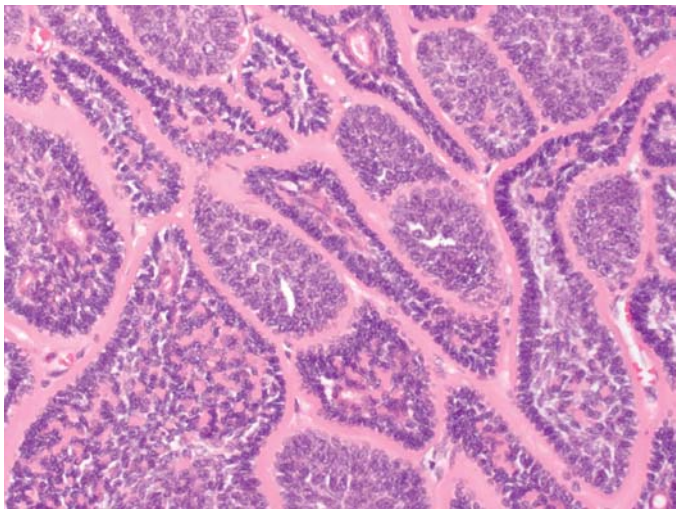

FIGURE 28-83. Cylindroma. Sharply circumscribed islands of basophilic epithelial cells reside in a jigsaw puzzle–like array. Dense eosinophilic hyaline sheaths surround each island.

Syringoma

Syringomas typically occur about the eyelid and upper cheek as small, elevated, flesh-colored papules. Small ducts resembling intraepidermal portions of eccrine sweat ducts are seen (Fig. 28-84).

Poroma

Poroma is a common, solitary neoplasm histologically similar to seborrheic keratosis but with narrow ductal lumina and occasional cystic spaces. The pattern has been interpreted as eccrine sweat gland differentiation. These tumors are firm, raised lesions, usually less than 2 cm in diameter, that develop on the sole or sides of the foot or on the hands or fingers. Poromas extend from the lower portion of the epidermis into the dermis as broad, anastomosing bands of uniform, cuboidal cells. Occasional malignant lesions with similar differentiation are called **porocarcinomas**.

Trichoepithelioma

Trichoepithelioma is a neoplasm that differentiates toward hair structures. It is usually a solitary lesion, but in "multiple trichoepithelioma syndrome," it occurs as an autosomal dominant trait. Lesions begin to appear at puberty, on the face, scalp, neck and upper trunk. Trichoepitheliomas resemble basal cell carcinomas but contain many "horn cysts" (keratinized centers surrounded by basophilic epithelial cells).

Fibrohistiocytic Tumors of the Skin Show a Varied Spectrum of Differentiation

Dermatofibroma

Dermatofibroma is a common, benign tumor of fibroblast-like cells and macrophages. The former are the neoplastic cells. These tumors occur on the extremities as dome-shaped, firm nodules with ill-defined borders and pink to dark brown pigmentation. They rarely exceed 5 mm. The papillary and reticular dermis are replaced by fibrous tissue that forms ill-defined small cartwheels, with small central vascular spaces (Fig. 28-85). The tumors are not well demarcated and blend

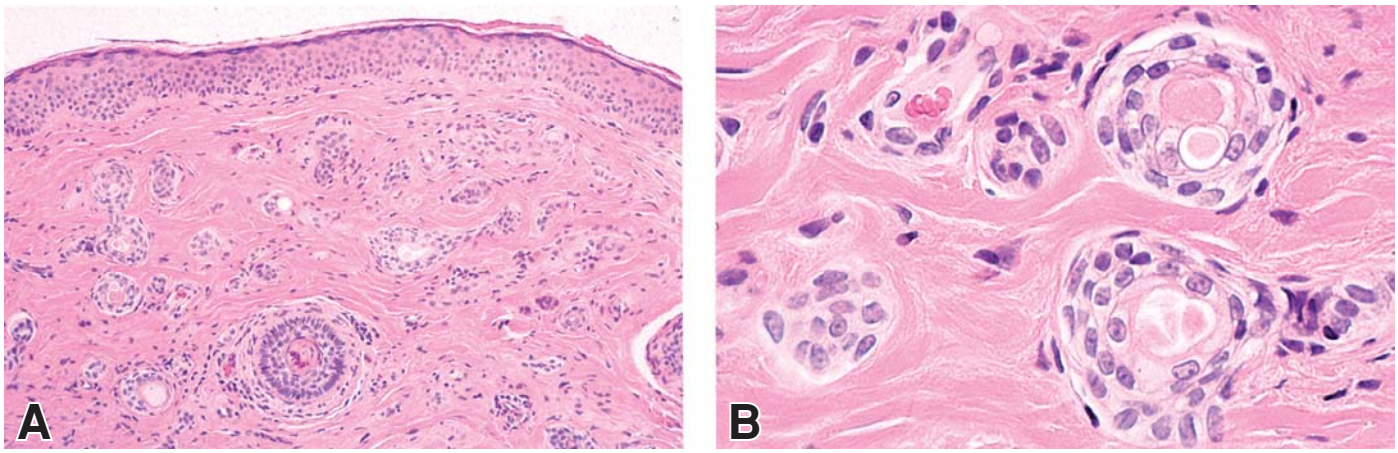

FIGURE 28-84. Syringoma. A. Within the upper dermis is an epithelial proliferation forming ducts, tubules and solid islands amid a dense fibrous stroma. **B.** The ductal differentiation closely mimics that of the straight dermal eccrine duct, with a central lumen and cuticle formation.

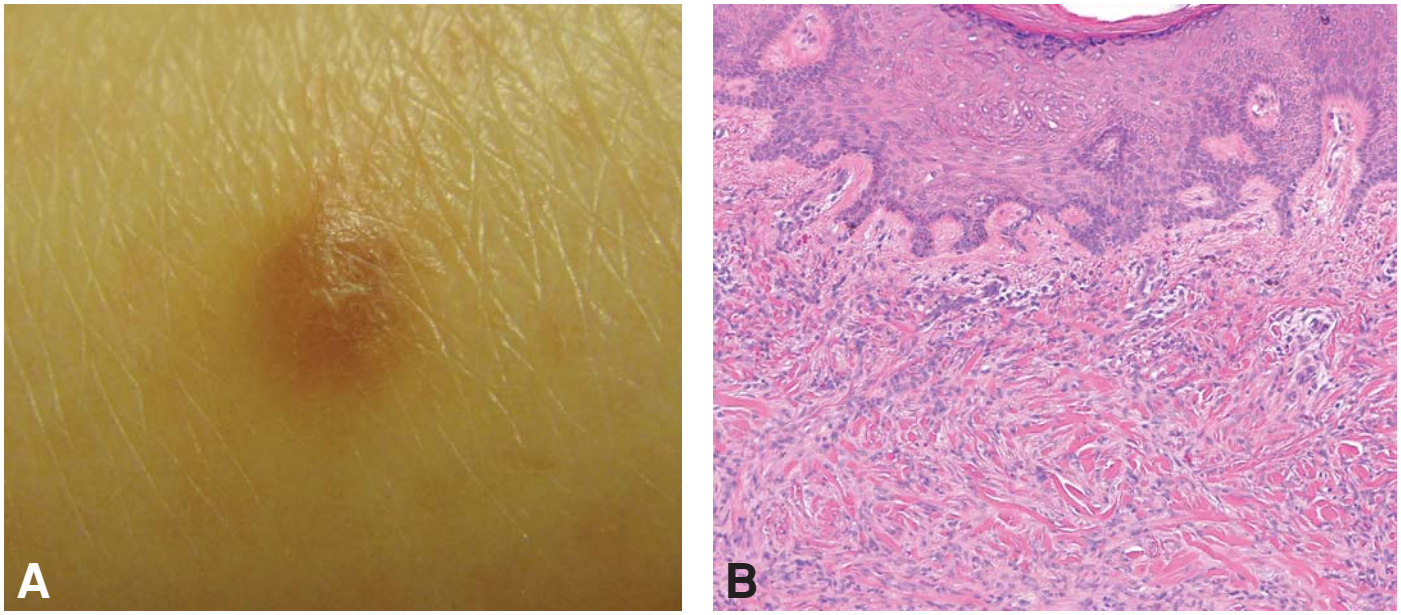

FIGURE 28-85. Dermatofibroma. A. A brown dome-shaped nodule occurring on the lower leg is a common clinical presentation. **B.** Fibrous tissue replaces the dermis and forms poorly defined cartwheels, with overlying epidermal hyperplasia and basaloid proliferation, resembling basal cell carcinoma.

into the surrounding dermis. The overlying epidermis is hyperplastic and often hyperpigmented.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP), a tumor with intermediate malignant potential, is a slowly growing nodule or indurated plaque that appears mostly on the trunk of young adults. Local recurrence after attempted complete excision is common, but metastases are rare. The most common histologic pattern is a poorly circumscribed, monotonous population of spindle cells arranged in a dense "storiform" (pinwheel-like) array (Fig. 28-86). The tumor extends into the subcutis along fat septa and interstices, creating an infiltrative, honeycomb-like pattern. Tumor cells display CD34, a marker of endothelial cells, and some neural tumor cells, as well as dermal fibroblast-like dendritic cells, the probable cell of origin. Positivity for CD34 may help distinguish this tumor from a dermatofibroma, which does not express this antigen.

MOLECULAR PATHOGENESIS: More than 90% of DFSPs have a chromosomal translocation t(17;22), which fuses the collagen gene (*COL1A1*) with the *PDGF-B* gene. This balanced translocation creates a fusion gene product that causes transcriptional upregulation of the *PDGF-B* gene and increased neoplastic growth.

Mycosis Fungoides Is a Variant of Cutaneous T-Cell Lymphoma

The etiology of mycosis fungoides (MF) is unknown, but this malignancy of helper T cells ($CD4^+$) may be a pathologic response to chronic exposure to an antigen.

PATHOLOGY: In the early stages of the disease, delicate, erythematous plaques appear, often by the buttocks. These plaques show psoriasiform changes in the epidermis. The early inflammatory cell infiltrates in the dermis are polymorphic and are often not diagnostic of MF.

Skin involvement becomes progressively more prominent and infiltrative (Fig. 28-87). The most important histologic feature of MF is the presence of lymphocytes in the epidermis ("epidermotropism"). In later stages, the dermal infiltrate becomes dense to the point of forming tumor nodules. Increasing numbers of atypical lymphocytes that display hyperchromatic, convoluted ("cerebriform") nuclei are seen in the papillary dermis and epidermis. Circumscribed nests of these atypical lymphocytes ("Pautrier microabscesses") eventually involve the epidermis. T-cell receptor gene rearrangement studies show a clonal cell population.

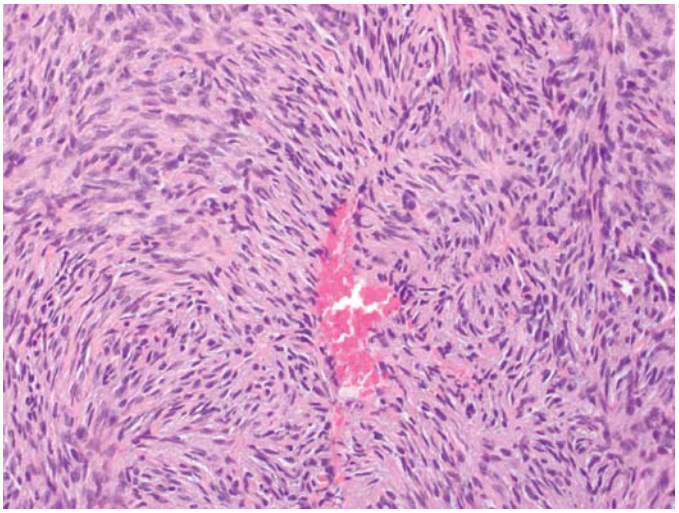

FIGURE 28-86. Dermatofibrosarcoma protuberans. Tumor cells form small cartwheels with central vascular spaces.

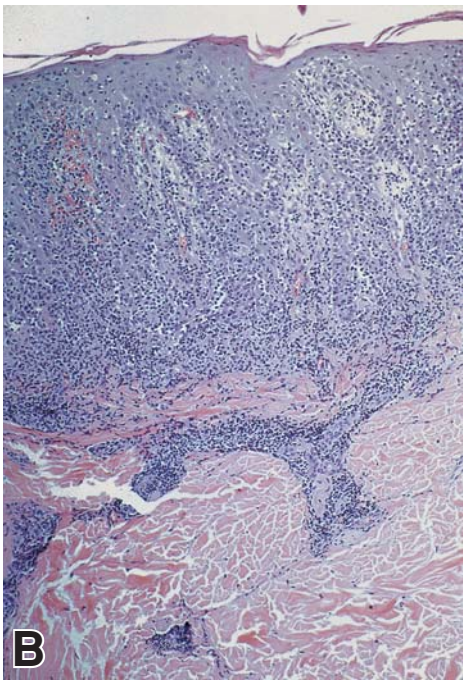

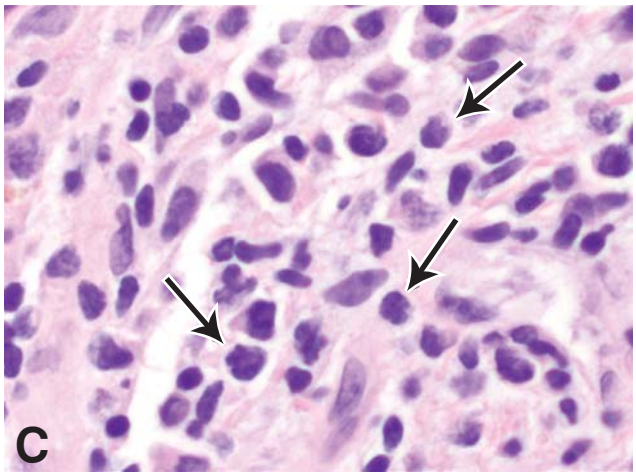

FIGURE 28-87. Mycosis fungoides. A. A 66-year-old woman presented with a 30-year history of erythematous scaly patches and plaques with telangiectases, atrophy and pigmentation. **B.** An atypical infiltrate of lymphocytes expands the papillary dermis and extends into the epidermis ("epidermotropism"). **C.** Some of the lymphocytes display hyperchromatic and convoluted ("cerebriform") nuclei (*arrows*).

Sézary syndrome is the systemic dissemination of MF. The characteristic feature is the presence of cerebriform lymphocytes in the peripheral blood.

CLINICAL FEATURES: MF affects older people, has a slight male predominance and preferentially affects blacks over whites. It is classically divided into 3 stages: patch, plaque and tumor. In the patch stage, which may persist for months, eruptions consist of scaly, erythematous macules that may be slightly indurated. They usually involve the lower abdomen, buttocks and upper thighs as well as women's breasts, and can mimic other dermatitides such as psoriasis or eczema (Fig. 28-87A). Plaque-stage lesions are more infiltrated and circumscribed. As these coalesce, involvement becomes more widespread. Large, variably shaped tumor nodules can form on existing indurated plaques or on apparently normal skin. Spread to lymph nodes or visceral involvement portends reduced survival. Therapy includes UV light, topical nitrogen mustard and electron beam therapy.

HIV Infection Is Associated with Various Skin Diseases

Kaposi Sarcoma

This malignant tumor of endothelial cells of blood vessels was once seen only in older people of Mediterranean descent or in Africans. With the advent of HIV infection, Kaposi sarcoma (KS) is most often seen in patients with AIDS. ***Human herpesvirus 8 (HHV8) is the etiologic agent of KS***.

PATHOLOGY: All cases of Kaposi sarcoma, whether associated with HIV or not, evolve through three stages: patch, plaque and nodule. In the patch stage, a subtle proliferation of irregular vascular channels, lined by a single layer of mildly atypical endothelial cells, radiates from preexisting blood vessels and extends almost imperceptibly into the surrounding reticular dermis. Extravasated red blood cells, hemosiderin deposition and a sparse inflammatory infiltrate of lymphocytes and plasma cells are common.

In the plaque stage (Fig. 28-88), the entire reticular dermis is involved, with frequent extension into the subcutis and formation of bundles of spindle cells. In the nodule stage (Fig. 28-89), well-circumscribed dermal nodules are composed of anastomosing fascicles of spindle cells surrounding numerous slit-like spaces. HHV8 nuclear expression can be readily demonstrated with an immunohistochemical stain.

Bacillary Angiomatosis

Bacillary angiomatosis is a pseudoneoplastic proliferation of capillaries that arises in response to infection with *Bartonella* species. Patients with late-stage AIDS are at risk for

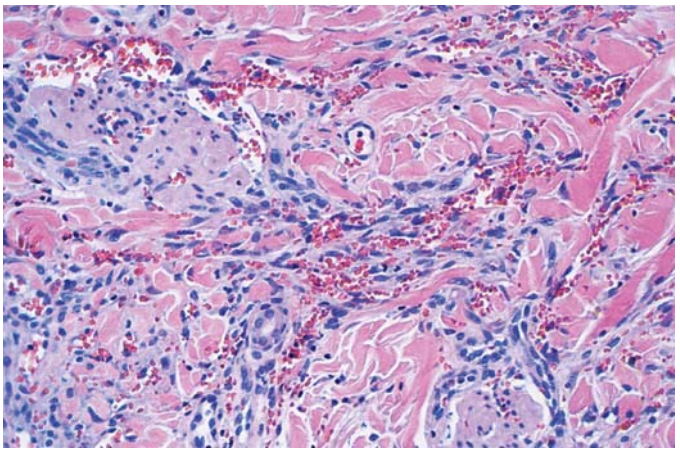

FIGURE 28-88. Kaposi sarcoma, plaque stage. Extending along the vascular arcades and amid reticular dermal collagen is a proliferation of endothelial cells. They form delicate vascular channels filled with red blood cells. Some endothelial cells are not canalized (have not formed lumina).

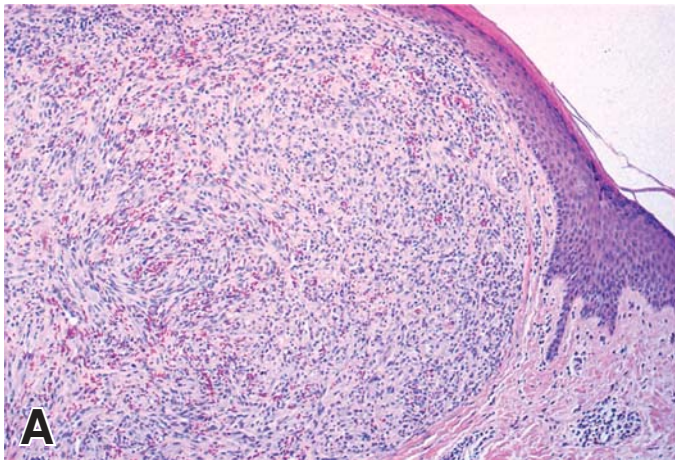
infection with these organisms. The proliferative lesions are red to brown papules, often in large numbers, and may be confused with Kaposi sarcoma. Silver impregnation stains show dense masses of bacilli within the basophilic deposits. Lesions clear with antibiotic treatment.

Eosinophilic Folliculitis

Eosinophilic folliculitis (EF) is a chronic pruritic eruption of papules, centered on hair follicles. Patients infected with HIV are a distinct population that displays EF, although variants that are not related to HIV infection occur in other populations. Lesions are most often on the trunk and proximal extremities. An infiltrate of lymphocytes, macrophages and many eosinophils is present in the intrafollicular and perifollicular areas and around dermal blood vessels.



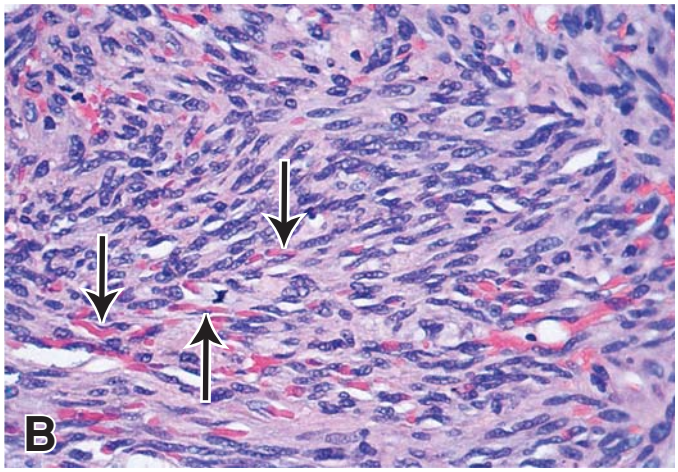


FIGURE 28-89. Kaposi sarcoma, nodule stage. A. A large nodule is composed of proliferating endothelial cells forming fascicles and vascular spaces. **B.** A higher-power view shows cytologic atypia of the spindle cells. Red blood cells appear agglutinated (*arrows*). The endothelial cells, in which the agglutinated red blood cells are present, form slit-like spaces.

PARANEOPLASTIC SYNDROMES INVOLVING THE SKIN

Diverse dermatologic manifestations may complicate internal malignancies, often preceding detection of the tumor itself. Pigmented lesions and keratoses are well-recognized paraneoplastic effects.

- **Acanthosis nigricans** is marked by hyperkeratosis and pigmentation of the axilla, neck, flexures and anogenital region. *It is of particular interest because more than half of patients with acanthosis nigricans have cancer.* The development of the disease may precede, accompany or follow the detection of the cancer. Over 90% of cases occur in association with gastrointestinal carcinomas, and more than half accompany cancers of the stomach.
- **Dermatomyositis or polymyositis** has a five- to sevenfold greater incidence in cancer patients than in the general population. The association is most conspicuous in affected men older than 50 years, among whom more than 70% have cancer. In most cases, the muscle disorder and cancer present within a year of each other. In men, lung and gastrointestinal cancers are most often associated with dermatomyositis, whereas in women, the most common association is with breast cancer.
- **Sweet syndrome** is a combination of elevated neutrophil count, acute fever and painful red plaques in the anus, neck and face. About 1/5 of cases occur with malignancies, particularly those of the hematopoietic system (see Chapter 26).

Oral Cavity

The oral cavity extends from the lips to the pharynx (Fig. 29-1). Its boundaries are:

- The vermilion border of the lips (anterior)
- A line from the junction of the hard and soft palate to the circumvallate papillae of the tongue (posterior)
- The hard palate until its junction with the soft palate (superior)
- The anterior two thirds of the tongue to the line of the circumvallate papillae (inferior)
- The buccal mucosa of the cheeks (lateral)

The oral mucosa consists of keratinized epithelia of the attached gingiva, hard palate mucosa and specialized keratinized gustatory mucosa of the dorsum of the tongue. It also includes nonkeratinized mucosal surfaces of the inner lip and inner cheek, the nonattached, movable gingiva that continues into the maxillary and mandibular sulci, ventral tongue, floor of the mouth, soft palate and tonsillar pillars.

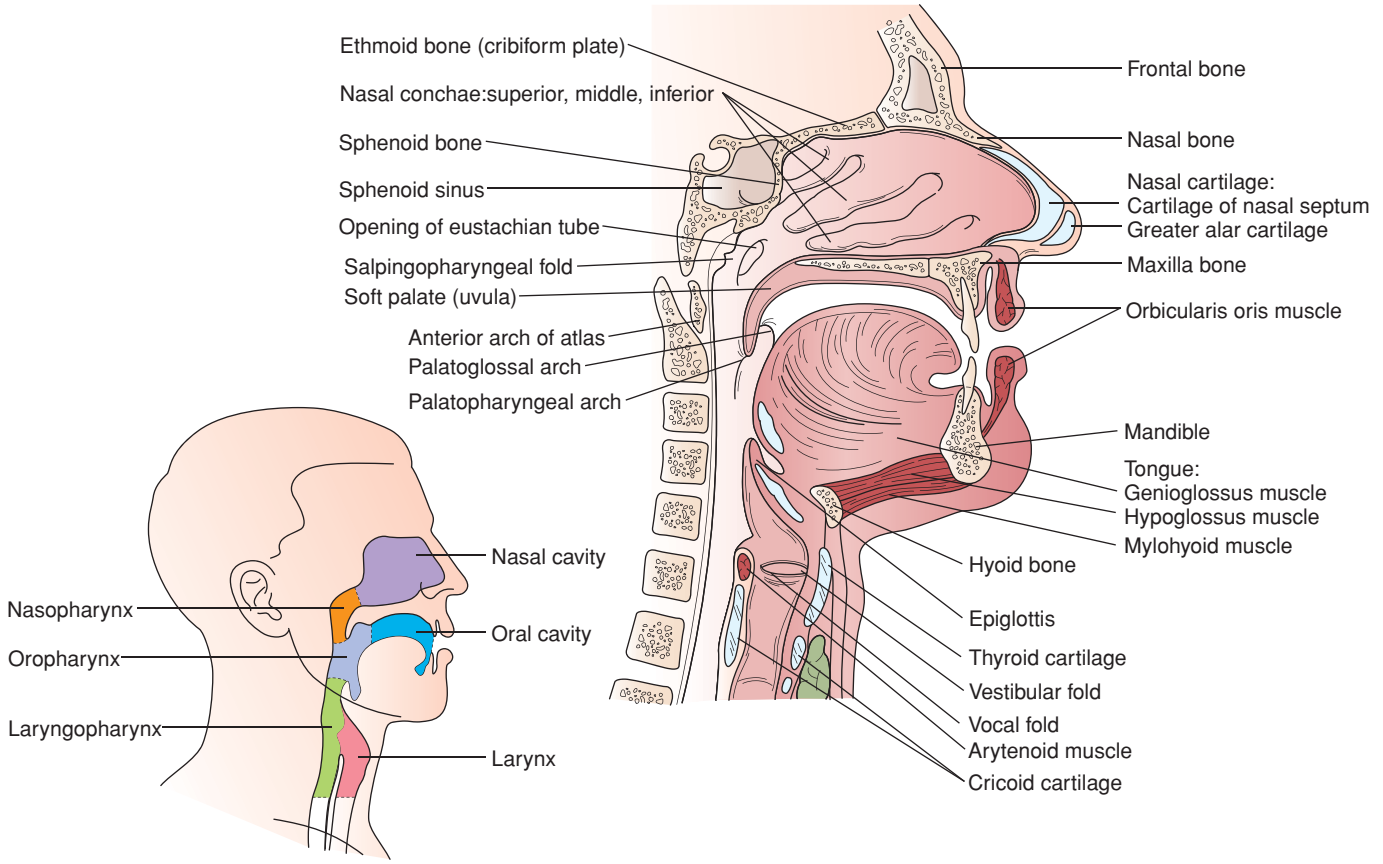

FIGURE 29-1. Structure of the oral cavity, oropharynx and larynx. Schematic diagram of the oral cavity, palate, oropharynx and larynx.

The epithelium is three to four times the thickness of epidermis. Under the epithelium is a lamina propria of fibrous tissue and blood vessels, beneath which is the densely fibrous periosteum of the hard palate or the alveolus of the maxilla and mandible. The term **submucosa** is sometimes loosely applied to the deep connective tissue just above the muscle layer, in which the minor salivary glands are often embedded.

Minor salivary glands are scattered throughout the oral cavity as unencapsulated small lobules within the mucosa and submucosa. There are mucous glands in the lamina propria, particularly in the posterior hard palatal mucosa. Minor salivary glands of pure mucous type exist in the anterior ventral portion of the tongue (called Blandin, or Nunn, glands). Serous salivary glands lie near circumvallate papillae on the posterior and lateral tongue (von Ebner glands). Mixed mucoserous and mainly mucous glands predominate in the rest of the oral cavity. There are minor salivary glands in the retromolar mandibular ridge, but not the anterior hard palate or gingiva.

The anterior two thirds of the dorsum of the tongue is covered by keratinized stratified squamous epithelium that is specialized to form **filiform papillae** (pointed projections of keratin). Between these are **fungiform papillae,** mushroom-shaped mucosal elevations containing taste buds. **Circumvallate papillae** separate the anterior 2/3 of the tongue from the posterior 1/3 and contain taste buds at their base. The final group is the **foliate papillae,** in the posterior lateral tongue in a series of ridges. Each taste bud is a barrel-shaped collection of modified epithelial cells that extend vertically from the basal lamina to the epithelial surface, opening via a taste pore.

DEVELOPMENTAL ANOMALIES

FACIAL CLEFTS: If facial structures fail to fuse in the 7th week of embryonic life, facial clefts form. The most common of these is cleft upper lip **(harelip)**. It may be unilateral or bilateral and often occurs in association with cleft palate (see Chapter 6).

Crouzon syndrome (craniofacial dysostosis) and **Apert syndrome** (acrocephalosyndactyly) are autosomal dominant disorders associated with craniosynostosis (premature fusion of the cranial sutures). This can lead to **brachycephaly** (flat head), **scaphocephaly** or **dolichocephaly** (the head is disproportionately long and narrow or "boat" shaped) or **trigonocephaly** (triangular shaped). Severe craniosynostosis may result in **Kleeblattschädel deformity** ("cloverleaf" skull). ***Both syndromes reflect mutations in fibroblast growth factor receptor 2 (FGFR2), on the long arm of chromosome 10.***

MOLECULAR PATHOGENESIS: The FGFR2 gene encodes a transmembrane protein that, upon binding its ligands, signals to induce bone maturation. In **Apert syndrome,** a mutant FGFR2 protein is produced, which promotes premature bone fusion in the calvarial (skull) bones.

HAMARTOMAS AND CHORISTOMAS: These lesions are common in the oral cavity. **Fordyce granules** are aggregates of

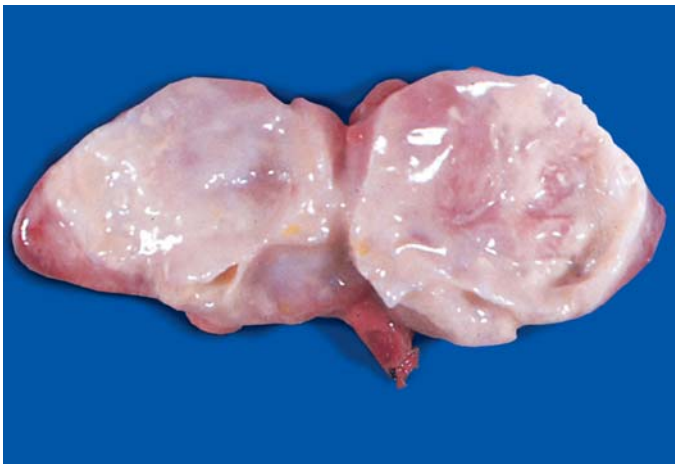

FIGURE 29-2. Branchial cleft cyst. Most of these cysts arise from the second branchial cleft and occur laterally in the neck. The cysts have a thin wall, contain turbid fluid and are lined by stratified squamous or respiratory-type epithelium.

sebaceous glands in the oral cavity **(choristoma)**. They occur on the buccal mucosa, lingual surface and lip in 70%–95% of adults; rarely, they coalesce to form mass lesions.

Abnormal descent of the thyroid during development may create submucosal foci of **ectopic thyroid** between the tongue and suprasternal notch. The base of the tongue between the foramen cecum and epiglottis is the most common site for ectopic thyroid **(lingual thyroid)**. Over 75% of patients with lingual thyroid lack a cervical thyroid ("total migration failure"). Thus, surgically removing a lingual thyroid may lead to hypothyroidism and stunted physical growth and mental development (**cretinism;** see Chapter 6). In fact, 70% of patients with symptomatic lingual thyroid are hypothyroid and 10% suffer from cretinism. Malignancies in ectopic thyroid glands are rare but are generally papillary thyroid carcinomas. The absence of a normally descended thyroid may also affect parathyroid gland development and localization.

Thyroglossal duct cysts result from persistence and cystic dilatation of the thyroglossal duct midline in the neck. The anomaly usually occurs above the thyroid isthmus but below the hyoid bone. Patients, usually under age 40, present clinically with a palpable 4–5-cm midline nodule, *which moves up and down upon swallowing.* Surgery is the treatment of choice. Malignancies, mostly papillary thyroid carcinomas, arise in up to 1% of thyroglossal duct cysts.

BRANCHIAL CLEFT CYST: Branchial cleft cysts originate from branchial arch remnants. They occur in the lateral anterior neck or parotid gland, mostly in young adults, and contain thin, watery fluid and mucoid or gelatinous material (Fig. 29-2). These cysts are usually lined by squamous epithelium, with occasional foci of ciliated respiratory or pseudostratified columnar epithelium.

INFECTIONS OF THE ORAL CAVITY

Bacteria and spirochetes, are present normally in the oral cavity and are generally harmless. If the mucosa is injured or immunity is impaired, otherwise normal oral flora may become pathogenic (see Chapter 9 for further discussion).

These terms are used to describe localized inflammation of the oral cavity:

- **Cheilitis** (lips)
- **Gingivitis** (gum)
- **Glossitis** (tongue)
- **Stomatitis** (oral mucosa)

Bacterial and Fungal Infections of the Oral Cavity May Involve Both Commensal and Invasive Species

SCARLET FEVER: Scarlet fever is mainly a disease of children, caused by several strains of β-hemolytic streptococci (*Streptococcus pyogenes*). Damage to vascular endothelium by the erythrogenic toxin results in a rash on the skin and oral mucosa. The tongue acquires a white coating, through which the hyperemic fungiform papillae project as small red knobs ("strawberry tongue"). Untreated scarlet fever can lead to glomerulonephritis and heart disease (**acute rheumatic fever;** see Chapters 11 and 16).

APHTHOUS STOMATITIS (CANKER SORES): Aphthous stomatitis is a common disease characterized by painful, recurrent, solitary or multiple, small ulcers of oral mucosa. Its cause is unknown, although various etiologies have been suggested. The lesion is a shallow ulcer covered by a fibrinopurulent exudate, with underlying mononuclear and polymorphonuclear inflammation. The lesions heal without scarring.

ACUTE NECROTIZING ULCERATIVE GINGIVITIS (VINCENT ANGINA): Vincent angina is an acute necrotizing ulcerative gingivitis caused by infection with two symbiotic organisms, a fusiform bacillus and a spirochete (*Borrelia vincentii*). The term **fusospirochetosis** is used for this infection. These organisms are found in the mouths of many healthy people, suggesting that other factors are involved, particularly decreased resistance to infection due to inadequate nutrition, immunodeficiency or poor oral hygiene. Vincent angina is characterized by punched-out erosions of the interdental papillae. The process tends to spread and eventually involves all gingival margins, which become covered by a necrotic pseudomembrane.

Noma (cancrum oris) is a severe fusospirochetal infection in people who are malnourished, debilitated from infections or weakened by blood dyscrasias. It features rapidly spreading gangrene of oral and facial tissues. Large masses of tissue slough and leave the bones exposed, especially in children (see Chapter 9).

LUDWIG ANGINA: Ludwig angina is a rapidly spreading cellulitis originating in the submaxillary or sublingual space but extending to involve both. Several aerobic and anaerobic oral bacteria have been implicated. Ludwig angina is a potentially life-threatening inflammatory process. It is uncommon in developed countries except in patients with chronic illnesses associated with immunosuppression.

Ludwig angina is most often related to dental extraction or trauma to the floor of the mouth. After extraction of a tooth, hairline fractures may occur in the lingual cortex of the mandible, providing microorganisms ready access to the submaxillary space. Infection may dissect into the parapharyngeal space along fascial planes and from there into the carotid sheath. A mycotic internal carotid artery aneurysm may result, erosion of which may cause massive hemorrhage. The inflammation may also dissect into the superior mediastinum to involve the pleural space and pericardium.

DIPHTHERIA: Infection with *Corynebacterium diphtheriae* is characterized by a patchy pseudomembrane, which often begins on the tonsils and pharynx but may also involve the soft palate, gingiva or buccal mucosa (see Chapter 9).

TUBERCULOSIS: Primary tuberculosis of the oral mucosa is rare. Most lesions spread from the lung, with bacilli carried in sputum and entering small breaks in the mucosa. There, they produce irregular, painful ulcers, mostly on the tongue. Caseating granulomatous inflammation is typical.

SYPHILIS: Primary syphilitic chancres may form on the lips, tongue or oropharyngeal mucosa after contact with an infectious lesion (see Chapter 9). Regional lymphadenitis follows and heals by itself in a few weeks. A diffuse mucocutaneous eruption of the secondary stage follows. Syphilitic lesions in the oral mucosa are multiple gray-white patches overlying ulcerated surfaces. They may remit and also recur spontaneously. **Gummas** on the palate and tongue may appear years after initial infection as firm nodular masses that ulcerate and may cause palatal perforation.

ACTINOMYCOSIS: Actinomycetes are common denizens of the oral cavity in healthy people. Invasive actinomycosis is most often caused by *Actinomyces bovis,* but *Actinomyces israelii* is sometimes seen. The organisms produce chronic granulomatous inflammation and abscesses that drain by fistula formation, with suppurative infection containing characteristic yellow "sulfur granules." In cervicofacial actinomycosis, soft tissue infection may extend to adjacent bones, most often to the mandible.

CANDIDIASIS: Also called **thrush** or **moniliasis,** oral candidiasis is caused by *Candida albicans* (see Chapter 9), which is common on the surfaces of the oral cavity, gastrointestinal tract and vagina. To cause disease, the fungus must penetrate tissues, albeit superficially. Oral candidiasis is mostly seen in diabetics and people with compromised immune systems. The incidence in patients with AIDS is 40%–90%. Lesions are white, slightly elevated, soft patches that consist mainly of fungal hyphae.

Oral Viral Diseases Are Mostly Recurrent Herpesvirus Infections

HERPES SIMPLEX VIRUS TYPE 1: Herpes labialis (cold sores, fever blisters) and herpetic stomatitis are caused by herpes simplex virus (HSV) type 1 and are among the most common viral infections of the lips and oral mucosa in children and young adults. Transmission is via aerosol, and the virus can be recovered from saliva of infected people. Disease starts with painful inflammation of affected mucosa, followed shortly by formation of vesicles. These result from "ballooning degeneration" of epithelial cells, some of which show intranuclear inclusions (Fig. 29-3). The vesicles rupture to form shallow, painful, 1–10-mm ulcers, which heal spontaneously without scarring.

Once HSV enters the body, it remains dormant in the trigeminal ganglion until stresses such as trauma, allergy, menstruation, pregnancy, exposure to ultraviolet light and other viral infections reactivate it. Recurrent oral cavity vesicles almost invariably develop on a mucosa that is tightly bound to periosteum, for example, the hard palate.

HUMAN PAPILLOMAVIRUS (HPV)–RELATED DISEASES: The HPV family of viruses (see Chapter 9) causes epithelial proliferations including papillomas (e.g., sinonasal, Schneiderian papillomas and other papillomas of upper aerodigestive tract sites). "High-risk" HPV, mainly types 16 and 18, as well as 31, 33 and 35, is strongly associated with oropharyngeal squamous cell carcinoma (see below).

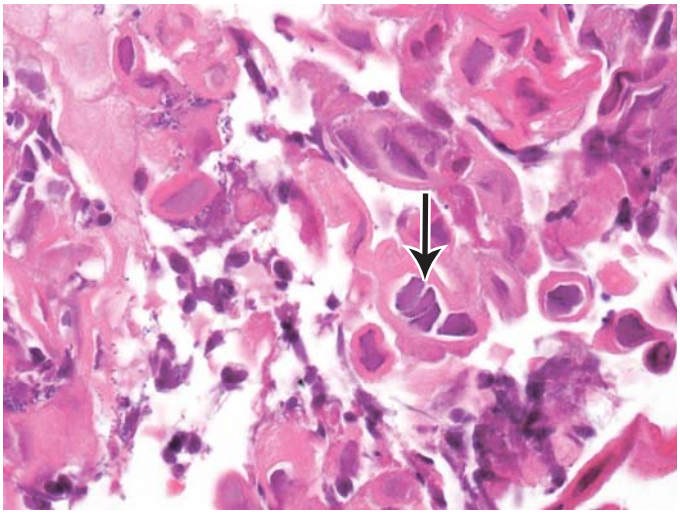

FIGURE 29-3. Herpes simplex virus type 1. A biopsy from a nonhealing ulcer on the tongue demonstrates intranuclear viral inclusions (*arrow*) within squamous cells infected by the virus.

EPSTEIN BARR VIRUS–RELATED DISEASES: Epstein-Barr virus (EBV) is a member of the *Herpesvirus* family that causes oral hairy leukoplakia, various lymphoid diseases (see Chapter 20) and epithelial cancers in the nose and pharynx (see below).

HUMAN HERPES VIRUS 8 (HHV8): HHV8 is associated with **Kaposi sarcoma** (KS). This tumor occurs most often in the skin (see Chapter 24) but can also involve, among other places, the tongue and oral cavity. These tumors resemble their cutaneous counterparts (Fig. 29-4). Immunosuppressed patients (e.g., transplant recipients or patients infected with HIV-1) are at very high risk for this disease. It is also seen in

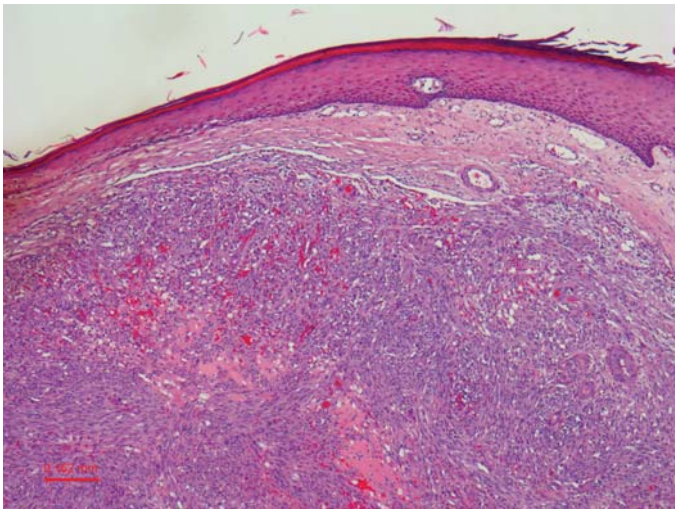

FIGURE 29-4. Kaposi sarcoma. This palate biopsy demonstrates an intact overlying squamous mucosa. Within the underlying lamina propria, there is a malignant spindle cell proliferation forming slit-like spaces filled with extravasated red blood cells.

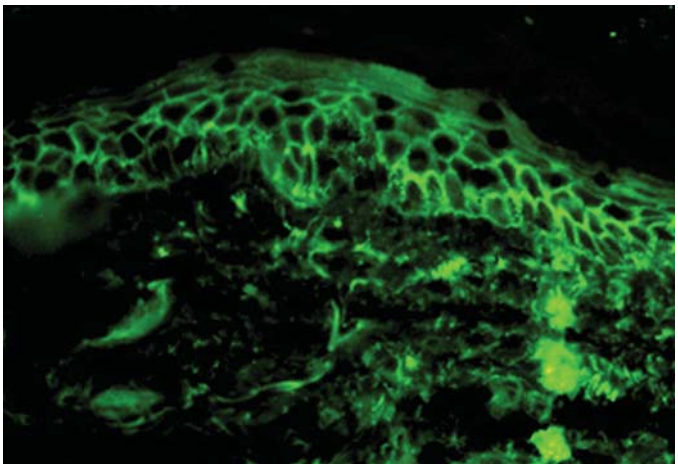

FIGURE 29-5. Pemphigus vulgaris. Direct immunofluorescence of auto-IgG antibodies demonstrates a lace-like pattern of reactivity. The antidesmoglein autoantibodies produced induce acantholysis, leading to vesicle formation in the oral cavity and the skin.

elderly men of Mediterranean/East European descent and in non–HIV-infected middle-aged adults and children in equatorial Africa.

MOLECULAR PATHOGENESIS: Details of herpesvirus molecular pathogenesis are presented in Chapter 9.

OTHER VIRAL INFECTIONS: Coxsackievirus causes **herpangina,** an acute vesicular oropharyngitis. A brief infection confers lasting immunity. **Cytomegalovirus** (CMV) infection typically presents with surface ulceration. Other virus infections that involve the oral mucosa include measles, rubella, chickenpox and herpes zoster.

Bullous Lesions of the Oral Cavity Resemble Those in the Skin

PEMPHIGUS VULGARIS: Autoantibodies against desmogleins disrupt intercellular bridges between squamous cells in the skin and oral mucosa, causing the blisters, or ***bullae,*** of **pemphigus vulgaris**. The oral cavity is often the site of initial presentation, with cutaneous bullae developing later. These blisters are very fragile and rupture so easily that one sees scabs more often than intact bullae. The disease occurs primarily in adults between 30 and 60 years old and is the most common type of pemphigus (*vulgaris* comes from the Latin meaning "common" or "derived from the common people"). This disease can be life-threatening. The diagnosis is made by observing an immunofluorescence pattern of a lace-like outline of the epidermal cells (Fig. 29-5). Treatment is with steroids or other immunosuppressive agents.

BULLOUS PEMPHIGOID: Clinically, this disease resembles pemphigus, but in bullous pemphigoid the autoantibodies are directed against the epidermal basement membrane. On immunofluorescence, one sees a line along the base of the epidermis. Resulting bullae are subepidermal, and thus less fragile than in pemphigus vulgaris. This is a disease of older patients and does not usually manifest in the mouth; the bullae are less delicate and less likely to get infected as they do not rupture as easily. Rarely, pemphigus may be caused by medications.

BENIGN TUMORS

Benign tumors found elsewhere in the body (e.g., nevi, fibromas, hemangiomas, lymphangiomas and squamous papillomas) are seen also in the oral cavity. Trauma may lead to ulceration of the lesions, causing bleeding or infection.

PAPILLOMA: Squamous papillomas are benign, exophytic epithelial tumors with branching fronds of squamous epithelium and fibrovascular cores (Fig. 29-6A). They are the most common benign oral cavity neoplasms and have been associated with HPV types 6 and 11, which are low-risk serotypes *not* associated with malignancy (Fig. 29-6B). They occur mainly in the third to fifth decades. The tongue, palate, buccal mucosa, tonsil and uvula are most often involved.

BENIGN MINOR SALIVARY GLAND TUMORS: **Pleomorphic adenoma** (benign mixed tumor) is the most common oral salivary gland tumor (see below). Monomorphic adenomas such as myoepithelioma or oncocytoma are less

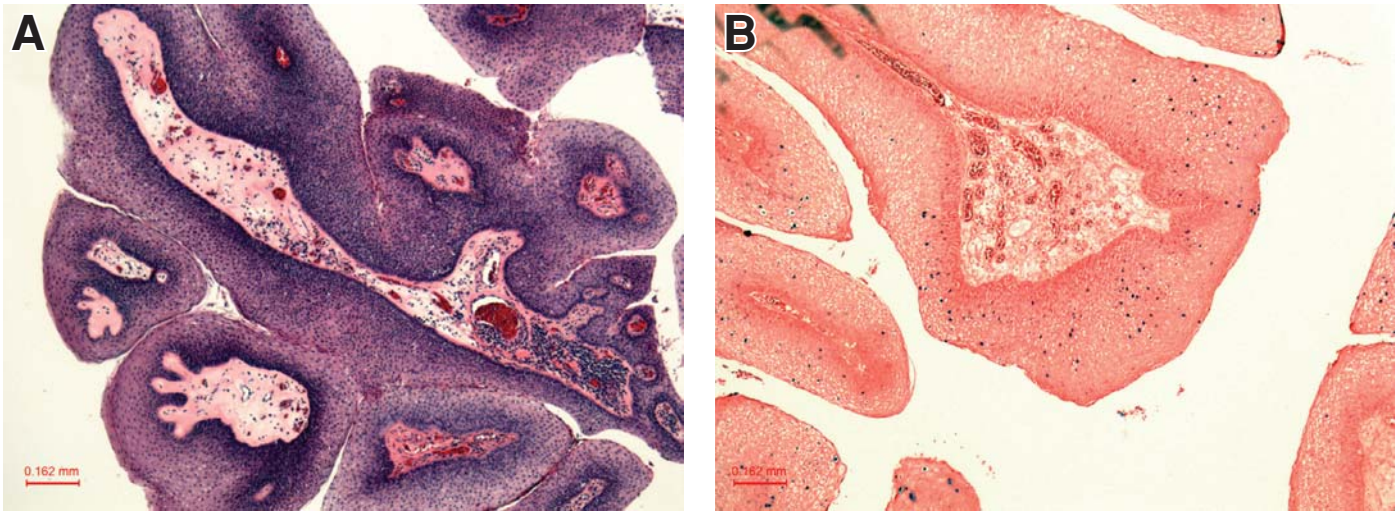

FIGURE 29-6. A. Squamous papilloma. This exophytic frond-like papillary tumor grew off of the patient's uvula. **B. In situ hybridization** for low-risk human papillomavirus (LR-HPV) demonstrates nuclear localization.

common. Benign mesenchymal tumors that may occur in the oral cavity include hemangiomas, leiomyomas and lipomas.

LOBULAR CAPILLARY HEMANGIOMA (PYOGENIC GRANULOMA; PREGNANCY TUMOR): Lobular capillary hemangiomas are benign polypoid capillary hemangiomas that occur mainly on the skin, mucous membranes and, most often, gingiva. The term "pyogenic granuloma" is a misnomer: it is neither infectious nor granulomatous. In the mouth, they are elevated, soft, red or purple lesions, from a few millimeters to a centimeter, with smooth, lobulated, ulcerated surfaces. They show lobules or clusters of submucosal vessels, with central capillaries and smaller ramifying tributaries. In time, the lesions may become less vascular and resemble fibromas.

An identical lesion in the gingiva **(pregnancy tumor)** may occur in pregnant women near the end of the third trimester. It may or may not regress after delivery.

PRENEOPLASTIC OR PRECURSOR EPITHELIAL LESIONS

Premalignant lesions of the upper aerodigestive tract include leukoplakia, erythroplakia or speckled leukoplakia, the terms describing a white, red or mixed white/red lesion, respectively. ***Leukoplakia*** *(from the Greek,* leukos, *"white," and* plax, *"plaque")* ***is an asymptomatic white lesion on the surface of a mucous membrane.*** It affects both sexes equally, mostly after the third decade. Some of these lesions may become squamous cell carcinomas (SCCs). Diverse diseases appear clinically as leukoplakia, including several keratoses and squamous carcinoma in situ. ***Thus, leukoplakia is a descriptive clinical term, not a pathologic diagnosis.*** Other diseases may also have white plaques on the oral mucosa (e.g., candidiasis, lichen planus, psoriasis, syphilis).

The causes of leukoplakia include tobacco use, alcoholism and local irritation. The same factors also appear to be important in the etiology of oral carcinoma.

Erythroplakia is the red equivalent of leukoplakia but occurs less often. Red areas associated with leukoplakic lesions are **speckled leukoplakia (speckled mucosa; erythroleukoplakia)**. Erythroplakia may represent moderate to severe dysplasia or carcinoma. However, not all red erythroplakic lesions indicate dysplasia/carcinoma, as many red oral mucosal lesions may be inflammatory.

PATHOLOGY: Leukoplakia (Fig. 29-7) occurs mostly on the buccal mucosa, tongue and floor of the mouth. Plaques may be solitary or multiple, small lesions to large patches. Erythroplakia is often associated with ominous histopathologic features, including severe dysplasia, carcinoma in situ or invasive SCC. In contrast, leukoplakic lesions may show a spectrum of histopathologies, from increased surface keratinization without dysplasia to invasive keratinizing squamous carcinoma. Leukoplakias, unlike erythroplakic lesions, tend to show well-demarcated margins. The risk of malignancy with leukoplakia is 10%–12%. The chance of speckled leukoplakia becoming cancer is intermediate between "pure" leukoplakic and "pure" erythroplakic lesions, but speckled leukoplakia should be considered a variant of erythroplakia.

Oral hairy leukoplakia has shaggy parakeratosis and edema, with or without associated inflammation. It occurs mainly in people who are HIV-1 positive, usually with

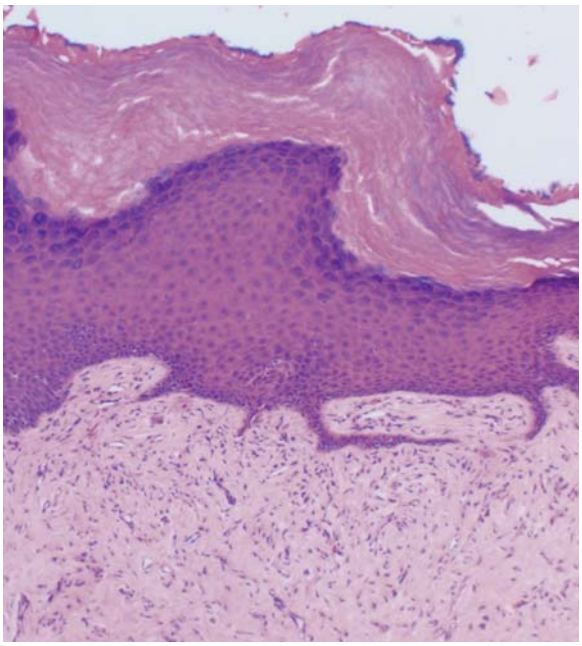

FIGURE 29-7. Leukoplakia. The lesion was seen as a white patch on the buccal mucosa of a heavy smoker. Histologically, epithelial hyperplasia and hyperkeratosis are evident.

associated candidiasis. The EBV-infected squamous cells are seen just beneath the keratin layer and have dense central eosinophilic inclusions and vacuolated cytoplasm. Oral hairy leukoplakia and candidiasis reflect immune status and together suggest low $CD4^+$ lymphocyte counts and high viral load.

SQUAMOUS CELL CARCINOMA

SCCs are the most common malignant tumors of the oral mucosa and may occur at any site. In the United States, there are over 40,000 cases yearly, most often involving the tongue, then, in descending order: the floor of the mouth, alveolar mucosa, palate and buccal mucosa. The male-to-female ratio is 2:1 for the gums but 10:1 for the lip. There is wide variation in the geographic distribution for oral cancer: it is the most common cancer of men in India, where it is associated with betel nut quid chewing, also known as *pan.*

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: Use of tobacco products, alcoholism, iron deficiency (Plummer-Vinson syndrome), Fanconi anemia, physical and chemical irritants, chewing of betel nuts, ultraviolet light on the lips and poor oral hygiene (craggy teeth and ill-fitting dentures), all predispose to oral SCC. Not surprisingly, several of these factors are also connected with leukoplakia. Multiple separate SCCs may be simultaneous (synchronous) or they may occur at intervals (metachronous) in the oral mucosa ("field cancerization"). Worldwide, 35%–50% of head and neck SCCs are associated with high-risk HPV, mostly HPV-16.

Midline carcinomas of the upper aerodigestive tract showing rearrangement of the *nuclear protein of the testis (NUT)* gene (NUT midline carcinoma) were first seen in children but have been identified increasingly in adults. These tumors have a balanced translocation (t15;19), creating a BRD4-NUT

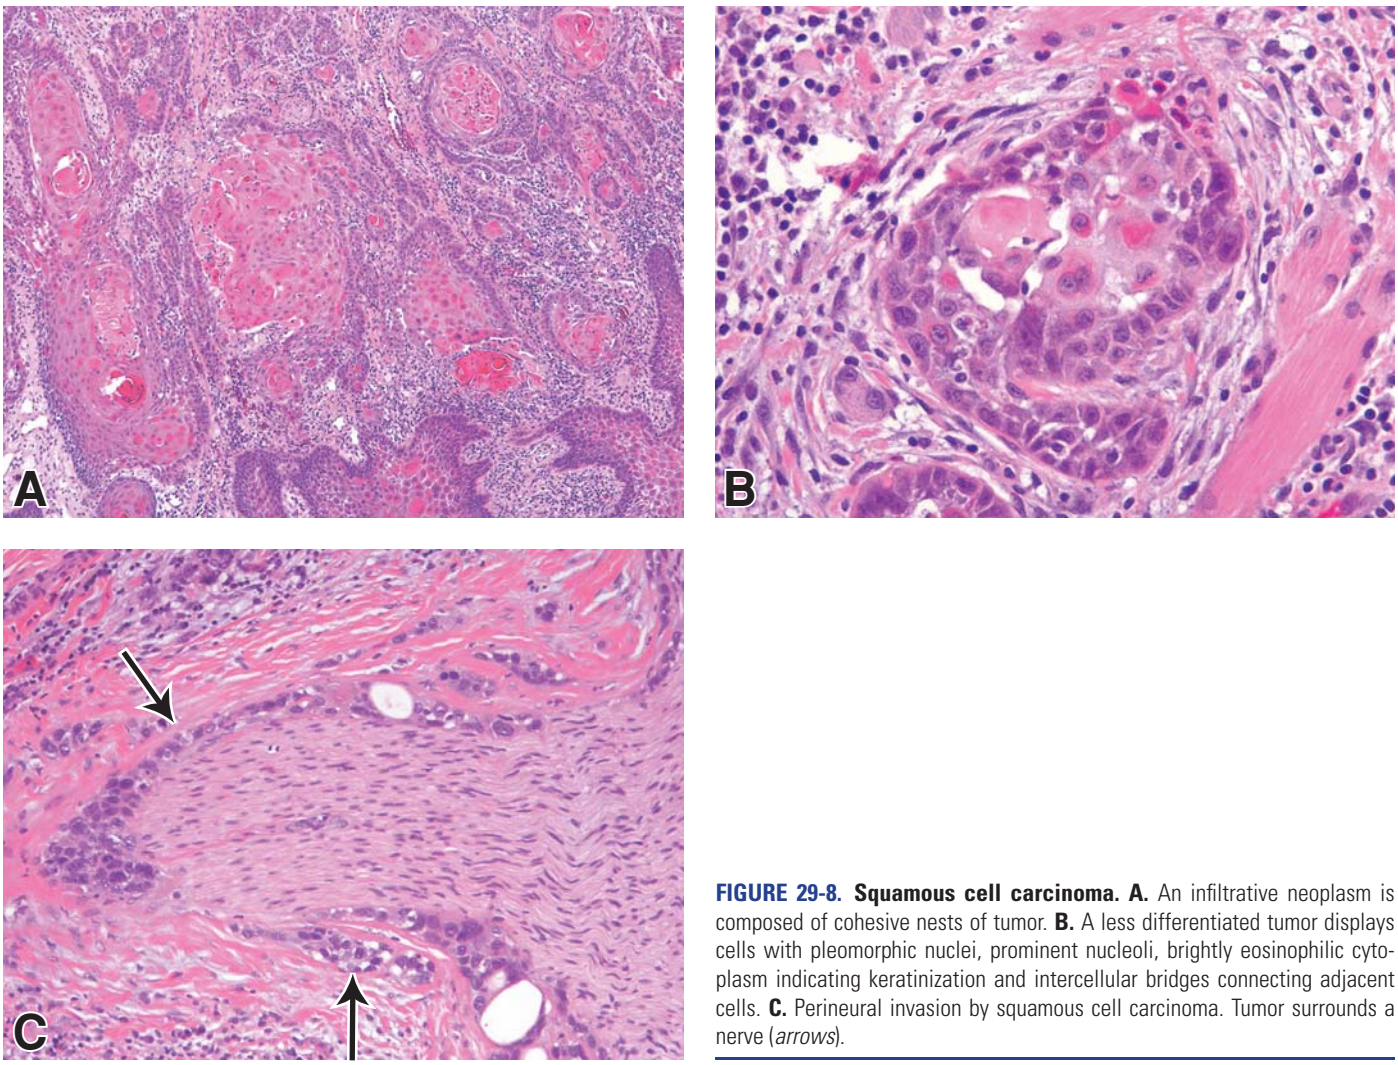

FIGURE 29-8. Squamous cell carcinoma. A. An infiltrative neoplasm is composed of cohesive nests of tumor. **B.** A less differentiated tumor displays cells with pleomorphic nuclei, prominent nucleoli, brightly eosinophilic cytoplasm indicating keratinization and intercellular bridges connecting adjacent cells. **C.** Perineural invasion by squamous cell carcinoma. Tumor surrounds a nerve (*arrows*).

oncogene. They tend to occur in midline structures of the upper aerodigestive tract (e.g., sinonasal tract) and non–head and neck sites (e.g., mediastinum) but may be away from the midline (e.g., parotid gland). NUT midline carcinomas are mainly undifferentiated or poorly differentiated SCCs.

PATHOLOGY: ***Invasive oral cavity SCC resembles the same tumor in other sites. It is generally preceded by carcinoma in situ.*** It ranges from well to poorly differentiated, plus undifferentiated and sarcomatoid variants. Well-differentiated, or grade I, tumors are frequently keratinizing (Fig. 29-8). At the other end of the spectrum, tumors may be so poorly differentiated that their origin is difficult to determine.

Oral SCC mainly metastasizes to submandibular, superficial and deep cervical lymph nodes, and at autopsy 18% of these patients have axillary metastases. More than half of patients who die of head and neck SCC have distant, blood-borne metastases, most often in lungs, liver and bones.

Local recurrence is predicted by a tumor's pattern of infiltration: single-cell invasion is less favorable than a broad, "pushing" border. Other prognostic factors include depth of tumor invasion, perineural invasion and lymphovascular tumor emboli. Negative resection margins are important in local and regional control of the tumor.

Verrucous carcinomas (VCs) are highly differentiated variants of squamous cell carcinoma that generally occur in the sixth and seventh decades; they are locally destructive but do not usually metastasize. They may arise anywhere in this region but are most common on the buccal mucosa, gingiva and larynx. These tumors are usually white, warty to fungating, or exophytic and generally have broad bases (Fig. 29-9A). They are composed of benign-appearing squamous epithelium (without dysplasia or atypia), with marked surface keratinization and a pushing border of bulbous rete pegs (Fig. 29-9B). These tumors carry a good prognosis if completely removed.

MALIGNANT MINOR SALIVARY GLAND NEOPLASMS

About 50% of intraoral minor salivary gland tumors are malignant. These include mucoepidermoid carcinomas, adenoid cystic carcinomas and polymorphous low-grade adenocarcinomas (see below). Some tumors that are more common malignancies of major salivary glands occur uncommonly in minor salivary glands (e.g., acinic cell adenocarcinoma), while low-grade adenocarcinoma and clear cell carcinoma are more common in the palate than in major salivary glands.

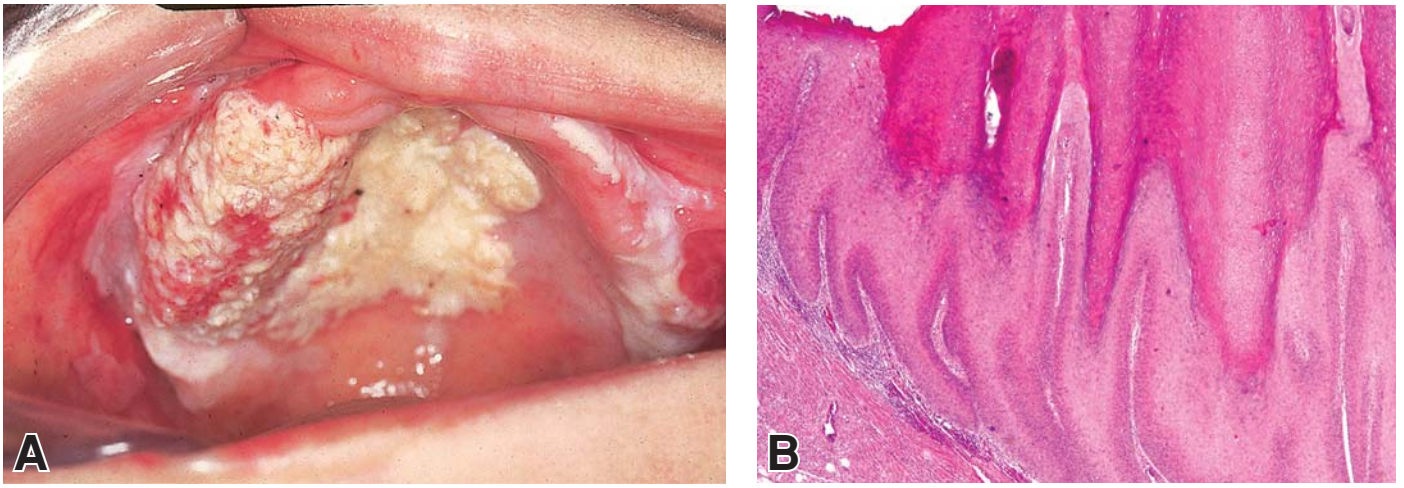

FIGURE 29-9. Verrucous carcinoma. A. The tumor is white with an exophytic appearance involving the alveolar ridge. Note the confluent flat white (leukoplakic) appearance of the palate. **B.** Microscopically, there is prominent surface keratinization ("church-spire" keratosis) composed of bland-appearing uniform squamous cells without dysplasia, and broad or bulbous rete pegs with a pushing margin into the submucosa.

BENIGN DISEASES OF THE LIPS

The lips are affected by many degenerative, inflammatory and proliferative processes. Some of these, particularly those expressed in the skin and mucous membranes, are systemic; others reflect localized disease. A **mucocele** is a mucus-filled cystic lesion associated with minor salivary glands that is probably caused by trauma (Fig. 29-10).

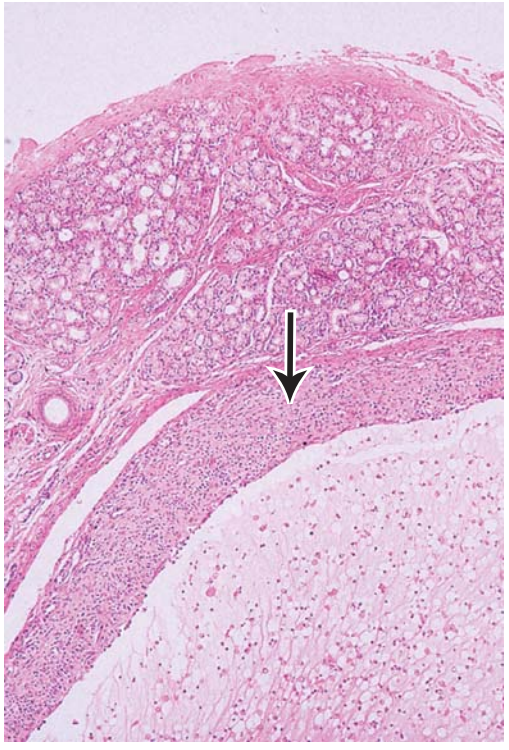

FIGURE 29-10. Mucocele of lower lip. This cystic lesion is associated with the minor salivary glands and is probably caused by trauma that permits escape of mucus. The cyst has a fibrous wall and is lined by granulation tissue (*arrow*). The lumen is filled with mucus that contains numerous macrophages.

BENIGN DISEASES OF THE TONGUE

MACROGLOSSIA: All parts of the tongue may be involved in localized or systemic diseases, some of which can cause tongue enlargement. If present at birth, macroglossia is usually due to diffuse lymphangioma (Fig. 29-11) or hemangioma, although it may rarely be caused by congenital neurofibromatosis or true muscle hypertrophy. An enlarged tongue that protrudes from the mouth occurs in congenital hypothyroidism, Hurler syndrome, glycogen storage disease type II (Pompe disease), Beckwith-Wiedemann syndrome and Down syndrome. Acquired macroglossia may be due to amyloidosis, acromegaly, or infiltration or lymphatic obstruction by tumors.

GLOSSITIS: Inflammation of the tongue can be caused by infectious or chemical agents, physical effects or systemic diseases. Some forms of glossitis reflect vitamin deficiencies of, for example, vitamin B_{12}, riboflavin, niacin (B_3) and pyridoxine (B_6).

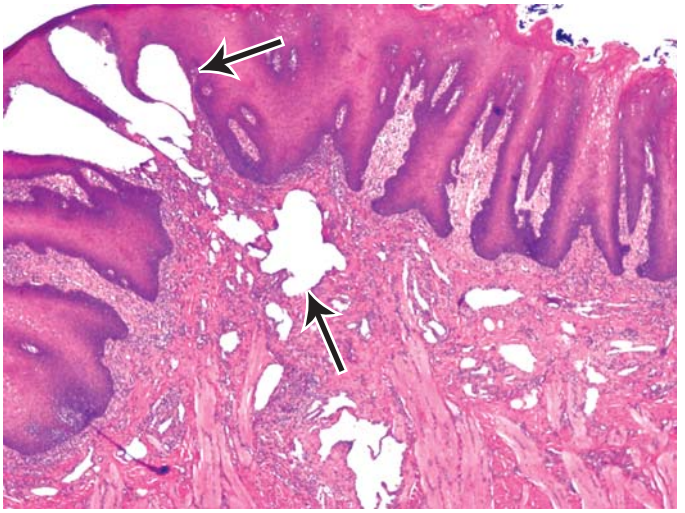

FIGURE 29-11. Lymphangioma of the tongue. Submucosal dilated lymphatics (*arrows*) splay skeletal muscle fibers.

DENTAL CARIES (TOOTH DECAY)

Caries is the most common chronic disease of the calcified tissues of teeth, affecting both sexes and every age group. Its incidence has plummeted with modern civilization.

ETIOLOGIC FACTORS: The interactions of several factors cause caries:

BACTERIA: Dental caries is a chronic infectious disease of tooth enamel, dentin and cementum, the guilty organisms being part of the normal oral flora. Tooth surfaces are colonized by many microorganisms. Unless the surfaces are cleaned thoroughly and frequently, bacterial colonies coalesce into a soft mass known as **dental plaque**.

Carious lesions occur because acids produced from food residues by microorganisms on tooth surfaces leach the minerals in teeth. The culprits include streptococci, lactobacilli and actinomycetes in the oral flora. Indirect evidence points strongly to *Streptococcus mutans* as the primary etiologic agent that initiates caries.

SALIVA: Saliva has a high buffering capacity that helps neutralize microbially produced acids in the mouth. It also contains bacteriostatic factors such as lysozyme, lactoferrin, lactoperoxidases and secretory immunoglobulins. **Xerostomia** (chronically dry mouth due to lack of saliva), which may be iatrogenic, for example, due to surgery or radiation therapy, results in rampant caries.

DIETARY FACTORS: One of the most important factors in the pathogenesis of caries is a high-carbohydrate diet. Roughage in raw and unrefined foods necessitates heavy mastication, which cleanses the teeth. By contrast, soft and refined foods tend to stick to the teeth and also require less chewing.

FLUORIDE: Fluoride protects from caries. It is incorporated into the crystal lattice structure of enamel, where it forms fluoroapatite, which is less acid soluble than is the apatite of enamel. Many communities fluoridated their drinking water, leading to huge reductions in dental caries in those children whose teeth were formed while they drank fluoride-containing water.

PATHOLOGY: Caries begins with disintegration of enamel prisms after decalcification of the interprismatic substance, events that lead to accumulation of debris and microorganisms (Fig. 29-12). These changes produce a small pit or fissure in the enamel. When the process reaches the dentinoenamel junction, it spreads laterally and also penetrates the dentin along the dentinal tubules. A substantial cavity then forms in the dentin, producing a flask-shaped lesion with a narrow orifice. Dentin decalcification causes the destroyed dentinal tubules to coalesce. Only when the vascular pulp of the tooth is invaded, does an inflammatory reaction **(pulpitis)** appear, accompanied for the first time by pain.

PERIODONTAL DISEASE

The gingiva (gum) is the part of the oral mucosa that surrounds the teeth. It ends in a thin edge (free gingiva) that adheres closely to teeth. A periodontal ligament of collagen fibers holds teeth in position in the socket (alveolus) of the jawbone. These structures form the periodontium.

Periodontal diseases are acute and chronic disorders of the soft tissues around the teeth, which eventually erode the supporting bone. Chronic periodontal disease typically occurs in adults with poor oral hygiene but may develop even in people with apparently impeccable habits who have strong family histories of periodontal disease. It causes more loss of teeth in adults than does any other disease, including caries.

Periodontal disease occurs when bacteria accumulate under the gingiva in the periodontal pocket. The mass of

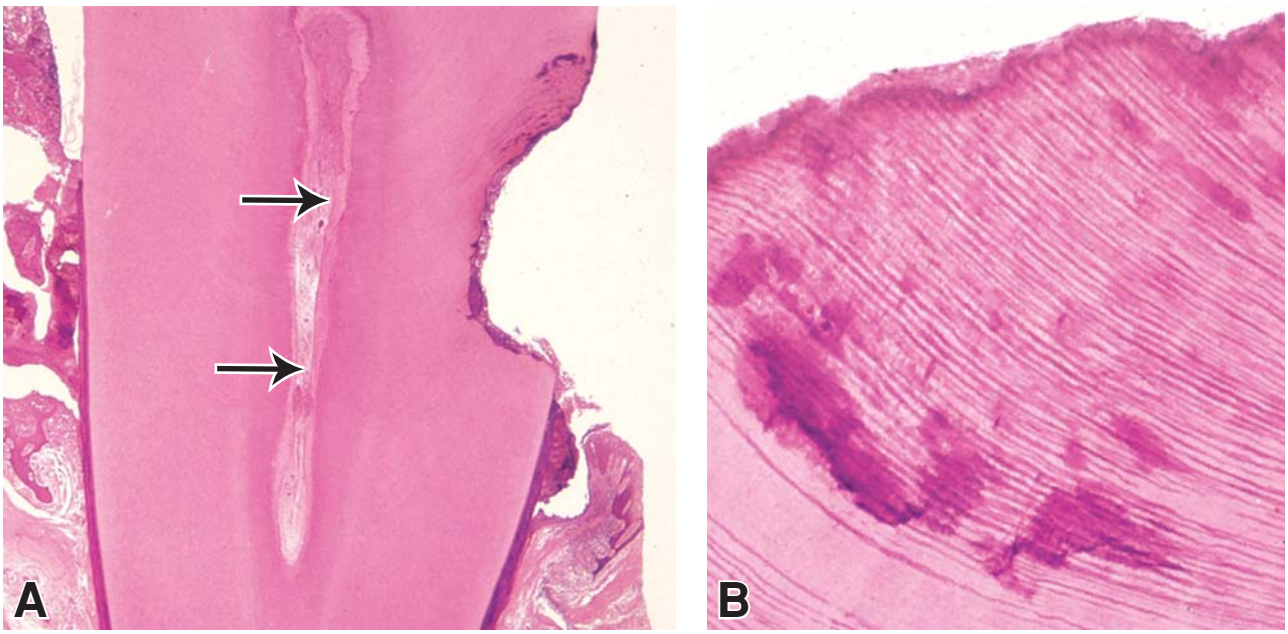

FIGURE 29-12. Dental caries. A. A large cavity close to the gingival margin is illustrated. *Arrows* indicate band of secondary dentin that lines the pulp chamber. This newly formed dentin is opposite the area of tooth destruction and was produced by the stimulated odontoblasts. **B.** Deposits of debris cover the surface. Bacterial colonies (*dark purple*) have extended into dentinal canals.

bacteria adhering to the tooth surface **(dental plaque)** ages, mineralizes and forms **calculus (tartar)**. Adult periodontitis is mostly associated with *Bacteroides gingivalis, Bacteroides intermedius, Actinomyces* sp. and *Haemophilus* sp., although other microorganisms may also participate.

Inflammation often starts as a marginal gingivitis. Untreated, it progresses to chronic periodontitis, in which the chronic inflammation weakens and destroys the periodontium, causing loosening and eventual loss of teeth.

Hematologic disorders may affect oral tissues. Agranulocytosis may lead to necrotizing ulcers anywhere in the oral and pharyngeal mucosa, but especially in the gingiva. Infectious mononucleosis often causes gingivitis and stomatitis, with exudation and ulceration. Acute and chronic leukemias of all types cause oral lesions. In **acute monocytic leukemia,** 80% of patients have gingivitis, gingival hyperplasia, petechiae and hemorrhage. Necrosis and ulceration of the gingiva lead to severe superimposed infection, which may cause loss of teeth and alveolar bone. A hemorrhagic diathesis may be reflected in gingival hemorrhage.

Mild scurvy (vitamin C deficiency; see Chapter 8) affects the marginal and interdental gingiva, which become swollen and bright red and bleed and ulcerate readily. Hemorrhage into the periodontal membrane causes loosening and loss of teeth.

ODONTOGENIC CYSTS AND TUMORS

Odontogenic cysts may be inflammatory or developmental. Most common are **radicular (apical, periodontal) cysts,** involving tooth apices, usually after infection of the dental pulp.

Dentigerous cysts are associated with the crowns of impacted, embedded or unerupted teeth, most often involving mandibular and maxillary third molars. They form after the crown has completely developed; fluid accumulates between the crown and overlying enamel epithelium. Dentigerous cysts may be complicated by ameloblastoma or SCC.

Ameloblastomas are tumors of odontogenic epithelia and are the most common clinically significant odontogenic tumors. They are slow growing and locally invasive, generally following a benign clinical course, even as they can be locally destructive. Most arise in the mandibular ramus or molar area, maxilla or floor of the nasal cavity. The tumors grow slowly as central lesions of bone, showing a characteristic "soap bubble" radiographic appearance. Ameloblastomas resemble the enamel organ in its various stages of differentiation, and a single tumor may show several histologic patterns. Thus, tumor cells resemble ameloblasts at the edges of epithelial nests or cords, where columnar cells are oriented perpendicularly to the basement membrane (Fig. 29-13). The prognosis is favorable, but incompletely excised tumors recur. Some may metastasize and yet remain histologically benign **(metastasizing ameloblastoma)**.

Ameloblastic carcinomas are frankly malignant, with atypia, necrosis, nuclear pleomorphism and abundant mitoses. Nuclei of ameloblastomas may show aberrant β-catenin expression. An APC gene missense mutation, which plays a role in colon cancer, may also participate in the pathogenesis of odontogenic tumors.

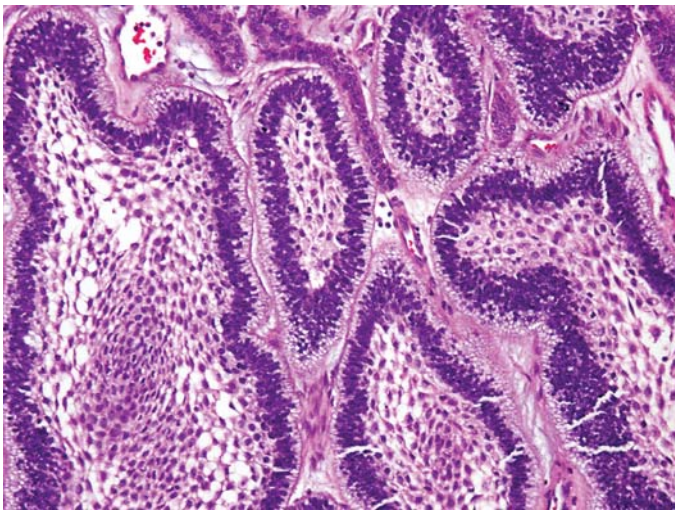

FIGURE 29-13. Ameloblastoma. A common histologic pattern is characterized by islands of odontogenic epithelium with a central stellate reticulum-like area, surrounded by basal cells with a "picket fence" appearance, due to subnuclear vacuoles.

Nasal Cavity and Paranasal Sinuses

ANATOMY: The **nostril apertures** (anterior nares) lead into the **nasal vestibule,** a space lined by skin that contains hairs and sebaceous glands. Beyond the nares, the median septum divides the nasal cavity into two symmetric chambers, the **nasal fossae**. Each nasal fossa has an **olfactory region,** consisting of the superior nasal concha and the opposed part of the septum, and a **respiratory region,** which is the rest of the cavity. Laterally, the inferior, middle and superior nasal conchae **(turbinates)** overhang the corresponding nasal passages or meatus.

The paranasal sinuses are paired air spaces that communicate with the nasal cavity. The respiratory portion of the nasal cavity is covered by ciliated, columnar epithelium with interspersed goblet cells.

These anatomic interrelations determine routes of disease spread (Fig. 29-14). Infections can spread to maxillary, ethmoid, frontal and sphenoid sinuses, causing intraorbital and intracranial disease. The vein of Vesalius, medial to the foramen ovale, puts the cavernous sinus at risk.

NONNEOPLASTIC DISEASES OF THE NOSE AND NASAL VESTIBULE

Virtually all diseases of the skin can occur on the external nose, including lesions due to solar damage (e.g., actinic keratosis, basal cell carcinoma, SCC and malignant melanoma). The many sebaceous glands of the nose are commonly affected in acne vulgaris.

Rosacea is a chronic skin disorder of the cheeks, nose, chin and central forehead, characterized by telangiectasias, flushing, erythema, papules, pustules, rhinophyma and ocular manifestations (Fig. 29-15). Bacteria (e.g., *Bacillus oleronius* and *Staphylococcus epidermidis*), as well as Demodex mites, have all been implicated. Inflammation is central to

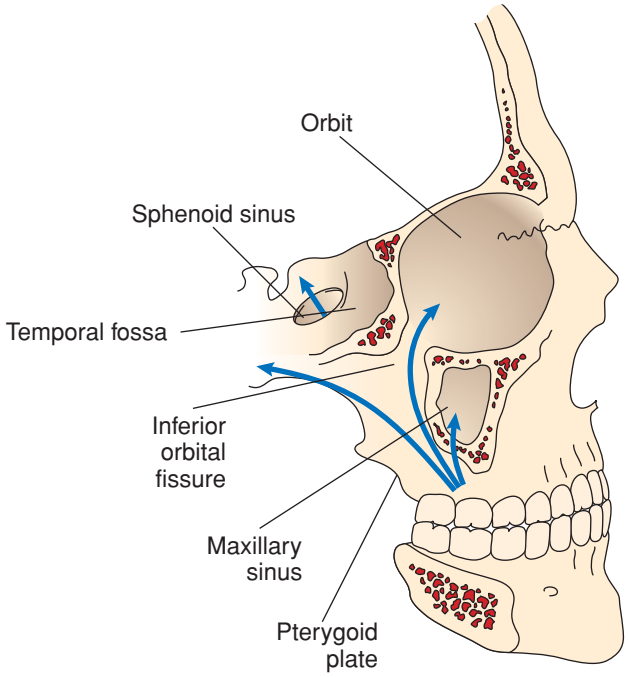

FIGURE 29-14. Pathways of infection to the intracranial cavity. Osseous pathways of infection from the jaws. *Arrows* indicate the direction of spread from the teeth to the maxillary sinus and through the inferior orbital fissure to the orbit. A deeper route is along the lateral pterygoid lamina up to the base of the skull, where, medial to the foramen ovale, a small aperture admits the vein of Vesalius. Through this small vein, the pterygoid plexus communicates with the cavernous sinus.

this disease, although the initiating factors and etiology of rosacea remain unknown. Antibiotics, such as tetracycline and metronidazole, are common therapies.

Rhinophyma is a protuberant bulbous mass on the nose caused by marked hyperplasia of sebaceous glands and chronic inflammation of the skin in acne rosacea.

Nosebleed (epistaxis) is most often due to trauma but has many causes, including hypertension, diverse hematologic abnormalities, inflammatory conditions and nasal mucosal tumors. Epistaxis often originates in a triangular area of the anterior nasal septum called "Little area," where the epidermis is thin and the anterior ethmoid, greater palatine, sphenopalatine and superior labial arteries anastomose to form the **Kiesselbach plexus**. Many dilated blood vessels, or telangiectasias, are often apparent. Ulcers and perforations, which may be caused by various diseases or by trauma to the septum, occur here (Table 29-1).

FIGURE 29-15. Rosacea. Typically characterized by erythema over the bridge of the nose and cheeks, as well as pustules and papules.

Malignant tumors

NONNEOPLASTIC DISEASES OF THE NASAL CAVITY AND SINUSES

Rhinitis Is Usually Viral or Allergic

Rhinitis is inflammation of the mucous membranes of the nasal cavity and sinuses. Its causes range from the common cold to unusual infections such as diphtheria, anthrax or glanders (see Chapter 9).

VIRAL RHINITIS: The most common cause of acute rhinitis is viral infection, especially the common cold **(acute coryza)**. The virus replicates in epithelial cells, and degenerating epithelial cells are shed. The mucosa is edematous and engorged, infiltrated by neutrophils and mononuclear cells. Clinically, mucosal swelling is felt as nasal stuffiness. Abundant mucus secretion and increased vascular permeability lead to **rhinorrhea** (free discharge of a thin watery mucus).

Secondary infection caused by normal nasal and pharyngeal flora may follow viral rhinitis by a few days. The abundant serous discharge then becomes mucopurulent, after which the surface epithelium is shed. Once inflammation subsides, the epithelium regenerates rapidly.

ALLERGIC RHINITIS (HAY FEVER): Allergens are constantly present in our environment, and sensitivity to any one of them can cause allergic rhinitis. Allergic rhinitis may be acute and seasonal, or chronic and perennial.

MOLECULAR PATHOGENESIS: Plasma cells of the nasal mucosa produce immunoglobulin E (IgE), which is bound by mast cells in the nasal mucosa. When air-borne allergens (e.g., pollens, molds, animal dander) deposit there, they activate IgE bound to mast cells or free in nasal secretions specifically directed against those allergens. Thus triggered, mast cells release cytoplasmic granules that contain diverse chemical mediators and enzymes. Some mediators are preformed and thus act rapidly (e.g., histamine); others (such as heparin or trypsin) elute slowly from the granule matrix; still others (e.g., leukotrienes) are newly synthesized. An immediate, rapid response ensues. It is followed by a prolonged inflammatory reaction as the various mediators exert their effects, causing the signs and symptoms of allergic rhinitis. Many of these responses are due to histamine, acting through its H_1 receptor.

PATHOLOGY: Vasodilators increase vascular permeability to cause edema of the nasal mucosa, especially of the inferior turbinates. Many eosinophils may be seen in the nasal mucosa or secretions. The late phase of mast cell–mediated reactions is associated with persistent mucosal edema and manifests clinically as nasal obstruction.

CHRONIC RHINITIS: Repeated bouts of acute rhinitis may lead to chronic rhinitis. In this condition, the nasal mucosa is thickened by persistent hyperemia, mucous gland hyperplasia and infiltration with lymphocytes and plasma cells.

Inflammatory Polyps Are Nonneoplastic Swellings

These polyps arise in the nose and sinuses, mostly from the lateral nasal wall or ethmoid recess. They may be unilateral or bilateral, single or multiple. Symptoms include nasal obstruction, rhinorrhea and headaches. Multiple etiologies are responsible, including allergy, cystic fibrosis, infections, diabetes mellitus and aspirin intolerance. These polyps are lined by respiratory epithelium and have mucous glands within a loose mucoid stroma, containing plasma cells, lymphocytes and eosinophils.

Sinusitis Is Inflammation of the Mucous Membranes

It usually reflects bacterial infections of the paranasal sinuses.

ETIOLOGIC FACTORS: Any condition (inflammation, neoplasm, foreign body) that interferes with sinus drainage or aeration renders it susceptible to infection. If a sinus ostium is blocked, secretions or exudate accumulate behind the obstruction.

Acute sinusitis is a disorder of less than 3 weeks' duration, largely caused by extension of infection from the nasal mucosa. *Haemophilus influenzae* and *Branhamella catarrhalis* are the most common organisms. Maxillary sinusitis may also be caused by odontogenic infections: bacteria from the roots of the first and second molars penetrate the thin bony plate that separates them from the floor of the maxillary sinus. Incomplete resolution of infection or recurrent acute sinusitis may lead to chronic sinusitis, in which the purulent exudate almost always includes anaerobic bacteria.

PATHOLOGY: Complications of acute or chronic sinusitis may include:

- **Mucocele:** Mucocele is an accumulation of mucous secretions in a nasal sinus. If infected, a mucocele may cause a sinus to fill with mucopurulent exudate, called a **pyocele**. Purulent exudation in a sinus is **empyema** (Fig. 29-16). Mucoceles occur most often in the anterior compartments ("cells") of frontal and ethmoid sinuses. They develop slowly and the pressure of their expansion causes bone resorption. Mucoceles of anterior ethmoid or frontal sinuses may be large enough to displace the contents of the orbit and occasionally, erode into the central nervous system.
- **Osteomyelitis:** Suppurative infection of nasal sinus walls may spread through Volkmann canals to the periosteum, producing periostitis and subperiosteal abscess. If these occur on the orbital side of the bone, an orbital cellulitis or abscess forms. Overlying skin is often markedly edematous, and subcutaneous cellulitis or a subcutaneous abscess also may develop. Osteomyelitis also may spread rapidly between the outer and inner tables of the skull.
- **Septic thrombophlebitis:** Sinus infections that penetrate the bone may spread to frontal and diploe venous systems. Resulting septic thrombophlebitis may involve the cavernous venous sinus through the superior ophthalmic veins and is a potentially life-threatening condition.
- **Intracranial infections:** Sinusitis may also spread infection to the cranial cavity. Lesions include epidural, subdural and cerebral abscesses and purulent leptomeningitis. Spread may be via lymphatics and veins and need not involve extensive destruction of bone.

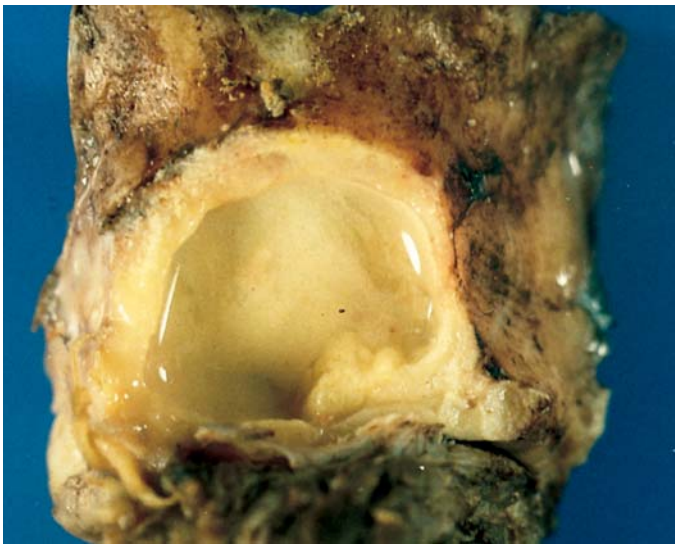

FIGURE 29-16. Empyema of the maxillary sinus (sagittal section). Infection followed chronic obstruction of the orifice caused by adenocarcinoma of the nasal mucosa.

Syphilis May Destroy the Nasal Bridge

Primary chancres in the nose are rare, but mucosal lesions of secondary syphilis are common in the nose and nasopharynx. In tertiary syphilis, inflammation may involve large portions of the nasal mucosa, underlying cartilage and bone. Perichondrial or periosteal gummas may destroy nasal cartilage and bone, causing the nasal bridge to collapse and producing "saddle nose." Destruction of nasal bony walls may also lead to perforation of the nasal septum, hard palate, wall of the orbit or maxillary sinus.

Leprosy Is Spread through Nasal Secretions

Mycobacterium leprae multiplies best at lower temperatures and so prefers cooler body sites, like the nares and anterior nasal mucosa. Nasal involvement is often the first manifestation of leprosy. Tuberculoid and intermediate forms of leprosy account for most cases (see Chapter 9). The skin around the nares and anterior nasal mucosa shows nodules, ulceration or perforations. Nasal involvement is important as leprosy is spread via nasal secretions teeming with bacilli.

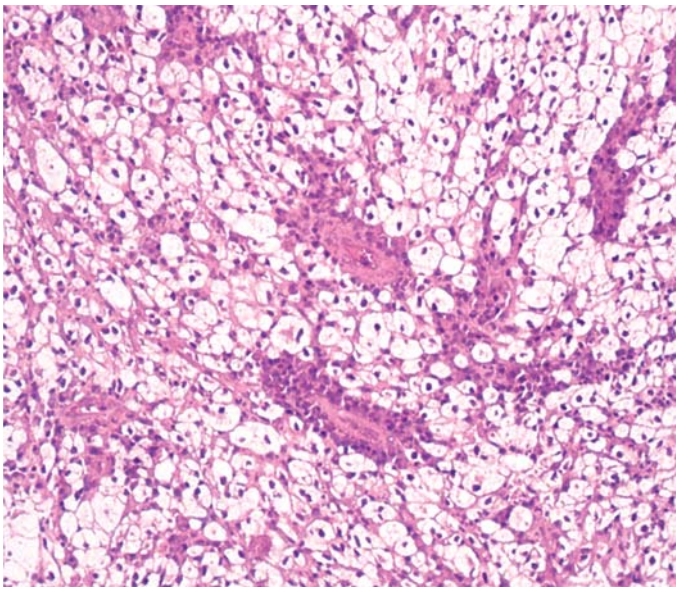

FIGURE 29-17. Rhinoscleroma. Granulation tissue contains numerous foamy macrophages (Mikulicz cells).

Rhinoscleroma (Scleroma) Is a Chronic Bacterial Infection

Rhinoscleroma is a chronic inflammatory process caused by a gram-negative diplobacillus, *Klebsiella rhinoscleromatis.* It begins in the nose and usually remains localized there but may extend slowly into the nasopharynx, larynx and trachea. It rarely involves other sites, such as the paranasal sinuses, orbital tissues, skin, lips, oral mucosa, cervical lymph nodes and gastrointestinal tract. Scleroma is endemic in parts of the Mediterranean basin, Asia, Africa and Latin America. Indigenous cases also occur in the United States. It affects both sexes and any age, and often reflects poor personal hygiene.

PATHOLOGY: Infected tissues are firm, thickened, irregularly nodular and often ulcerated. The granulation tissue is very rich in plasma cells, lymphocytes and foamy macrophages (Fig. 29-17). Characteristic large macrophages or Mikulicz cells, contain masses of phagocytosed bacilli. The disease is treatable with antibiotics.

Most Fungal Infections of the Nose and Sinuses Are Opportunistic

Pathogenic fungi may involve the nose and paranasal sinuses as part of cutaneous or mucocutaneous infection, particularly in a setting of immunodeficiency (see Chapter 9).

Candidiasis is the most common fungus infection of the nasal mucosa. It usually accompanies oral and pharyngeal candidiasis **(thrush)**. **Aspergillosis** is uncommon, and when it occurs it generally involves a paranasal sinus. Fungi may disseminate to venous sinuses, meninges and the brain. Aspergillosis of the sinonasal tract may be noninvasive or invasive, including angioinvasive. Noninvasive aspergillus sinusitis includes **allergic fungal sinusitis** (AFS) and **sinus mycetoma** (so-called fungus ball).

Allergic Fungal Sinusitis

Allergic fungal sinusitis (AFS) reflects hypersensitivity to fungal antigens, such as allergic bronchopulmonary aspergillosis (see Chapter 12). AFS occurs at all ages but is most common in children or young adults, especially those who are atopic or immunologically "hypercompetent." Any sinus may be affected, but maxillary and ethmoid sinuses are most often involved.

Fungus balls, or **aspergillomas,** occur in immunologically normal patients, usually with chronic sinusitis and poor drainage. In this setting, fungi proliferate to form a dense mass of hyphae that causes nasal obstruction. Evidence of bone destruction and ocular symptoms may be present.

Invasive Fungal Sinusitis

Invasive fungal sinusitis usually affects immunocompromised patients (Fig. 29-18). In the rare **rhinocerebral aspergillosis,** the organisms penetrate venous sinuses and spread to the meninges and brain. Few patients survive.

Mucormycosis is a potentially life-threatening infection, particularly in diabetic and immunosuppressed patients. It typically involves the nasopharynx but can invade the skin, bone, orbit and brain.

Nasal **rhinosporidiosis** is caused by the fungus *Rhinosporidium seeberi.* The disease is endemic in Sri Lanka and parts of India, and Central and South America. Affected nasal mucosa contains vascular polyploid masses that show marked chronic inflammation and characteristic spherical 50–350-µm-diameter sporangia.

Leishmaniasis (Also Known as Kala-Azar)

Mucocutaneous leishmaniasis, due to *Leishmania braziliensis,* commonly affects the nose (see Chapter 9). The nasal disease, known as **espundia,** occurs in Central and South America. Initial skin sores heal within a few months, to be followed in some patients by mucocutaneous lesions of the nose or upper lip months or years later. Infection most likely spreads by nasal contact with contaminated fingers. Early

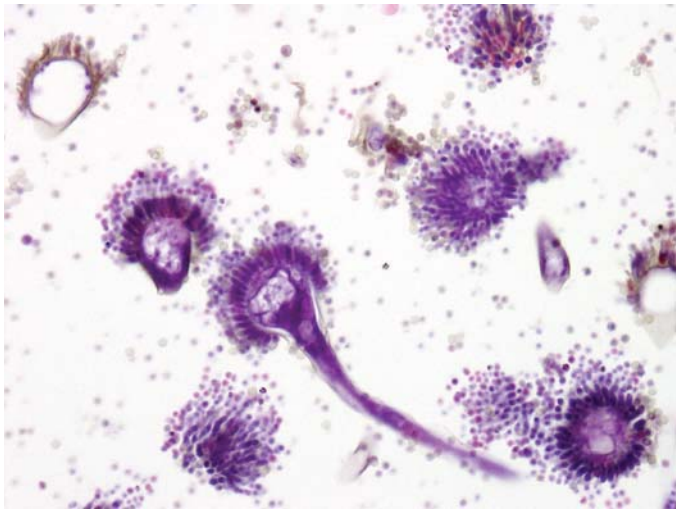

FIGURE 29-18. Aspergillus. A green, nasal mass in a patient with lymphoma demonstrated abundant fruiting bodies.

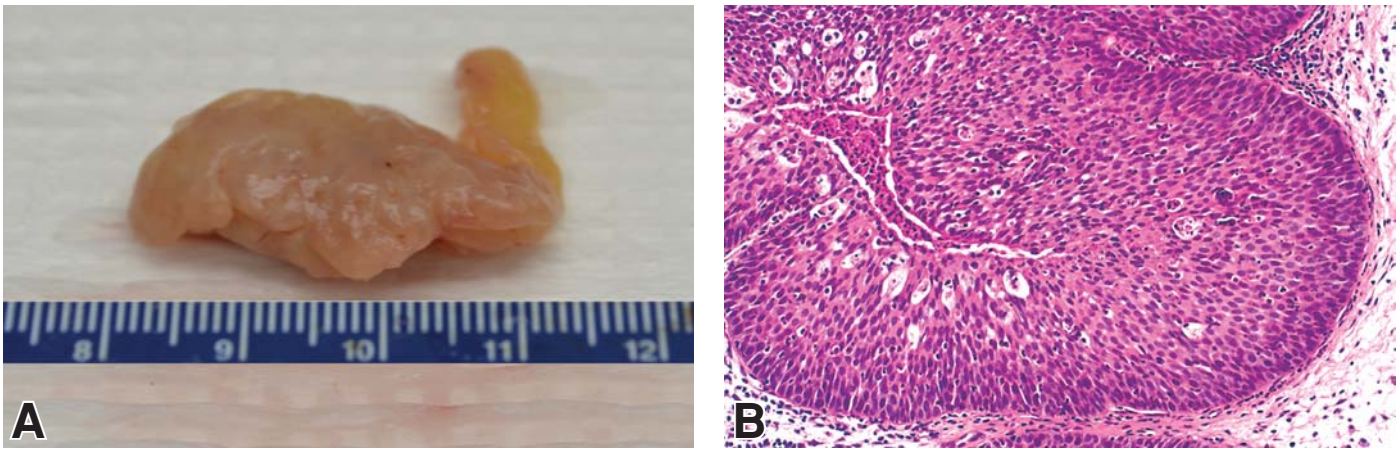

FIGURE 29-19. Sinonasal inverted papilloma. A. Gross photograph of sinonasal inverted papilloma. **B.** Epithelial nests are growing downward (inverted) into the submucosa. They are composed of a uniform cellular proliferation, which displays an inflammatory cell infiltrate and scattered microcysts.

in infection, the mucosa has polypoid inflammatory lesions, and superficial ulcers with macrophages contain parasites. Later, tuberculoid granulomatous responses develop, with few recognizable parasites. Bacterial infection may supervene and lead to soft tissue destruction and collapse of the anterior cartilaginous nasal septum.

Granulomatosis with Polyangiitis Is a Systemic Disease That Affects the Nose and Lower Airways

PATHOLOGY: This condition, once called Wegener granulomatosis, may affect many organs (see Chapters 10, 12 and 16). The sinonasal tract may be the only involved site, or it may be part of systemic disease. Septal perforation and mucosal ulceration may be followed by slowly progressive destruction of the nose and paranasal sinuses, leading to a saddle nose deformity. Constitutional symptoms, such as fever, malaise and weight loss, may accompany resulting "runny nose," sinusitis and nosebleeds. Nasal lesions show ischemic-type necrosis, vasculitis, mixed chronic inflammation, scattered multinucleated giant cells and microabscesses. Well-formed granulomas are not seen. Elevated serum antineutrophil cytoplasmic antibodies (ANCAs; see Chapter 4) and proteinase 3 (PR3) are associated with active disease.

Benign Tumors of the Nasal Cavity and Paranasal Sinuses

SQUAMOUS PAPILLOMA: This is the most common benign tumor of the nasal cavity. It resembles a wart (verruca vulgaris) and almost always occurs in the nasal vestibule.

SCHNEIDERIAN PAPILLOMAS: These benign neoplasms arise from the sinonasal (Schneiderian) mucosa and are composed of a squamous or columnar epithelial proliferation with associated mucous cells. There are three morphologically distinct lesions collectively called Schneiderian papillomas: **inverted, oncocytic** (cylindrical or columnar cell) and **fungiform** (exophytic, septal) papillomas. Schneiderian papillomas represent less than 5% of sinonasal tract tumors (Fig. 29-19A).

INVERTED PAPILLOMA: This tumor involves the lateral nasal wall and may spread to the paranasal sinuses. Inverted papillomas occur mainly in middle-aged people. As the name implies, they show inversion of surface epithelium into underlying stroma (Fig. 29-19B). HPV types 6 and 11 and, rarely, types 16, 18, 33, 40, or 57 are detected but are of uncertain significance. Although benign, these tumors may erode bone by pressure. Surgical resection must extend beyond the boundaries of grossly visible lesions, or they may recur. In 5% of cases, inverted papillomas give rise to SCC.

MALIGNANCIES OF THE NASAL CAVITY AND PARANASAL SINUSES

SCC Is Often Associated with Occupational Risk Factors

Over half of cancers of the nasal cavity and paranasal sinuses arise in the maxillary sinus antrum, one third in the nasal cavity, 10% in the ethmoid sinus and 1% in sphenoid and frontal sinuses (Fig. 29-20). Most are keratinizing or nonkeratinizing SCCs (Table 29-2). Some 15% are adenocarcinomas, or undifferentiated carcinomas.

TABLE 29-2
VARIANTS OF SQUAMOUS CELL CARCINOMA

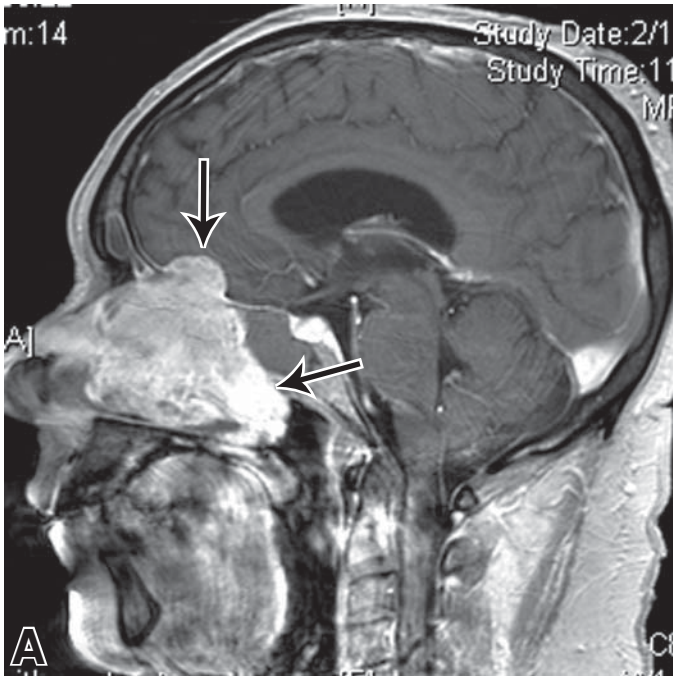
Adenosquamous carcinoma
Basaloid squamous cell carcinoma
Carcinoma cuniculatum
Papillary squamous cell carcinoma
Spindle cell squamous carcinoma
Verrucous carcinoma
Lymphoepithelial carcinoma (non-nasopharyngeal)

FIGURE 29-20. Squamous cell carcinoma of the maxillary sinus caused an obvious facial deformity, owing to invasion outside the confines of the sinus. Involvement of the orbit and facial nerve is evident. The latter is defined by drooping of the mouth to the side of the facial nerve paralysis.



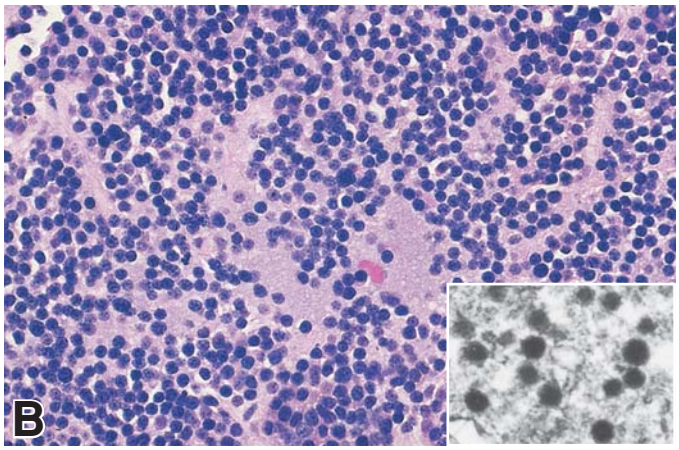


FIGURE 29-21. Olfactory neuroblastoma. A. Sagittal T1 postcontrast magnetic resonance image (MRI) demonstrates a hyperintense mass (*arrows*) arising from the cribriform plate and filling the nasal cavity. **B.** The tumor is composed of small round cells with hyperchromatic nuclei and a background eosinophilic stroma representing neurofibrillary matrix. *Inset.* An electron micrograph shows intracytoplasmic, secretory-type, membrane-bound granules with dense cores.

ETIOLOGY: Several industrial chemicals may cause cancer of the nose and sinuses, including nickel, chromium and aromatic hydrocarbons. Occupational settings reportedly with increased risk for cancer of the nose and sinuses (but for which a specific chemical agent is not identified) are woodworking in the furniture industry, use of cutting oils and leather textile industries.

Nickel workers are prone to SCCs, mostly from the middle turbinate, with latencies from 2 to over 30 years. Most other occupational exposures mainly lead to adenocarcinomas and occur mostly in the maxillary and ethmoid sinuses. Because of these occupational risk factors, cancers of the nose and sinuses occur far more often in men and after age 50. These tumors grow relentlessly and invade adjacent structures but typically do not metastasize. Survival is usually only a few years.

Olfactory Neuroblastoma Is of Neural Crest Origin

This tumor, also called esthesioneuroblastoma, is uncommon. It has a slight male predominance and occurs in people between 3 years of age and in the ninth decade but a bimodal distribution in the second and sixth decades are most common.

PATHOLOGY: This cancer arises from the olfactory mucosa covering the superior third of the nasal septum, cribriform plate (Fig. 29-21A) and superior turbinate. It is usually polypoid and highly vascular and shows diverse histologies, depending on the amount of intercellular neurofibrillary material. Tumor cells are slightly larger than lymphocytes, with round nuclei and inconspicuous cytoplasm (Fig. 29-21B). They may form pseudorosettes (Homer Wright rosettes) or true neural rosettes (Flexner-Wintersteiner rosettes). The World Health Organization (2005) adopted a four-tiered grading system, based on lobular architecture, mitosis, necrosis, nuclear pleomorphism, fibrillary matrix and rosettes. Olfactory neuroblastomas express synaptophysin and neuron-specific enolase (NSE) but not cytokeratin and epithelial membrane antigen (EMA). S-100 protein often surrounds nests or lobules **(sustentacular cells),** mostly in lower-grade tumors. The cells of olfactory neuroblastomas have intracytoplasmic neurosecretory granules like those of neuroblastomas at other sites.

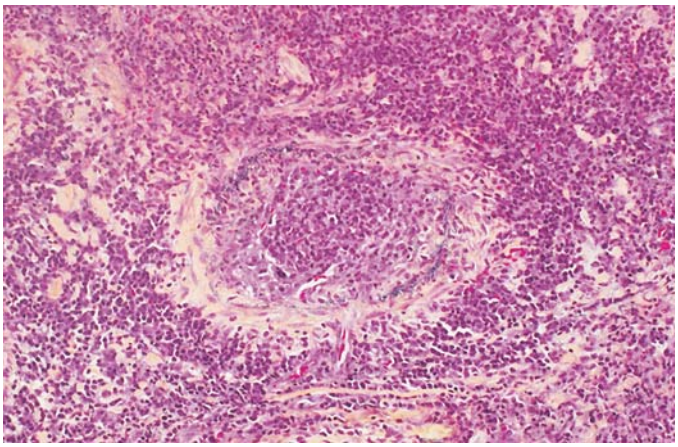

FIGURE 29-22. Angiocentric natural killer (NK)/T-cell lymphoma. A malignant cellular infiltrate growing around and into a medium-sized blood vessel with disruption of the external elastic membrane and occlusion of the vessel lumen.

CLINICAL FEATURES: Olfactory neuroblastomas invade and destroy bony structures slowly. They spread readily via lymphatics to regional and distant lymph nodes. Hematogenous spread occurs less often. Prognosis usually corresponds to tumor grade. Complete removal is critical, and craniofacial resection with chemotherapy and/or radiation therapy provides 85% 5-year survival.

Nasal-Type Angiocentric Natural Killer/T-Cell Lymphoma Is Highly Lethal

These tumors, once called **lethal midline granulomas,** midline malignant reticulosis and polymorphic reticulosis, are now recognized as malignant lymphomas.

PATHOLOGY: The characteristic lymphoid infiltrate is necrotizing and polymorphic. Similar infiltrates may occur in the upper airways, lungs and alimentary tract, but any organ can be involved. Tumor cells surround small to medium-sized blood vessels (angiocentric); infiltrate through their walls (angioinvasion), often occluding vessel lumens like a thrombus; and cause necrosis in adjacent tissues (ischemic type) (Fig. 29-22). ***EBV infection is associated with this type of lymphoma.***

CLINICAL FEATURES: Nasal-type natural killer (NK)/T-cell lymphoma usually begins insidiously as nonspecific rhinitis or sinusitis. Gradually, the nasal mucosa is focally swollen, indurated and eventually ulcerated. Ulcers are covered by a black crust, under which cartilage and bone are eroded, causing defects of the nasal septum, hard palate and nasopharynx, with serious functional consequences. The skin of the midface is often involved. Half of patients have localized disease, but wide dissemination is common. Death is due to secondary bacterial infection, aspiration pneumonia or hemorrhage from eroded large blood vessels. These lymphomas are, at least initially, radiosensitive, and remission with cytotoxic agents has also been reported.

Nasopharynx and Oropharynx

ANATOMY: The nasopharynx is continuous anteriorly with the nasal cavities; its roof is formed by the body of the sphenoid bone and its posterior wall by the cervical vertebrae. Eustachian tube openings are on the lateral walls of the nasopharynx. In newborns, it is covered by pseudostratified ciliated columnar epithelium. With advancing age, the nasopharynx is replaced by a stratified squamous epithelium over large areas (80%). The mucosa has many mucous glands and abundant lymphoid tissue.

Waldeyer ring ***is a circular band of lymphoid tissue at the opening of the oropharynx into the respiratory and digestive tracts.*** Lymphoid tissue on the superior posterior wall forms the nasopharyngeal tonsils, which, when hyperplastic, are called **adenoids**. The palatine tonsils are lateral, where the pharynx connects with the oral cavity. They are covered by stratified squamous epithelium, which lines infoldings **(tonsillar crypts)** into the lymphoid tissue. Crypts normally contain desquamated epithelium, lymphocytes, some neutrophils and saprophytic organisms, such as bacteria, *Candida* and actinomycetes. Pathogens (e.g., *Corynebacterium diphtheriae,* meningococcus) may also be seen in the pharynx of healthy people.

Waldeyer ring is well developed in children and its follicles have germinal centers. In fact, the tonsils represent the largest collections of B lymphocytes in a normal child. Pharyngeal lymphoid tissue diminishes considerably by adulthood. It gradually involutes with age but does not totally disappear.

PHARYNGEAL LYMPHOID HYPOPLASIA AND HYPERPLASIA

Bruton sex-linked agammaglobulinemia (see Chapter 4) affects only males, who have minimal or no lymphoid tissue in their tonsils, pharynx and intestines (Peyer patches and appendix). They have a normally developed thymus.

Atrophy of pharyngeal lymphoid tissue is common in chronically immunosuppressed patients. Local radiation therapy also causes marked loss of lymphoid tissue in the Waldeyer ring.

Hyperplasia of nasopharyngeal lymphoid tissue follows infections or chronic irritation due to dust, smoke and fumes. Tonsils may enlarge in some primary immunodeficiencies (dysgammaglobulinemia type I or nodular lymphoid hyperplasia), presumably reflecting an adaptive response by the immune system.

INFECTIONS

Pharyngitis and tonsillitis are among the most common diseases of the head and neck. Nasopharyngeal inflammation occurs mainly in children but is also common in adolescents and young adults. Viral or bacterial infections may be limited to the palatine tonsils but may also involve nasopharyngeal tonsils or adjacent pharyngeal mucosa, often as part of a general upper respiratory tract infection. Viruses are the usual culprits: influenza, parainfluenza, adenovirus,

respiratory syncytial virus and rhinovirus, spread by droplet or by direct contact.

S. pyogenes is the most important cause of pharyngitis and tonsillitis, because it may cause serious suppurative and nonsuppurative sequelae. **Diphtheria** still produces pharyngitis in some countries. These infections are characterized by an exudate or, in the case of diphtheria, a pseudomembrane on the tonsils and pharynx.

Acute tonsillitis is usually due to *S. pyogenes* (group A β-hemolytic streptococci). In **follicular tonsillitis,** pinpoint exudates may be extruded from the crypts.

In **pseudomembranous tonsillitis,** a necrotic mucosa is covered by a coat of exudate, as in diphtheria or **Vincent angina**. The latter is caused by fusiform bacilli and spirochetes that are part of the normal oral flora. They become pathogenic when local or systemic resistance is low (e.g., after mucosal injury or in malnutrition).

Recurrent or chronic tonsillitis is not as common as once believed, and enlarged tonsils in children do not necessarily signify chronic tonsillitis. However, repeated infections can cause tonsils and adenoids to enlarge and obstruct air passages. Repeated streptococcal tonsillitis may lead to rheumatic fever or glomerulonephritis in children, who may benefit from tonsillectomy.

Peritonsillar abscesses (quinsy) are collections of pus behind the posterior capsule of the tonsil, usually due to α- and β-hemolytic streptococci. About one third of patients have histories of tonsillitis. Untreated, such abscesses may be life-threatening since (1) aided by gravity, they may dissect inferiorly to the pyriform sinus to obstruct, or rupture into, the airway; (2) they may extend laterally into the parapharyngeal space (parapharyngeal abscess) and weaken the carotid artery wall; or (3) they may penetrate along the carotid sheath inferiorly into the mediastinum or, superiorly, to the base of the skull or cranial cavity, with disastrous consequences.

Infectious mononucleosis (mostly due to EBV) often presents with exudative tonsillitis, pharyngitis and posterior cervical lymphadenopathy. **Adenoids** represent chronic inflammatory hyperplasia of pharyngeal lymphoid tissue. This condition is often accompanied by chronic tonsillitis or rhinitis, almost always in children. Enlarged adenoids may partly or completely obstruct the eustachian tube, leading to otitis media.

NEOPLASMS

Nasopharyngeal Angiofibroma Is a Tumor of Adolescent Boys

These tumors, once called "juvenile nasopharyngeal angiofibromas," are uncommon, highly vascular neoplasms of the nasopharynx. They are histologically benign but locally aggressive. These tumors most often arise in adolescent males but are not restricted to this age group.

PATHOLOGY: Angiofibromas are multinodular, lobulated or smooth pink-white masses, which may show surface ulceration and obvious blood vessels (Fig. 29-23A). They typically arise in the submucosa of the **posterolateral nasal wall** and tend to expand into adjacent structures, causing local mass effects. These tumors may grow into fissures and foramina of the skull or destroy bone and spread into adjacent structures, such as the nasal

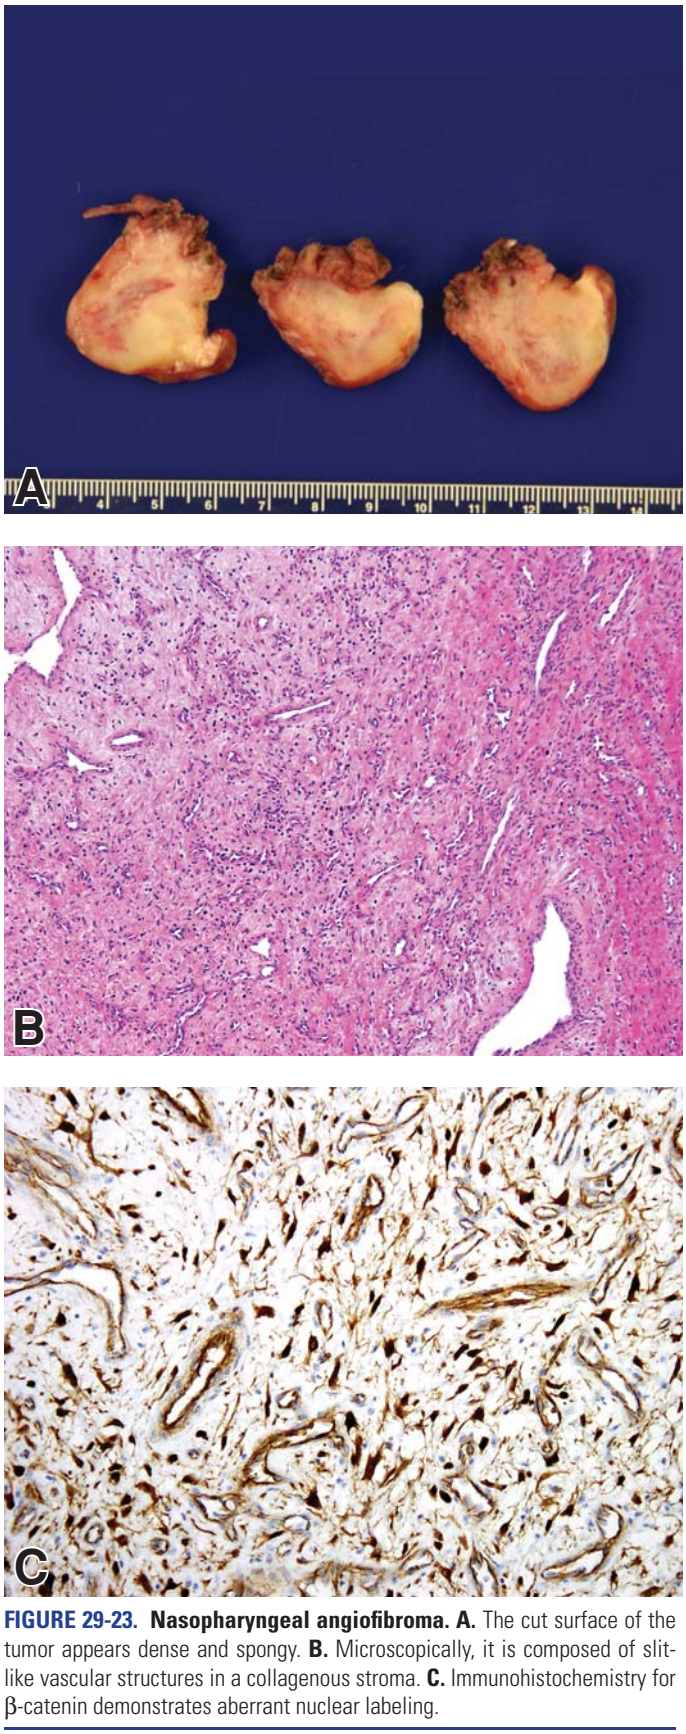

FIGURE 29-23. Nasopharyngeal angiofibroma. A. The cut surface of the tumor appears dense and spongy. **B.** Microscopically, it is composed of slit-like vascular structures in a collagenous stroma. **C.** Immunohistochemistry for β-catenin demonstrates aberrant nuclear labeling.

cavity, paranasal sinuses, orbit, middle cranial fossa or pterygomaxillary fossa.

Angiofibromas have vascular and stromal components (Fig. 29-23B). Blood vessels vary in size and shape; the smooth muscle in their walls is not layered, but rather arranged irregularly. Stromal fibroblasts express aberrant nuclear β-catenin (Fig. 29-23C).

CLINICAL FEATURES: Many angiofibromas regress spontaneously after puberty. They respond to estrogen therapy, and so may be hormonally regulated and androgen dependent. Vessel wall defects preclude vasoconstriction, leading to brisk bleeding after trauma. Biopsies may thus be dangerous and are contraindicated. Radiation therapy is also effective. Preoperative embolization may be used to reduce vascularity prior to surgery. There is a familial tendency for these tumors; they occur 25 times more often in patients with familial adenomatous polyposis (FAP) syndrome.

Oropharyngeal SCCs Are Usually Associated with HPV

In the United States, 80% of oropharyngeal SCCs are associated with high-risk HPV serotypes. These cancers, called HPV-associated head and neck squamous cell carcinomas (HPV-HNSCCs), arise mainly from palatine and lingual tonsils and are nonkeratinizing tumors of the basaloid cell type (Fig. 29-24A). Such tumors may be small and difficult to detect and often present as metastatic cancer in a cervical lymph node.

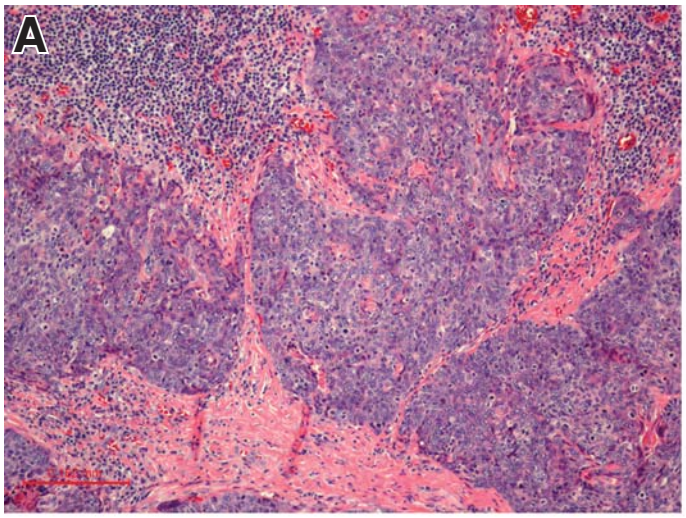
Compared to non–HPV-HNSCCs, HPV-HNSCCs tend to occur in younger people without the risk factors for HNSCC as often seen in older patients (i.e., smoking, alcohol). HPV-HNSCCs also are radiosensitive and have better overall better prognosis than non–HPV-associated HNSCCs (Fig. 29-24B,C).

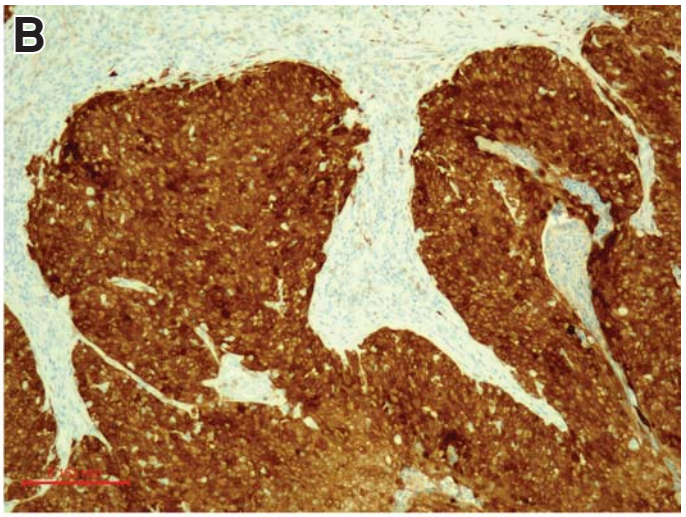
The pathogenetic roles played by cancer-associated HPV serotypes and their associated proteins are described elsewhere (see Chapters 5 and 18).

Nasopharyngeal Carcinoma Is Related to Epstein-Barr Virus

Nasopharyngeal carcinoma (NPC) is divided into keratinizing and nonkeratinizing types. The latter are associated with EBV infection and may be differentiated or undifferentiated.

EPIDEMIOLOGY: ***Undifferentiated nonkeratinizing carcinomas are particularly common in southeast Asia and parts of Africa.*** By far the most





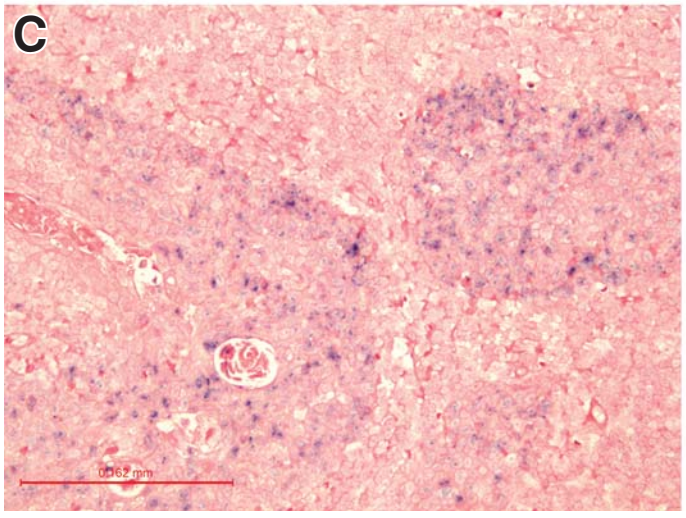


FIGURE 29-24. Human papillomavirus (HPV)-associated squamous cell carcinoma of the tonsil. A. Nests of invasive carcinoma are positive for p16 immunohistochemistry **(B)**. **C.** In situ hybridization for high-risk HPV (including types 16 and 18) demonstrates nuclear localization (blue dots).

common cancer of the nasopharynx, NPC is the most common of all cancers in China. In Hong Kong, it represents 18% of all malignancies, compared with 0.25% worldwide. Chinese born in the United States have a 20-fold greater mortality from this tumor than do other ethnicities.

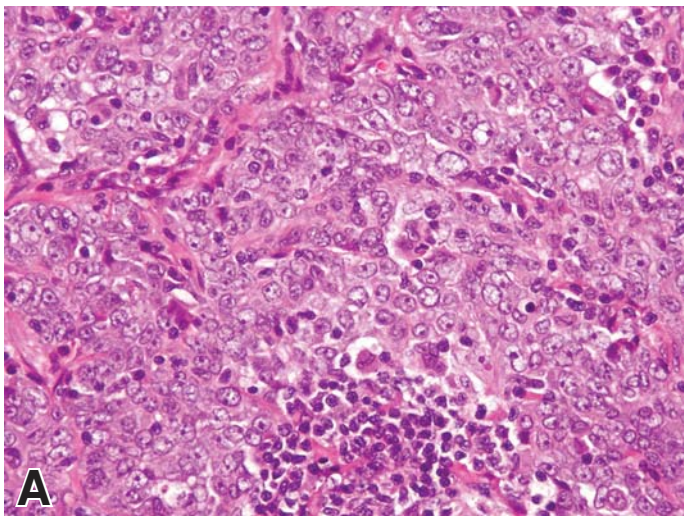
MOLECULAR PATHOGENESIS: Environmental risk factors for NPC have remained elusive. The A2/sin human leukocyte antigen (HLA) profile is more common in Chinese patients, suggesting a genetic susceptibility. Frequent deletions in several chromosomes, in particular 3p, 9p and 14q, occur in NPCs.

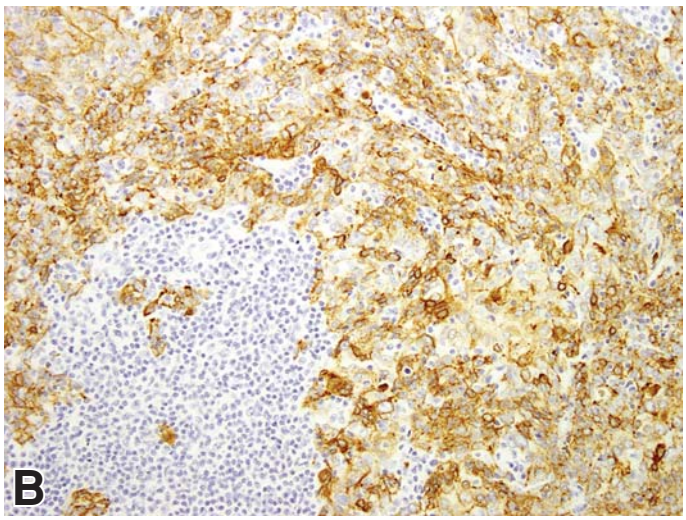
About 85% of patients with NPC have antibodies to EBV. The virus genomes are detected in 75%–100% of nonkeratinizing and undifferentiated types of NPC. EBV is more variable in keratinizing NPCs (see Chapters 5 and 9 for more detail).

PATHOLOGY: Differentiated nonkeratinizing NPCs have a stratified appearance and distinct cell margins. By contrast, in undifferentiated tumors, clusters of poorly delimited or syncytial cells have large oval nuclei and scant eosinophilic cytoplasm (Fig. 29-25A). Lymphoid infiltrates may be prominent in undifferentiated tumors, accounting for the obsolete (and misleading) term "lymphoepithelioma." Both subtypes express cytokeratin (Fig. 29-25B), but not hematologic or lymphoid markers. In situ hybridization studies usually identify EBV DNA (Fig. 29-25C).

CLINICAL FEATURES: Owing to their location, most NPCs are asymptomatic for a long time and in half of patients first present as palpable cervical lymph node metastases. Even then, many patients still have no complaints referable to the nasopharynx. Tumors invade nearby regions, such as the parapharyngeal space, orbit and cranial cavity, causing neurologic symptoms and hearing disturbances. Invasion of the base of the skull leads to cranial nerve involvement. Tumors in the fossa of Rosenmüller and the lateral wall of the nasopharynx cause symptoms referable to the middle ear. Eustachian tube obstruction is common. The abundant local lymphatic network gives rise to frequent and early metastases to cervical lymph nodes.

Nasopharyngeal undifferentiated carcinoma is radiosensitive, and most patients with tumors restricted to the nasopharynx survive 5 years or more. Cranial nerve involvement or metastases to cervical lymph nodes or beyond portend poor survival.





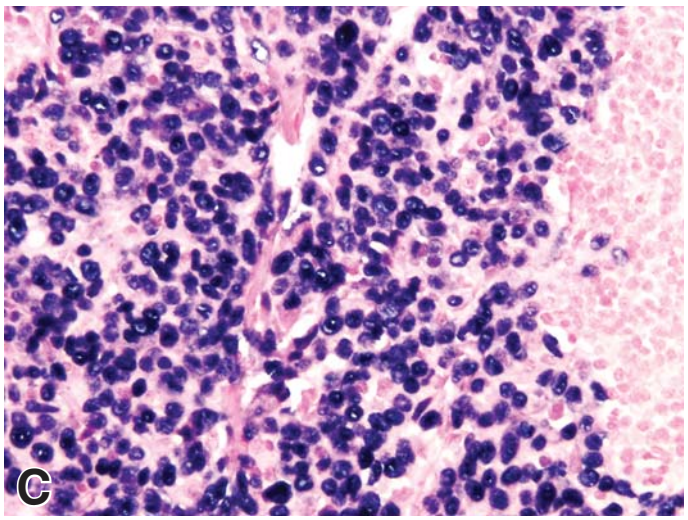


FIGURE 29-25. Nasopharyngeal nonkeratinizing carcinoma, undifferentiated type. **A.** The cells have large nuclei and prominent eosinophilic nucleoli. **B.** The cells are cytokeratin positive (by immunohistochemistry), indicating an epithelial cell proliferation. **C.** In situ hybridization for Epstein-Barr virus (EBER-ISH).

Lymphomas of the Waldeyer Ring Are Mostly Diffuse B-Cell Tumors

Lymphomas account for 5% of head and neck cancers. The Waldeyer ring is by far the most common site of origin of lymphoma in this region: the palatine tonsils first, then the nasopharynx and base of the tongue. These lymphomas are histologically diffuse (90%), and over half are large cell lymphomas. In the United States and Asia, the vast majority are of B-cell origin.

Most Extramedullary Plasmacytomas Occur in the Head and Neck

These tumors occur in the nasopharynx, nasal cavity and paranasal sinuses and behave like other extramedullary plasmacytomas. Head and neck plasmacytomas may remain localized or may evolve into systemic plasma cell myelomas (see Chapter 20).

Chordomas Are Derived from Remnants of Embryonic Notochord

Chordomas are uncommon cancers in people under age 40. In the cranial region, they originate from the area of the sphenooccipital synchondrosis or **clivus,** and in one third of cases, they extend into the nasopharynx. These tumors have large vacuolated **(physaliferous)** cells, surrounded by abundant intercellular matrix (Fig. 29-26). Chordomas grow slowly, but they infiltrate bone and are difficult to excise completely by surgery. Patients with cranial region chordomas rarely survive over 5 years.

Other Malignancies of the Nasopharynx Are Rare

They may derive from various components of mucosa or adjacent supportive soft tissues and skeleton. **Embryonal rhabdomyosarcomas** (Fig. 29-27) are highly malignant tumors of pharyngeal tissues of young children. They invade contiguous structures and metastasize via the bloodstream and lymphatics. Nasopharyngeal **Kaposi sarcomas** may occur in patients with AIDS, in association with HHV8.

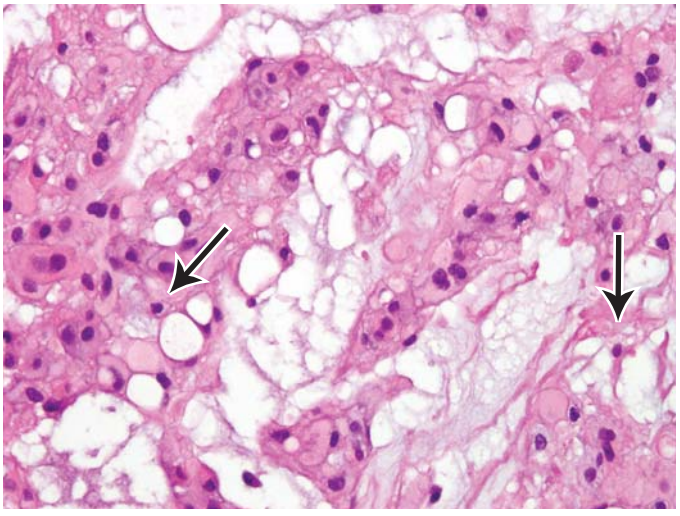

FIGURE 29-26. Chordoma. Large vacuolated (physaliferous) tumor cells (*arrows*) are evident.

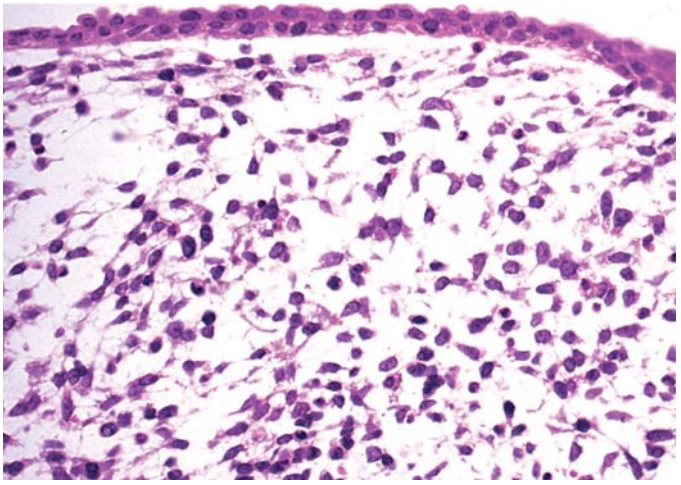

FIGURE 29-27. Embryonal rhabdomyosarcoma from a 3-year-old girl. This highly malignant tumor arose in the parapharyngeal space and invaded the adjacent structures. The oval or tadpole-shaped tumor cells under the epithelium have hyperchromatic, eccentric nuclei and immunohistochemical and ultrastructural features of rhabdomyoblasts.

Larynx and Hypopharynx

INFECTIONS

EPIGLOTTITIS: Inflammation of the epiglottis is most commonly caused by *H. influenzae* type B. It occurs in infants and young children and may be a life-threatening emergency. Swelling of an acutely inflamed epiglottis may obstruct airflow. Inspiratory stridor (loud wheezing on inspiration) and the onset of cyanosis may indicate airway obstruction so severe as to require tracheostomy.

CROUP: Croup is a laryngotracheobronchitis of young children who have symptoms of inspiratory stridor, cough and hoarseness, due to varying degrees of laryngeal obstruction. It is a complication of an upper respiratory infection, with marked laryngeal edema and a "barking cough." This was once a deadly complication of diphtheria. However, antibiotics and immunizations have helped prevent or treat it, and today, it is most commonly caused by the parainfluenza viruses.

VOCAL CORD NODULE AND POLYP

Also called *singer's nodules,* these are stromal reactions related to inflammation and/or trauma. They may be seen in all age groups but are most common between the third and sixth decades (Fig. 29-28). Symptoms related to vocal cord polyps and nodules are similar: hoarseness or voice changes ("cracking" of the voice). Lesions occur after voice abuse, infection (laryngitis), excessive alcohol consumption,

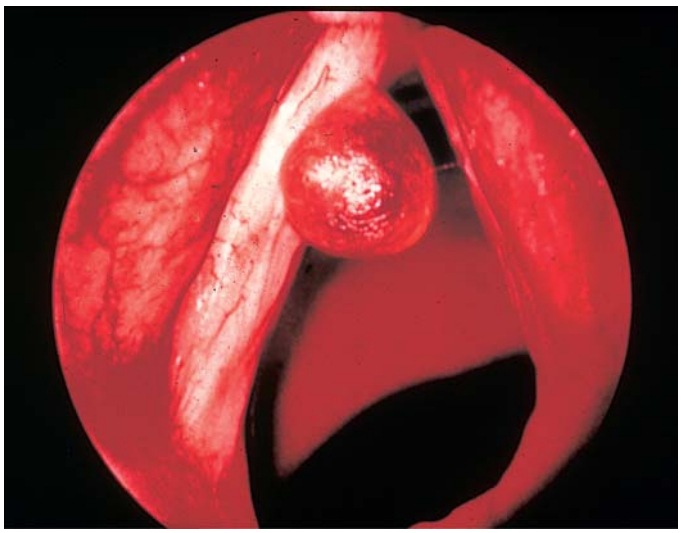

FIGURE 29-28. Vocal cord polyp. A solitary polypoid lesion with a glistening appearance is seen arising from the true vocal cord.

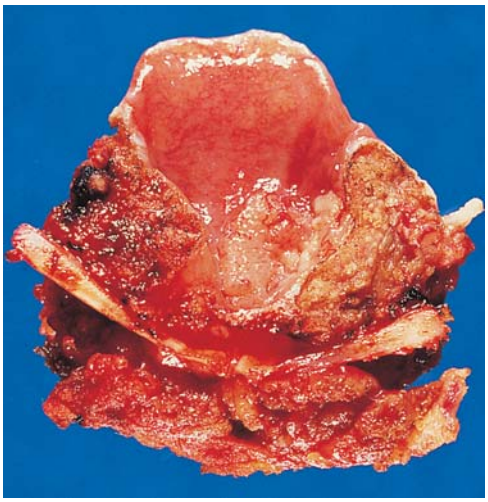

FIGURE 29-29. Supraglottic laryngectomy specimen for squamous cell carcinoma. The carcinoma appears as an irregular raised granular-appearing area in the right supraglottic larynx.

smoking or endocrine dysfunction (e.g., hypothyroidism). Histologies vary from a myxoid, edematous, fibroblastic stroma in early stages to a hyalinized, densely fibrotic stroma later.

NEOPLASMS OF THE LARYNX

SQUAMOUS PAPILLOMA AND PAPILLOMATOSIS: These papillomas are solitary or multiple papillary growths of the mature squamous cells that line the surface of fibrovascular cores. They may be multiple in children or adolescents **(juvenile laryngeal papillomatosis)** and may extend into the trachea and bronchi. HPV, especially serotypes 6 and 11, are the main causes. The condition may cause life-threatening respiratory obstruction and, rarely, evolve into overt SCC, particularly in smokers or after radiation therapy. Surgical excision may not be curative, as the viral infection is often widespread, and these tumors tend to recur over many years. Solitary laryngeal squamous papilloma occurs in adults, mostly men, and is usually cured surgically.

SQUAMOUS CELL CARCINOMA: Almost all laryngeal cancers are SCCs, predominantly in men, most of whom smoke cigarettes. HPV is found in a quarter of cases.

- **Glottic carcinoma** is limited to one or both true vocal cords and accounts for 2/3 of laryngeal SCCs. It metastasizes late to lymph nodes and has a good prognosis.
- **Supraglottic carcinomas** arise in the ventricle, false cords or epiglottis and, by definition, do not involve the true cords. Up to 1/3 of laryngeal cancers arise in this location. Nodal metastases are more common than in glottic tumors.
- **Transglottic carcinoma** by definition involves true and false cords (Fig. 29-29). It spreads to lymph nodes and often requires total laryngectomy.
- **Infraglottic carcinomas** are uncommon. Found below the true cords or involving the true cords with infraglottic extension and frequent extension into the trachea, they commonly spread to lymph nodes. Total laryngectomy is usually required.

CHONDROSARCOMA: Chondrosarcomas account for 75% of nonepithelial laryngeal malignancies. In the larynx, they grow as exophytic, polypoid masses and can cause airway obstruction. Most patients are men in their 70s. It also occurs in the nasopharynx, mandible, maxilla and nasal and paranasal sinuses. Patients present with hoarseness, airway obstruction and dyspnea.

Salivary Glands

The salivary glands develop as buds of oral ectoderm. They are tubuloalveolar structures that secrete saliva. Major salivary glands are paired organs. Parotid glands secrete serous saliva, and submandibular and sublingual glands make mixed serous and mucous saliva. Minor salivary glands are widespread under the mucosa of the lips, cheeks, palate and tongue. Lymph nodes are normally embedded in the parotid gland and may be involved in inflammatory, reactive, proliferative or malignant processes.

XEROSTOMIA: Xerostomia is chronic mouth dryness due to lack of saliva and has many causes. Diseases that involve major salivary glands and lead to xerostomia include mumps, Sjögren syndrome, sarcoidosis, radiation-induced atrophy (Fig. 29-30) and drug sensitivity (e.g., antihistamines, tricyclic antidepressants, phenothiazines).

SIALORRHEA: Increased salivary flow is associated with many conditions, including acute inflammation of the oral cavity (e.g., as in aphthous stomatitis), Parkinson disease, rabies, mental retardation, nausea and pregnancy.

ENLARGEMENT: Unilateral enlargement of major salivary glands is usually caused by cysts, inflammation or neoplasms. Bilateral enlargement is due to inflammation (mumps, Sjögren syndrome; see below), granulomatous disease (sarcoidosis) or diffuse neoplastic involvement (leukemia or lymphoma).

SIALOLITHIASIS: Calcific stones in salivary gland ducts mostly occur in the submandibular gland. They obstruct ducts, leading to inflammation distally.

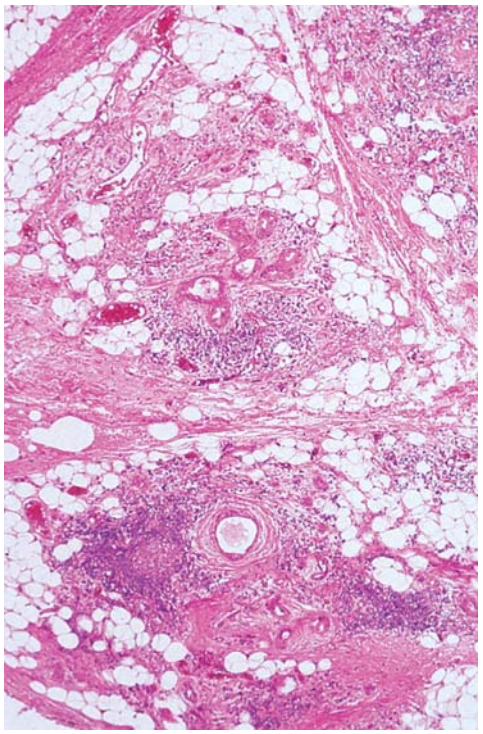

FIGURE 29-30. Chronic sialadenitis. Severe chronic inflammation and marked atrophy of the submandibular gland are present after irradiation of an adjacent oral cancer. The atrophic acini have been replaced by fat.

PAROTITIS: Bacteria (usually *Staphylococcus aureus*) may ascend from the oral cavity when salivary flow is reduced and cause acute suppurative parotitis. It is most often seen in debilitated or postoperative patients. Salivary duct stricture or obstruction by stones may cause acute or chronic parotitis. Stagnant secretions serve as a medium for retrograde bacterial invasion.

Epidemic parotitis (mumps) is an acute viral disease of the parotid glands that spreads via infected saliva. Submandibular and sublingual glands also may be affected. Involved glands have dense lymphocytic and macrophage infiltrates, epithelial degeneration and necrosis.

Sjögren Syndrome Is a Systemic Autoimmune Disease Affecting the Salivary and Lacrimal Glands

The disease may be limited to these sites, or it may be associated with a systemic autoimmune disease (see Chapter 11). In the salivary glands, it leads to xerostomia. Involvement of the lacrimal glands results in dry eyes **(keratoconjunctivitis sicca)**. The pathogenesis and clinical features of Sjögren syndrome are discussed in Chapters 11 and 4.

PATHOLOGY: In Sjögren syndrome, parotid glands, and sometimes submandibular glands, are enlarged unilaterally or bilaterally, but their lobulation is preserved. Initial periductal chronic inflammation gradually extends into the acini, until the glands are completely replaced by a sea of polyclonal lymphocytes, immunoblasts, germinal centers and plasma cells. Proliferating myoepithelial cells surround remnants of damaged ducts and form so-called epimyoepithelial islands (**lymphoepithelial sialadenitis;** Fig. 29-31). Similar changes occur in the lacrimal glands and minor salivary glands. Focal lymphocytic sialadenitis is also present in minor salivary glands. Late in the course of the disease, affected glands become atrophic, with fibrosis and fatty infiltration of the parenchyma. Lymphocytes in Sjögren syndrome may show restricted immunoglobulin types but may remain localized, without invasion.

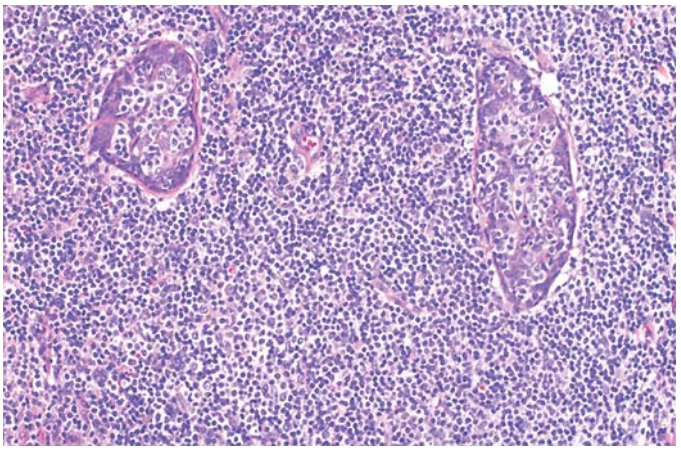

FIGURE 29-31. Sjögren syndrome. There is infiltration of the involved salivary gland by a mixed chronic inflammatory cell infiltrate. Extension of the infiltrate into epithelial (ductal) structures results in metaplasia and characteristic epimyoepithelial islands.

BENIGN SALIVARY GLAND NEOPLASMS

Pleomorphic Adenoma Is the Most Common Salivary Gland Tumor

These neoplasms, also called **mixed tumors,** are benign proliferations with admixed epithelial and stromal elements. Two thirds of major salivary gland tumors, and about half of those in the minor glands, are pleomorphic adenomas. These tumors occur nine times more often in the parotid than in the submandibular gland and usually arise in the superficial lobe of the former. Middle-aged people and women are most affected.

MOLECULAR PATHOGENESIS: Loss of heterozygosity of chromosome 8q17p and rearrangements in 3p21 and 12q13-15 have been found in pleomorphic adenomas. In most of these tumors, PLAG1 (pleomorphic adenoma gene 1), which encodes a zinc finger protein, is activated by reciprocal chromosomal translocations involving 8q12. Carcinomas that develop from pleomorphic adenomas may have 8q12 rearrangements, alterations in 12q13-15 and mutations in *HMGIC* and *MDM2* genes.

PATHOLOGY: Pleomorphic adenomas are slowly growing, painless, movable, firm masses with smooth surfaces (Fig. 29-32). Those arising deep in the parotid may grow between the ramus of the mandible, the styloid process and the stylomandibular ligament into the parapharyngeal space and appear as swellings

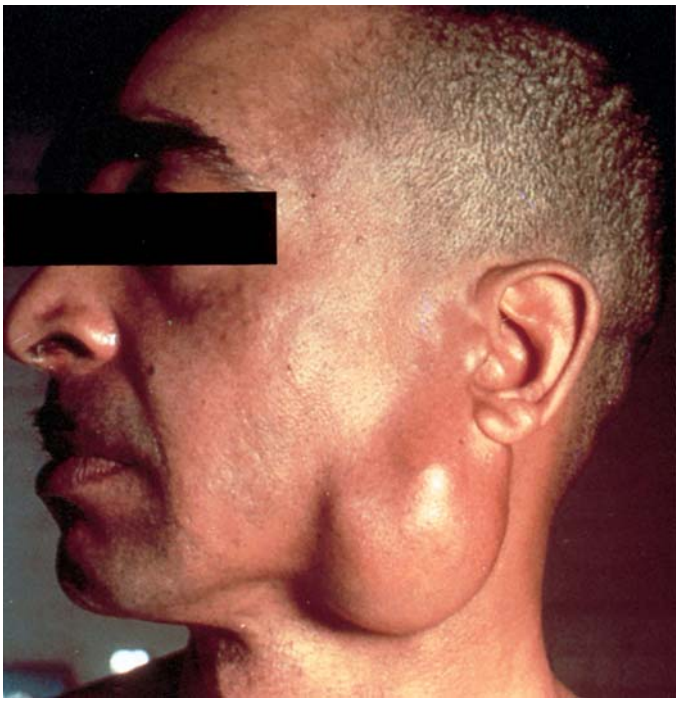

FIGURE 29-32. Pleomorphic adenoma of the parotid. A conspicuous tumor mass is seen at the angle of the jaw.

of the lateral pharyngeal or tonsillar regions. These tumors show epithelial tissue mingled with myxoid, mucoid or chondroid areas (Fig. 29-33A), hence the older term **benign mixed tumor**. However, the neoplasm is considered to be of epithelial origin.

The epithelial component consists of myoepithelial and ductal cells. The cells that line the ducts form tubules or small cystic structures and contain clear fluid or eosinophilic, periodic acid–Schiff (PAS)-positive material. Around ductal epithelial cells are smaller myoepithelial cells, which are the main cellular component. These cells form well-defined sheaths, cords or nests and are often separated by a cellular ground substance that resembles cartilaginous, myxoid or mucoid material.

CLINICAL FEATURES: Pleomorphic adenomas have fibrous capsules. As they grow, surrounding fibrous tissue condenses around them. The tumors expand and often protrude focally into adjacent tissues, becoming nodular and occasionally forming "podocytes" (Fig. 29-31B). These tumor projections can be missed if a tumor is not carefully excised with its capsule intact, plus an adequate margin of gland parenchyma. Tumor implanted during surgery or tumor nodules left behind continue to grow and recur in scars from previous operations. Recurrences usually represent local regrowth, not malignancy. Definitive surgery may necessitate sacrificing the facial nerve.

Carcinomas may rarely arise in pleomorphic adenomas **(carcinoma ex pleomorphic adenoma)**. In this case, the tumor that was present for many years then begins to grow rapidly or becomes painful. Such carcinomas are most frequently high-grade malignancies set in otherwise benign pleomorphic adenomas. However, virtually any type of salivary gland malignancy may occur in this setting, including mucoepidermoid or adenoid cystic carcinomas. If the malignancy is confined to the tumor capsule and does not invade the adjacent salivary gland, it is considered **in situ** or **noninvasive carcinoma ex pleomorphic adenoma**. If the cancer invades beyond the tumor capsule but not more than 1.5 mm, it is called **minimally invasive carcinoma ex pleomorphic adenoma**. These entities have an excellent prognosis. However, tumors invading beyond 1.5 mm (i.e., ***widely invasive tumor***) act aggressively, recur often, metastasize and have a poor prognosis.

Monomorphic Adenomas Represent 5%–10% of Benign Salivary Gland Tumors

In monomorphic adenomas, the epithelium is arranged in a regular, usually glandular, pattern with no mesenchymal component. Monomorphic adenomas include (1) Warthin tumors, (2) basal cell adenomas, (3) oxyphilic adenomas or

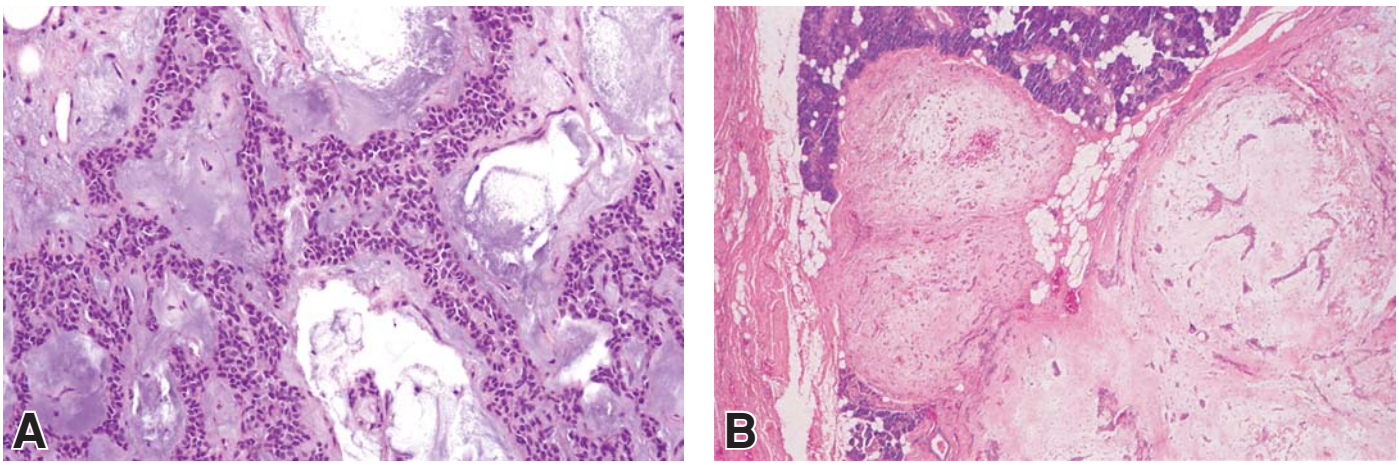

FIGURE 29-33. Pleomorphic adenoma of the parotid gland. A. Cellular components of pleomorphic adenomas include an admixture of glands and myoepithelial cells within a chondromyxoid stroma. **B.** The tumor contains characteristic myxoid and chondroid portions. The tumor is partly encapsulated, but a nodule protruding into the parotid gland lacks a capsule. If such nodules are not included in the resection, the tumor will recur.

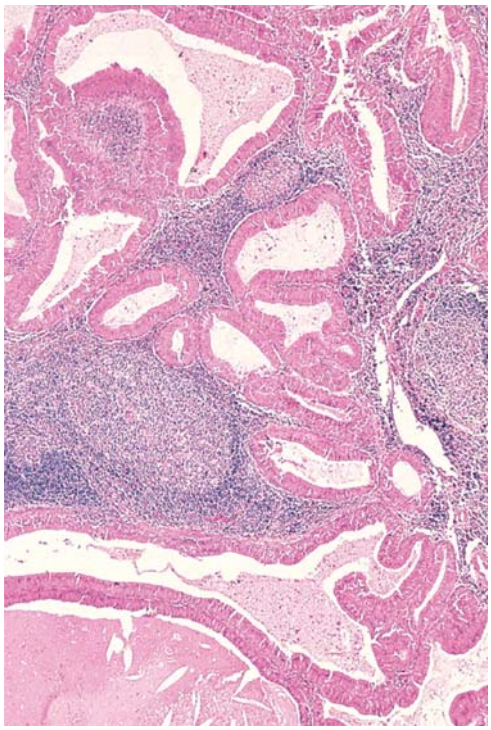

FIGURE 29-34. Warthin tumor. Cystic spaces and duct-like structures are lined by oncocytes. Follicular lymphoid tissue is present.

oncocytomas, (4) canalicular adenomas, (5) myoepitheliomas and (6) clear cell adenomas.

Warthin Tumor (Papillary Cystadenoma Lymphomatosum)

Warthin tumors are the most common monomorphic adenomas. They are benign parotid gland neoplasms composed of cystic glandular spaces within dense lymphoid tissue. Clearly benign, they may be bilateral (15% of cases) or multifocal within one gland. These are the only salivary gland tumors that are more common in men than in women. They generally occur after age 30, and most arise after age 50.

PATHOLOGY: Warthin tumors have glandular spaces that tend to become cystic, with papillary projections. The cysts are lined by eosinophilic epithelial cells (oncocytes), surrounded by dense lymphoid tissue with germinal centers (Fig. 29-34).

The histogenesis of this tumor is uncertain. Lymph nodes are normally found in the parotid gland and its immediate vicinity and usually contain a few ducts or small islands of salivary gland tissue. Warthin tumors may arise from proliferation of these salivary gland inclusions.

Oncocytoma (Oxyphil Adenoma)

Oncocytes are benign epithelial cells swollen with mitochondria, which impart a granular appearance to the cytoplasm. They are normally scattered or in small clusters among epithelial cells of various organs (e.g., thyroid, parathyroid). Oncocytes first appear in early adulthood and increase in number with age. Rare adenomas of nests or cords of oncocytes occur in parotid glands of the elderly.

MALIGNANT SALIVARY GLAND TUMORS

Salivary gland tumors account for 5% of all head and neck cancers. Most (75%) arise in the parotid glands, 10% in the submandibular glands and 15% in the minor salivary glands of the upper aerodigestive tract. Malignancies of the sublingual glands are rare.

Mucoepidermoid Carcinomas Show Mixed Cell Populations

Mucoepidermoid carcinomas (MECs) derive from ductal epithelium, which has a great potential for metaplasia. They account for 5%–10% of major salivary gland tumors and 10% of tumors in minor salivary glands. Over half of MECs in the major glands arise in the parotid. Among minor salivary glands, they develop mostly in the palate. Most MECs arise in adult women but may occur in adolescents.

MOLECULAR PATHOGENESIS: Over 60% of MECs are characterized by a t(11;19)(q21-22;p13) translocation (Fig. 29-35). This recombination generates a fusion gene (**MECT1–MAML2** fusion) that disrupts NOTCH signaling.

PATHOLOGY: Mucoepidermoid carcinomas grow slowly and present as firm, painless masses. Low-grade tumors contain irregular solid, duct-like and cystic spaces that include squamous cells, mucus-secreting cells and intermediate cells (Fig. 29-36). Intermediate-grade tumors tend to grow in more solid patterns, with more epidermoid and intermediate cells and fewer mucus-secreting cells. High-grade MECs are very pleomorphic, with minimal differentiation, save for scattered glandular cells.

CLINICAL FEATURES: Even low-grade mucoepidermoid carcinomas may metastasize, but over 90% of patients survive 5 years, regardless of the primary site. Survival with high-grade tumors is much

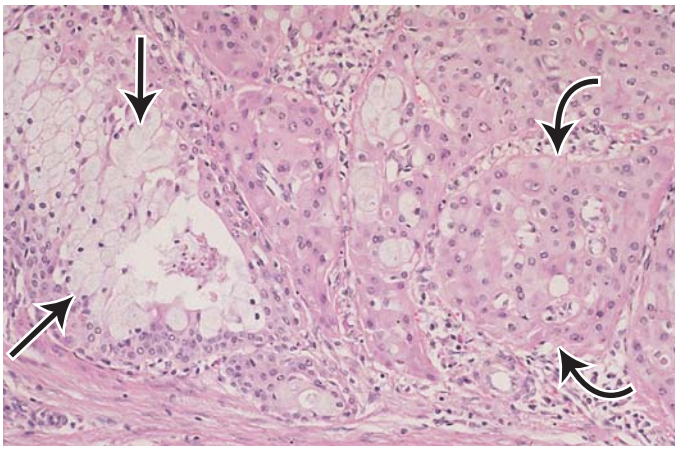

FIGURE 29-35. Mucoepidermoid carcinoma is characterized by an admixture of mucocytes (*straight arrows*), epidermoid cells (*curved arrows*) and intermediate cells. The mucocytes are clustered and have a clear cytoplasm with eccentrically situated nuclei. Epidermoid cells are squamous-like cells but lack keratinization and intercellular bridges. Intermediate cells (best seen at *lower left*) are smaller than epidermoid cells.

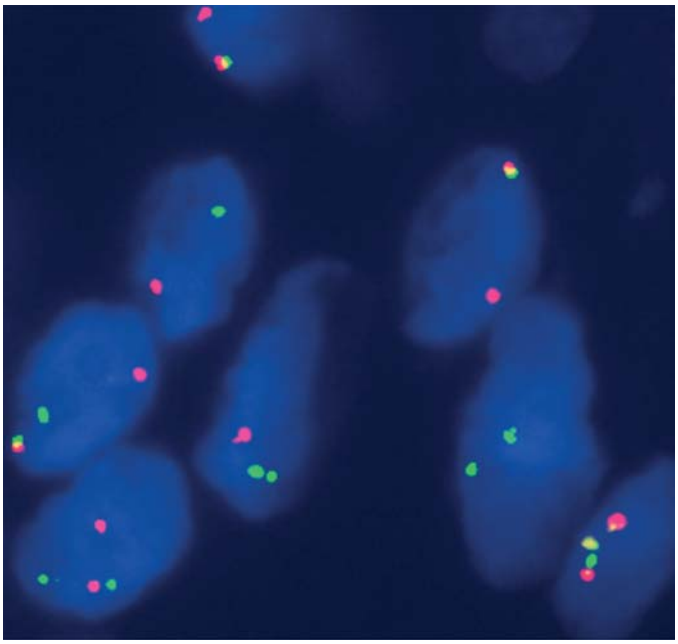

FIGURE 29-36. Mucoepidermoid carcinoma fluorescence in situ hybridization (FISH) MAML2-positive case. The green and red break-apart probes are both designed for the *MAML2* gene of chromosome 11. Yellow signals are essentially interpreted as an intact *MAML2* gene, whereas the solitary green and red probes are consistent with gene disruption or translocation. *Photograph courtesy of Dr. Joaquin Garcia, Mayo Clinic.*

worse (20%–40%). Treatment is dictated by grade; low-grade tumors are treated surgically, but high-grade tumors require both surgery and radiation therapy.

Adenoid Cystic Carcinomas Invade Locally and Often Recur After Resection

Adenoid cystic carcinomas (ACCs) tend to grow slowly. One third of ACCs arise in the major salivary glands and two thirds in the minor ones. They represent 5% of major salivary gland tumors and 20% of those of the minor salivary glands. ACCs may occur not only in the oral cavity but also in the lacrimal glands, nasopharynx, nasal cavity, paranasal sinuses and lower respiratory tract. They are most common in people 40–60 years old.

MOLECULAR PATHOGENESIS: ACCs consistently demonstrate t(6;9) translocations and chromosome 6 deletions. The translocation t(6;9)(q22-23;p23-24) results in a novel fusion of the MYB proto-oncogene with NFIB, a transcription factor.

PATHOLOGY: ACCs show variable histology. The tumor cells are small, have scant cytoplasm and grow in solid sheets or as small groups, strands or columns. Within these structures, tumor cells interconnect to enclose cystic spaces, resulting in solid, tubular or cribriform (sieve-like) patterns (Fig. 29-37). Grading ACCs depends on the proportions of tubular and cribriform patterns, with over 30% solid growth defining "high grade." Such high-grade tumors have a 5-year survival rate of about 15%. Tumor cells produce a homogeneous basement membrane material that gives them the characteristic "cylindromatous" appearance.

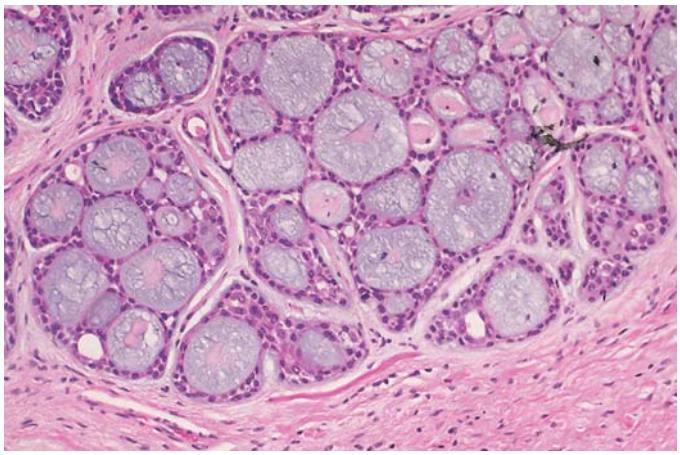

FIGURE 29-37. Adenoid cystic carcinoma showing cribriform growth in which cyst-like spaces are filled with basophilic material. The cyst spaces are really pseudocysts surrounded by myoepithelial cells.

ACCs probably arise from cells that differentiate toward intercalated ducts and myoepithelium. ***They tend to infiltrate perineural spaces and thus are often painful.*** Most do not metastasize for years, but they are often diagnosed late, are difficult to eradicate completely and have a poor long-term prognosis.

Acinic Cell Adenocarcinomas Arise from Secretory Cells

These uncommon parotid tumors (10% of salivary gland tumors) arise occasionally in other salivary glands. They occur mainly in young men ages 20–30 years. Acinic cell carcinomas are encapsulated, round masses, usually under 3 cm, and may be cystic. They are composed of uniform cells with a small central nucleus and abundant basophilic cytoplasm, similar to the secretory (acinic) cells of normal salivary glands (Fig. 29-38). They may spread to regional lymph nodes. Most

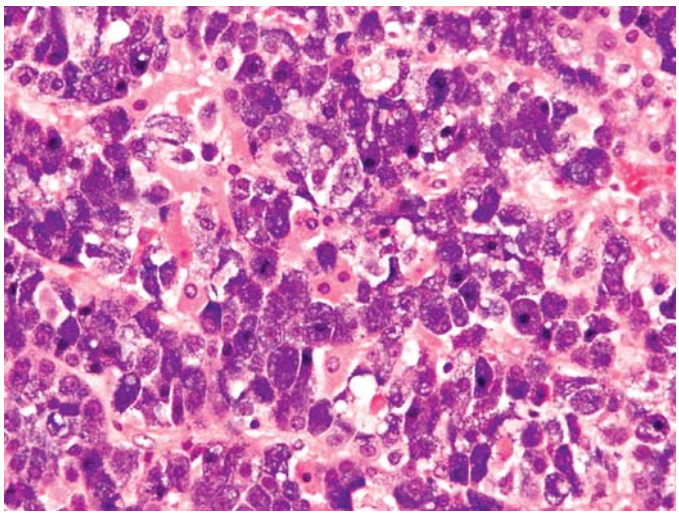

FIGURE 29-38. Acinic cell adenocarcinoma. This tumor demonstrates a solid growth pattern and is composed of basophilic cells with abundant cytoplasm filled with zymogen granules.

(90%) patients survive 5 years with surgery, but 1/3 experience local recurrences. Only half survive for 20 years.

Mammary Analog Secretory Carcinomas Resemble ACCs

These tumors compose a distinct histological entity. They have an associated unique translocation t(12;15)(p13;q25) that leads to the ETV6–NTRK3 fusion oncogene. Mammary analog secretory carcinomas mainly arise in the parotid gland.

The Ear

EXTERNAL EAR

ANATOMY: The outer portion of the external ear includes the auricle or pinna, leading into the external auditory canal. The external auditory canal or meatus extends from the concha medially to the tympanic membrane (eardrum). Its lateral wall is cartilage and connective tissue, and its medial wall is bone. The eardrum sits obliquely at the end of the external auditory canal, sloping medially from above downward and from behind forward, separating the external ear and the middle ear.

The auricle is composed of keratinizing, stratified squamous epithelium with associated adnexa (hair follicles, sebaceous glands, eccrine sweat glands). The outer third of the external auditory canal also has ceruminal glands, modified apocrine glands that replace the eccrine glands of the auricular dermis. They produce cerumen and contain clusters of cuboidal cells with eosinophilic cytoplasm, often with granular, golden yellow pigment and secretory droplets by their luminal border. Peripheral to the secretory cells are flattened myoepithelial cells. Ceruminal gland ducts end in hair follicles or on the skin. The inner portion of the external auditory canal has no adnexa. The eardrum is airtight. Its outer surface is squamous epithelium, continuous with the skin of the external ear canal. Its inner surface is lined by cuboidal epithelium. Between these two is a middle layer of dense fibrous tissue.

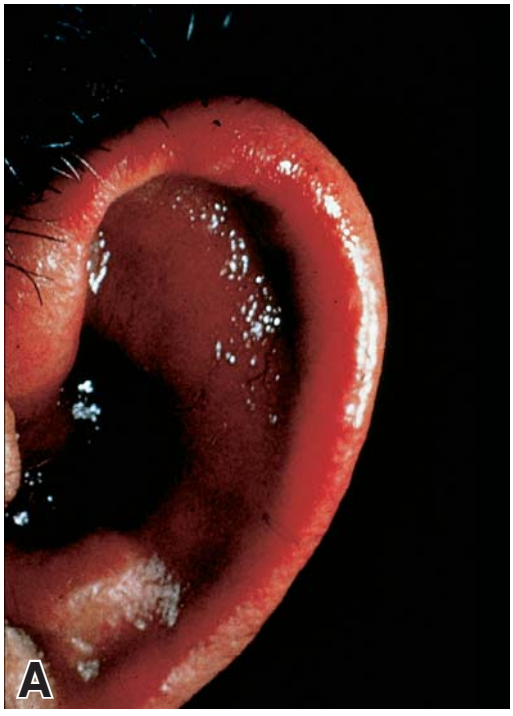
KELOIDS: Keloids are very common on the ear lobes after piercing for earrings or other trauma (see Chapter 3). They are much more common in blacks and Asians than in whites. Keloids can attain considerable size and tend to recur. They are composed of thick, hyalinized bundles of collagen in the deep dermis (see Chapter 3).

CAULIFLOWER EARS: These deformities are particularly common in wrestlers and boxers and result from repeated mechanical trauma to the external ear. Blows to the ears cause subperichondrial hematomas, which organize and deform the ears.

RELAPSING POLYCHONDRITIS: This rare, chronic disorder of unknown origin is characterized by intermittent inflammation that destroys hyaline, elastic or fibrocartilage of the ears, nose, larynx, tracheobronchial tree, ribs and joints.

The etiology of relapsing polychondritis is obscure; immune mechanisms are suspected. During acute attacks, patients may have serum antibodies to cartilage, type II collagen and chondroitin sulfate. Immune complexes can be detected in involved cartilage. Relapsing polychondritis may occur alone or with other connective tissue diseases. Noncartilaginous tissues, such as the sclera and cardiac valves, also may be affected. Aortic involvement can lead to fatal rupture of the aorta.

PATHOLOGY: The perichondrium is infiltrated by lymphocytes, plasma cells and neutrophils, which also extend into the adjacent cartilage (Fig. 29-39). Chondrocytes die. The cartilaginous matrix degenerates and fragments. Ultimately, the cartilage is destroyed and replaced by granulation tissue and fibrosis.



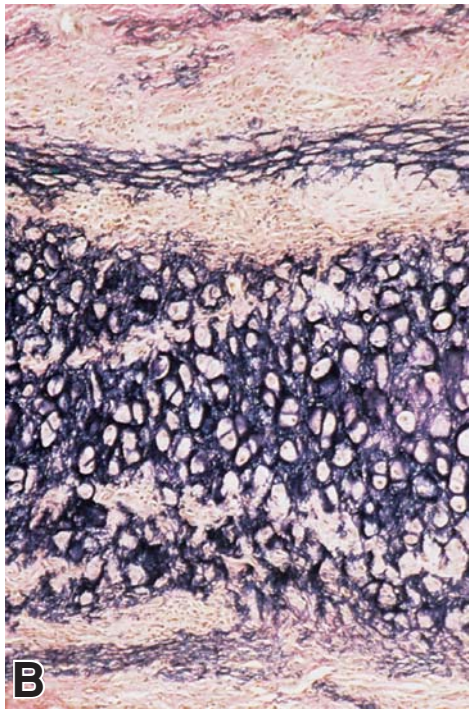


FIGURE 29-39. Relapsing polychondritis. A. The ear is beefy red. **B.** The perichondrium and elastic cartilage are infiltrated and partially destroyed by inflammatory cells and replaced by fibrosis.

"MALIGNANT" OTITIS EXTERNA: This infection of the external auditory canal is caused by *Pseudomonas aeruginosa.* Infection may spread through the skin and cartilage to cause mastoiditis or osteomyelitis of the skull, venous sinus thrombosis, meningitis and death. Malignant otitis externa occurs mainly in elderly diabetics but also in patients with blood dyscrasias (e.g., leukemia, granulocytopenia).

AURAL POLYPS: These benign inflammatory lesions arise in the external ear canal or extrude into the canal from the middle ear. Aural polyps are ulcerated, inflamed granulation tissue, which bleeds readily. Those arising in the middle ear result from chronic otitis media.

NEOPLASMS: Benign and malignant tumors of the external ear include the gamut of skin-related neoplasms: squamous papillomas, seborrheic keratosis, basal cell carcinoma, SCC and benign and malignant adnexal tumors.

Ceruminal gland tumors are unique to this area. Benign tumors include ceruminal gland adenomas and salivary gland–type tumors (e.g., pleomorphic and monomorphic adenomas). Malignant tumors include adenocarcinoma and malignant salivary gland–type tumors (e.g., adenoid cystic and mucoepidermoid carcinomas).

MIDDLE EAR

ANATOMY: The middle ear, or tympanic cavity, is an oblong space in the temporal bone lined by a mucous membrane. Together with the mastoid air sinuses, it forms a closed mucosal compartment, also called the **middle ear cleft**. Most of its lateral wall is the tympanic membrane. Anteriorly, the eustachian tube connects the middle ear to the nasopharynx. This air passage allows air pressure on both sides of the tympanic membrane to equalize. The three auditory ossicles—the malleus, incus and stapes—are a chain that connects the tympanic membrane with the oval window located at the medial wall of the tympanic cavity. They conduct sound across the middle ear. Free motion of the ossicles, mainly the stapes in the oval window, is more important for hearing than is an intact tympanic membrane. The middle ear opens posteriorly into the mastoid antrum, a honeycomb of small, aerated, bony compartments (air cells) lined by a thin mucous membrane continuous with that of the middle ear.

Otitis Media Often Follows Obstruction of the Eustachian Tube

Otitis media is inflammation of the middle ear. It usually results from upper respiratory tract infections that spread from the nasopharynx. Obstruction of the eustachian tube is important in production of middle ear effusions. When the pharyngeal end of the eustachian tube is swollen, air cannot enter the tube. Air in the middle ear is absorbed through the mucosa, and negative pressure causes transudation of plasma and occasional bleeding. Antibiotics usually cure or suppress the condition.

ETIOLOGY: Acute otitis media may be due to viral or bacterial infection or sterile obstruction of the eustachian tube. Viral otitis media may resolve without suppuration or lead to secondary invasion by pus-forming bacteria. Microorganisms ascend from the nasopharynx, through the eustachian tube, to the middle ear. Otitis media almost invariably penetrates through the mastoid antrum into the mastoid cells.

ACUTE SEROUS OTITIS MEDIA: Obstruction of the eustachian tube may result from sudden changes in atmospheric pressure (e.g., during flying in an aircraft or deep-sea diving). This effect is particularly severe if there is an upper respiratory tract infection, acute allergic reaction or viral or bacterial infection at the eustachian tube orifice. Inflammation may also occur without bacterial invasion of the middle ear. Over half of children in the United States have at least one bout of serous otitis media before their third birthday. Repeated otitis media in early childhood often leads to residual (usually sterile) fluid in the middle ear, which contributes to unsuspected hearing loss.

CHRONIC SEROUS OTITIS MEDIA: The same conditions that cause acute obstruction of the eustachian tube also cause recurrent or chronic middle ear serous effusions. Carcinoma of the nasopharynx may cause chronic serous otitis media in adults and should be suspected if a unilateral middle ear effusion occurs in an adult.

PATHOLOGY: In chronic serous otitis media, mucus-producing (goblet) cell metaplasia may be seen in the mucosal lining of the middle ear. Hemorrhage (e.g., in the mastoid cells) may accompany acute obstruction. Extravasation of blood and degradation of erythrocytes liberate cholesterol. Cholesterol crystals stimulate a foreign body response and granulation tissue, called a **cholesterol granuloma**. If large, these granulomas may destroy tissue in the mastoid or antrum. If they are allowed to persist for many months, the granulation tissue may become fibrotic, which may eventually lead to complete obliteration of the middle ear and mastoid by fibrous tissue.

ACUTE SUPPURATIVE OTITIS MEDIA: One of the most common infections of childhood, acute suppurative otitis media, is caused by pyogenic bacteria that invade the middle ear, usually via the eustachian tube. The most common culprit in all age groups (30%–40%) is *Streptococcus pneumoniae* (pneumococcus). *H. influenzae* causes about 20% of cases, but less often with increasing age. An accumulating purulent exudate in the middle ear may rupture the eardrum, causing a purulent discharge. In most cases, infection is self-limited and may heal even without therapy.

ACUTE MASTOIDITIS: Infection of the mastoid bone was once a common complication of acute otitis media, before the advent of antibiotics. It is still seen, rarely, if otitis media is not treated adequately. Mastoid air cells are filled with pus, and their thin osseous intercellular walls are destroyed. If the infection spreads to contiguous structures, serious complications may ensue (Fig. 29-40).

CHRONIC SUPPURATIVE OTITIS MEDIA AND MASTOIDITIS: Neglected or recurrent middle ear and mastoid infections may lead to chronic inflammation of the mucosa or destruction of the periosteum of the ossicles (Fig. 29-41). Chronic otitis media occurs much more commonly in people who have had ear disease in early childhood, which may have arrested normal development of the air cells in the mastoid.

PATHOLOGY: Inflammation tends to be insidious, persistent and destructive. In chronic otitis media, by definition, the eardrum is always perforated. Painless discharge **(otorrhea)** and variable hearing

FIGURE 29-40. Acute mastoiditis. An unusual complication of otitis media, acute mastoiditis, appears as large bulging lesions above the child's ear.

loss are constant symptoms. Exuberant granulation tissue may form polyps, which can extend through the perforated eardrum into the external ear canal.

A **cholesteatoma** is a mass of accumulated keratin and squamous mucosa due to growth of squamous epithelium from the external ear canal through a perforated eardrum into the middle ear. There, it continues to produce keratin. Cholesteatomas are identical to epidermal inclusion cysts. They are surrounded by granulation tissue and fibrosis. The keratin mass often becomes infected and protects bacteria from antibiotics. The main dangers of cholesteatoma arise from bony erosion, which may destroy important contiguous structures (e.g., auditory ossicles, facial nerve, labyrinth).

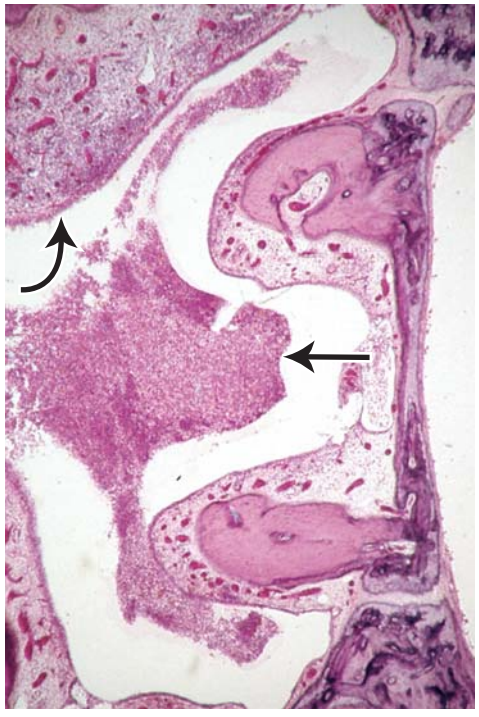

FIGURE 29-41. Chronic suppurative otitis media. A purulent exudate (*straight arrow*) is present in the middle ear cavity. The entire mucosa (*curved arrow*) is thickened by chronic inflammation and granulation tissue. The footplate and the crura of the stapes are at right.

COMPLICATIONS OF ACUTE AND CHRONIC OTITIS MEDIA: Antibiotic therapy has fortunately made complications of otitis media uncommon. However, suppurative middle ear infections may still cause these serious complications:

- Destruction of the facial nerve
- Deep cervical or subperiosteal abscess, if cortical bone of the mastoid process is eroded
- Petrositis, when infection spreads to the petrous temporal bone through the chain of air cells
- Suppurative labyrinthitis, due to infection of the internal ear
- Epidural, subdural or cerebral abscess, when infection extends through the inner table of the mastoid bone
- Meningitis, when infection reaches the meninges
- Sigmoid sinus thrombophlebitis, if infection traverses the dura to the posterior cranial fossa

Jugulotympanic Paragangliomas Arise from Middle Ear Paraganglia

Jugulotympanic paragangliomas are the most common benign tumors of the middle ear. They grow slowly but, over years, may destroy the middle ear and extend into the internal ear and cranial cavity. Metastases are rare.

Middle ear paragangliomas resemble those arising elsewhere, with characteristic lobules of cells in richly vascular connective tissue (Fig. 29-42). Paraganglial cells are of neural crest origin and contain varying amounts of catecholamines, mostly epinephrine and norepinephrine.

INTERNAL EAR

ANATOMY: The petrous portion of the temporal bone contains the labyrinth, which shelters the end organs for hearing **(cochlea)** and equilibrium **(vestibular labyrinth)**. The complex cavities of the osseous labyrinth contain the **membranous labyrinth,** a series of communicating membranous sacs and ducts. The osseous labyrinth connects to the subarachnoid space via the cochlear aqueduct. It is filled with perilymph, a clear fluid that mingles with cerebrospinal

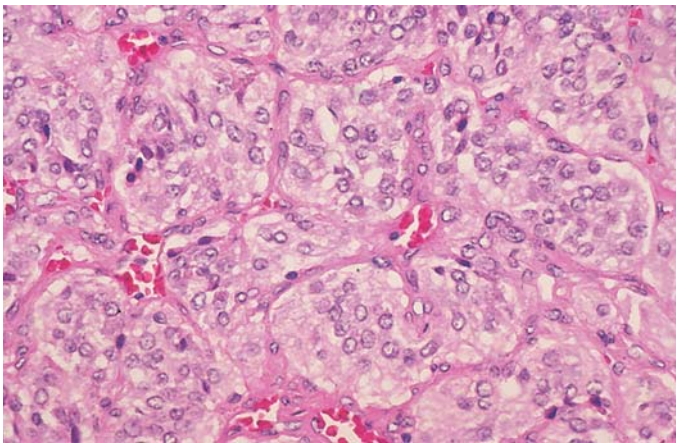

FIGURE 29-42. Jugulotympanic paraganglioma. Tumor cell nests are composed of cells with ill-defined cell borders and prominent eosinophilic cytoplasm (chief cells).

fluid. The membranous labyrinth contains a different fluid, the endolymph, which circulates in a closed system. Because there are no barriers between the cochlear and vestibular labyrinths, injury or disease of the inner ear frequently affects both hearing and equilibrium.

The **cochlea** is coiled upon itself like a snail shell and makes 2-1/2 turns. It has three compartments: two that contain perilymph and a third (the cochlear duct) with endolymph. The cochlear duct encompasses the end organ of hearing, **the organ of Corti,** which rests on the basement membrane and is arranged as a spiral, with three rows of outer hair cells and a row of inner hair cells. When hairs of these neuroepithelial cells are bent or distorted by vibration, the mechanical force is converted into electrochemical impulses and interpreted in the temporal cortex as sound. The vestibular part of the membranous labyrinth consists of the utricle, saccule and semicircular canals, each with specialized neuroepithelium that determines equilibrium.

Otosclerosis Is Formation of New Spongy Bone about the Stapes

Otosclerosis causes progressive deafness. ***It is an autosomal dominant hereditary defect and is the most common cause of conductive hearing loss in young and middle-aged adults in the United States.*** This disorder affects 10% of white and 1% of black adult Americans, although 90% of cases are asymptomatic. The female-to-male ratio is 2:1, and both ears are usually affected.

PATHOLOGY: Although any part of the petrous bone may be affected, otosclerotic bone tends to form at particular points. The most frequent (85%) site is immediately anterior to the oval window. The focus of sclerotic bone extends posteriorly and may infiltrate and replace the stapes, progressively immobilizing the footplate of the stapes. The developing bony ankylosis is functionally manifested as a slowly progressive conductive hearing loss.

Otosclerosis begins with resorption of bone and formation of highly cellular fibrous tissue, with wide vascular spaces and osteoclasts. The resorbed bone is later replaced by immature bone, which, with repeated remodeling, becomes mature (Fig. 29-43). Otosclerosis is treated by surgical mobilization of the auditory ossicles.

Ménière Disease Is a Triad of Vertigo, Sensorineural Hearing Loss and Tinnitus

Several etiologies have been suggested, but the cause of **Ménière disease** is uncertain. About 45,500 new cases are diagnosed in the United States annually. Viral etiologies, vascular causes and, possibly, autoimmune mechanisms have all been suggested. Tinnitus is usually unilateral and is most frequent between 40 and 60 years of age. A familial association suggests an underlying genetic predisposition.

PATHOLOGY: The earliest change is dilatation of the cochlear duct and saccule. As the disease **(hydrops)** progresses, the entire endolymphatic system dilates and the membranous wall may tear (Fig. 29-44). Ruptures can be followed by collapse of the membranous labyrinth, but atrophy of sensory and neural

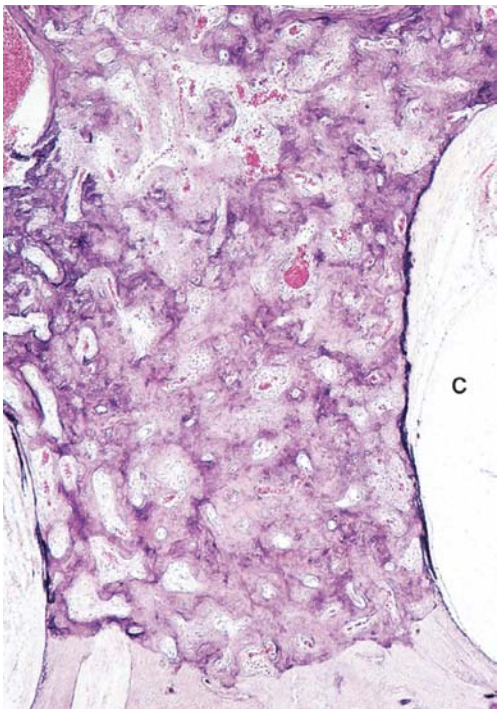

FIGURE 29-43. Otosclerosis. In the lateral wall of the cochlea, the basophilic and more vascular bone is well demarcated. *C* = organ of Corti.

structures is rare. Symptoms occur when endolymphatic hydrops causes rupture, and endolymph escapes into the perilymph.

CLINICAL FEATURES: Attacks of vertigo, often with incapacitating nausea and vomiting, last less than 24 hours. Weeks or months go by before another episode. In time, remissions become longer. Hearing loss recovers between attacks but later may become permanent. Ménière disease may improve with a low-salt diet and diuretics.

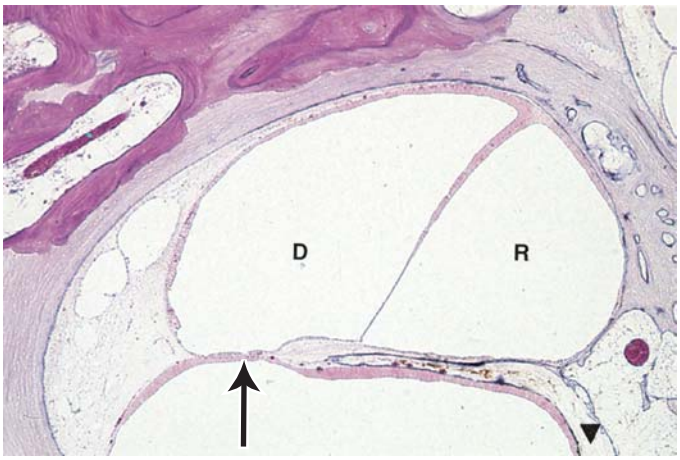

FIGURE 29-44. Ménière disease. The cochlear duct (D) is markedly distended, and the Reissner membrane (R) is pushed back by endolymphatic hydrops. Neither the organ of Corti (*arrow*) nor the spiral ganglion (*arrowhead*) is in its usual location.

Labyrinthine Toxicity Is a Cause of Drug-Induced Deafness

Aminoglycoside antibiotics are the most common ototoxic drugs, producing irreversible damage to vestibular or cochlear sensory cells. Other antibiotics, diuretics, antimalarials and salicylates may also lead to transient or permanent sensorineural hearing loss. Among antineoplastic drugs, cisplatin causes temporary or permanent hearing loss.

The labyrinth of the developing embryo is very sensitive to some drugs. Maternal use of antimalarials and other drugs may cause congenital deafness.

Viral Labyrinthitis Can Result in Congenital Deafness

Viral infections may cause inner ear disorders, particularly deafness. This is mostly due to viral invasion of the labyrinth. CMV and rubella are the best-known prenatal viral infections that cause congenital deafness via maternal-to-fetal transmission.

Mumps is the most common postnatal viral cause of deafness. It can cause rapid hearing loss, which is unilateral in 80% of cases. By contrast, prenatal infection of the labyrinth with rubella is usually bilateral, with permanent loss of cochlear and vestibular function. A number of other viruses are suspected to cause labyrinthitis, including influenza and parainfluenza viruses, EBV, herpesviruses and adenoviruses. Such cases show severe damage to the organ of Corti, with almost total loss of inner and outer hair cells.

Acoustic Trauma

Noise-induced hearing loss is a significant problem in industrialized countries. Occupational or recreational exposure to loud noises may impair hearing temporarily or permanently, as in people exposed to jet engines or loud music. The external hair cells of the organ of Corti are damaged earliest. Loss of sensory hairs is followed by deformation, swelling and disintegration of the hair cells.

Schwannoma Is the Most Common Tumor of the Inner Ear

SCHWANNOMA: Nearly all schwannomas in the internal auditory canal arise from the vestibular nerves. Vestibular schwannomas, which account for about 10% of all intracranial tumors, are slow growing and encapsulated. Larger tumors protrude from the internal auditory meatus into the cerebellopontine angle and may deform the brainstem and adjacent cerebellum. Schwannomas cause slowly progressive vestibular and auditory symptoms. In neurofibromatosis type 2 (NF-2; see Chapter 28), bilateral vestibular schwannomas identical to other vestibular schwannomas occur frequently.

MENINGIOMA: Meningiomas of the cerebellopontine angle originate from the meningothelial cells in the arachnoid villi. The favored sites for these tumors are the sphenoid ridge and petrous pyramid. Meningiomas may extend into the adjacent temporal bone or dural sinuses (see Chapter 28).

Bones

The functions of bone are mechanical, mineral storage and hematopoietic. Mechanical functions of bone include protection for the brain, spinal cord and chest organs; rigid internal support for limbs; and deployment as lever arms in the skeletal muscle. Bone is the principal reservoir for calcium and stores other ions such as phosphate, sodium and magnesium. The bones also serve as hosts for hematopoietic bone marrow.

The mechanical properties of bone are related to its construction and internal architecture. Although extremely light, it has high tensile strength. This combination of strength and light weight results from its hollow tubular shape, layering of bone tissue and internal buttressing of the matrix.

The term **bone** can refer to both an organ and a tissue. The "organ" is composed of bone tissue, cartilage, fat, marrow elements, vessels, nerves and fibrous tissue. Bone "tissue" is described in microscopic terms and is defined by the relation of its collagen and mineral structure to the bone cells.

ANATOMY

Macroscopically, two types of bone are recognized:

- **Cortical bone** is dense, compact bone, whose outer shell defines the shape of the bone. It composes 80% of the skeleton. Because of its density, its functions are mainly biomechanical.
- **Coarse cancellous bone** (also called **spongy, trabecular** or **medullary bone**) is found at the ends of long bones within the medullary canal. Cancellous bone has a high surface-to-volume ratio and contains many more bone cells per unit volume than cortical bone. **Changes in the rate of bone turnover are manifested principally in cancellous bone.**

All bones contain both cancellous and cortical elements (Fig. 30-1), but their proportions differ. The body or shaft of a long tubular bone, such as the femur, is composed of cortical bone and its marrow is mainly fat. Toward the ends of the femur, the cortex becomes thin and coarse cancellous bone becomes the predominant structure. By contrast, the skull is formed by outer and inner tables of compact bone, with only a small amount of cancellous bone within the marrow space, called the **diploë**.

The anatomy of bone is defined in relation to a transverse cartilage plate, which is present in the growing child. This structure is the **growth plate,** the **epiphyseal cartilage plate** or **the physis** (Fig. 30-2A–C). The terms **epiphysis, metaphysis** and **diaphysis** are defined in relation to the growth plate.

- **The epiphysis** is the area of the bone that extends from the subarticular bone plate to the base of the growth plate.
- **The metaphysis** contains coarse cancellous bone and is the region from the side of the growth plate facing away from the joint to the area where the bone develops its fluted or funnel shape.
- **The diaphysis** corresponds to the body or shaft of the bone and is the zone between the two metaphyses in a long tubular bone.

The metaphysis blends into the diaphysis and is the area where coarse cancellous bone dissipates. This area of bone is particularly important in hematogenous infections, tumors and skeletal malformations.

Two additional terms are essential to an understanding of bone organization:

- **Endochondral ossification** is the process by which bone tissue replaces cartilage.
- **Intramembranous ossification** refers to the mechanism by which bone tissue supplants membranous or fibrous tissue laid down by the periosteum.

All bones are formed by at least some intramembranous ossification. Some bones (e.g., the calvaria of the skull) are forged purely by intramembranous ossification. Because bone tumors tend to recapitulate their embryologic origins, it is not surprising that cartilaginous tumors of the frontal bone have not been seen, because the calvaria of the skull do not originate from cartilage.

The Bone Marrow Resides in the Marrow Space, or Medullary Canal

The marrow space is enclosed by cortical bone. It is supported by a delicate connective tissue framework that enmeshes marrow cells and blood vessels. Three types of marrow are evident to the naked eye:

- **Red marrow** corresponds to hematopoietic tissue and is found in virtually all bones at birth. At adolescence, it is confined to the axial skeleton, which includes the skull, vertebrae, sternum, ribs, scapulae, clavicles, pelvis and proximal humerus and femur. Its presence may also be pathologic, depending on the patient's age and the site of the marrow. For example, red marrow in the femoral diaphysis of a 55-year-old man is abnormal and may reflect underlying disease, such as leukemia.
- **Yellow marrow** is fat tissue and is found in the limb bones. In a normally hematopoietic area, such as a vertebral body, yellow marrow is abnormal at any age.
- **Gray or white marrow** is deficient in hematopoietic elements and is often fibrotic. ***It is always a pathologic tissue in a nongrowing adult bone or in areas distant from the growth plate in a child.***

Blood Supply Enters Bone through Specialized Canals

The long tubular bones are provided with blood from two sources and contain canals to supply the tissues.

- **Nutrient arteries** enter bone through a nutrient foramen and supply the marrow space and the internal one third to one half of the cortex.
- **Perforating arteries** are small straight vessels that extend inward from periosteal arteries on the external surface of the periosteum (the fibrous capsule of the bone). Perforating arteries anastomose in the cortex with branches from nutrient arteries coming from the marrow space.
- **Haversian canals** are spaces in cortical bone that course parallel to the long axis of the bone for a short distance and then branch and communicate with other similar canals. Each canal contains one or two blood vessels, lymphatics and some nerve fibers (Fig. 30-2D).
- **Volkmann canals** (Fig. 30-2E) are spaces within the cortex that run perpendicular to the long axis of the cortex to connect adjacent Haversian canals. Volkmann canals also contain blood vessels.

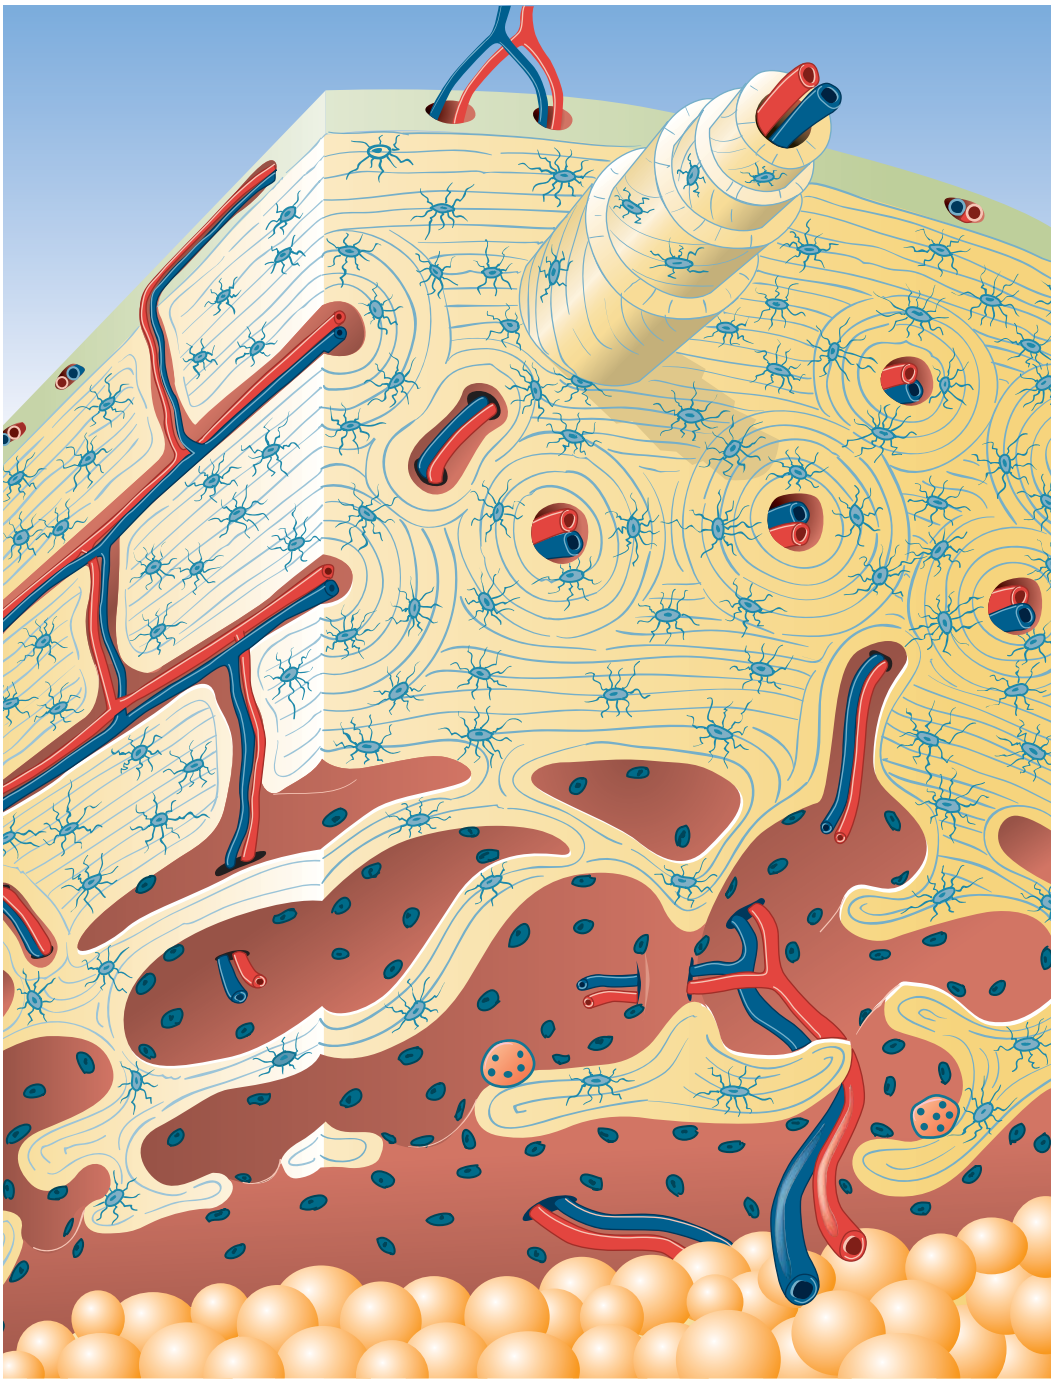

FIGURE 30-1. Anatomy of bone. A schematic representation of cortical and trabecular bone. The longitudinal section (*left*) shows the vasculature entering the periosteum via the periosteal perforating arteries and coursing through the bone perpendicular to the long axis in Volkmann canals. The vessels that proceed longitudinally, or parallel to the long axis, are located in Haversian canals. Each artery is accompanied by a vein. Within the cortex, osteocytes reside in lacunae, and their cell processes extend into the canaliculi. The cross-sectional view (*right*) illustrates the various types of lamellar bone in the cortex. Circumferential lamellar bone is located adjacent to the periosteum and borders the marrow space. Concentric lamellar bone surrounds the central Haversian canals to form an **osteon**. Each layer of the concentric lamellar bone displays a change in the pitch of the collagen fibers, such that each layer has a different arrangement of collagen. The interstitial lamellar bone occupies the space between osteons. The marrow space is filled with fat, and its trabecular bone is contiguous with the cortex. Multinucleated osteoclasts are present, and palisaded osteoblasts surround the bone surfaces. The perforating arteries from the periosteum and the nutrient artery from the marrow space communicate within the cortex via Haversian and Volkmann canals.

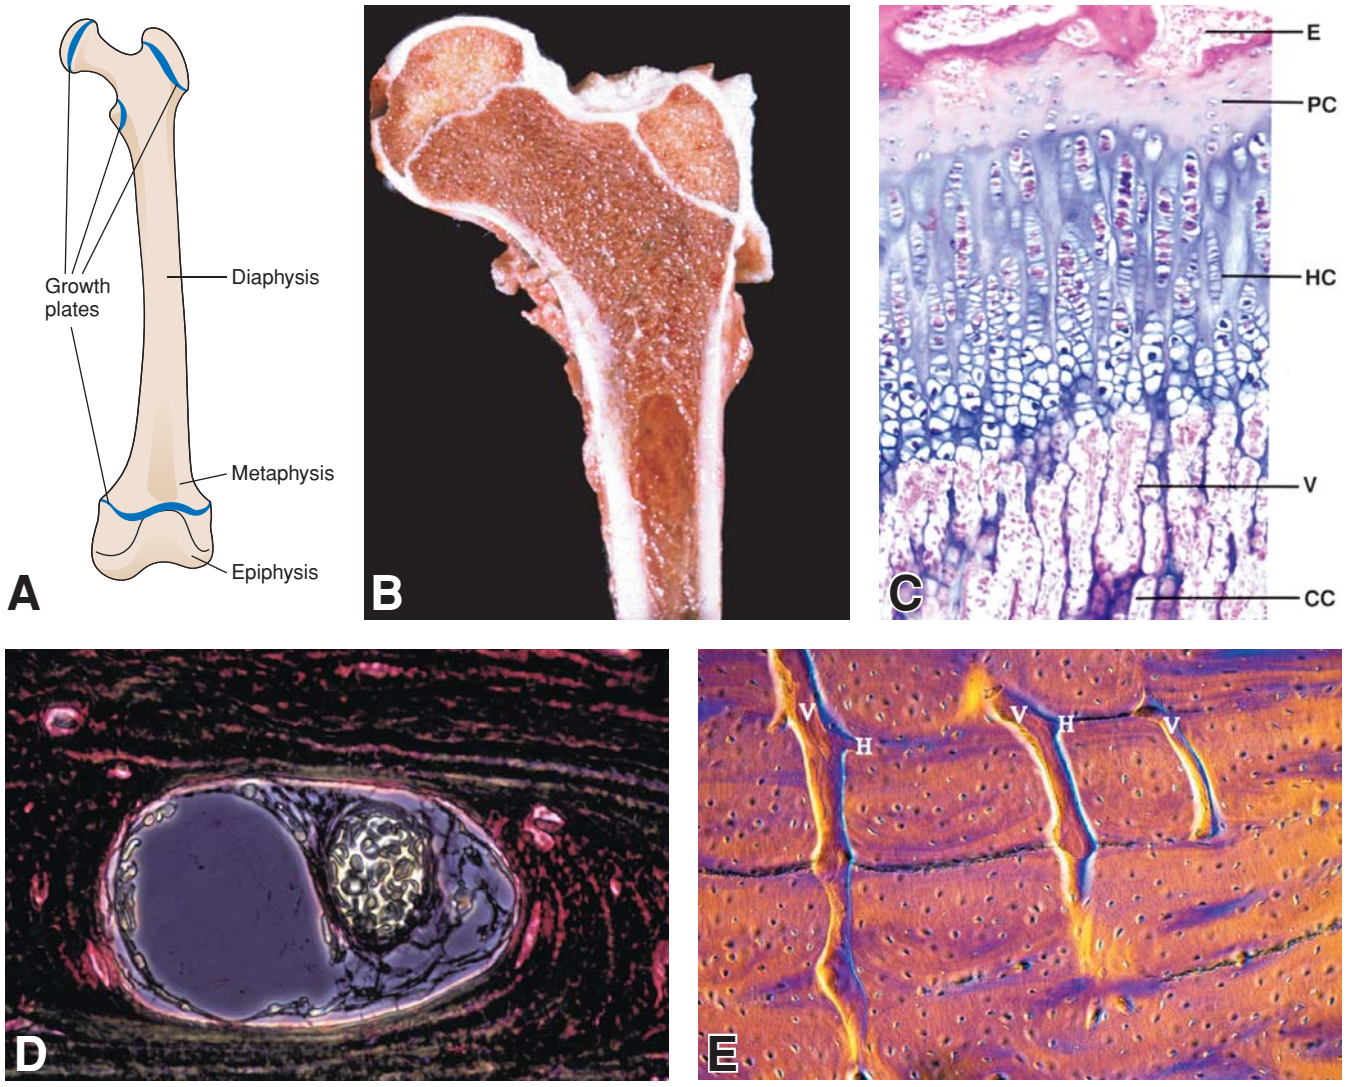

FIGURE 30-2. Anatomy of a long bone. A. Diagram of the femur illustrates the various compartments. **B. Coronal section of the proximal femur** illustrates the various anatomic parts of a long bone. The epiphysis of the femoral head and the apophysis of the greater trochanter are separated from the metaphysis by their respective growth plates. The cortex and the medullary cavity are well visualized. The medullary cavity contains cancellous bone until the metaphysis narrows into the diaphysis (shaft) of the bone, which is almost completely devoid of bone and filled with marrow. **C. A section of the epiphysis** with a zone of proliferating cartilage cells. Beneath this zone, the hypertrophic cartilage cells are arrayed in columns. At the *bottom,* the calcifying matrix is invaded by blood vessels. *CC* = calcified cartilage; *E* = epiphysis; *HC* = hypertrophic cartilage; *PC* = proliferative cartilage; *V* = vascular invasion. **D. Haversian canal** containing a venule (thin-walled wider vessel on *left*) and an arteriole (thicker-walled narrow vessel on the *right*). **E. Volkmann canals.** In this photograph, three Volkmann canals are seen running parallel to each other (*V*) and perpendicular to the cortex. The openings of two Haversian canals (*H*) are visible.

Each artery has its paired vein and, perhaps, free nerve endings. Venous drainage proceeds from the cortex outward to the periosteal veins, or inward into the marrow space and out the nutrient veins.

Periosteum Covers All Bones and Can Form Bone

The periosteum is the fibrous tissue that envelopes the outer surface of the bone and demarcates it from the surrounding soft tissue. It is connected to the bone by collagenous fibers called **Sharpey fibers**. The internal layer of the periosteum, the **cambium layer,** is applied to the surface of the bone and consists of loosely arranged collagenous bundles, with spindle-shaped connective tissue cells and a network of thin elastic fibers. The outer **fibrous layer** is contiguous with soft tissue planes and fascia. It is composed of dense connective tissue containing blood vessels. The inner cambium layer is responsible for the process of intramembranous ossification and formation of the cortex. If the periosteum is irritated (e.g., infection, trauma or tumor), it can produce a significant amount of reactive bone that can be seen radiographically and in certain circumstances may reflect the biological potential of the underlying lesion.

Bone Matrix Is Organic and Heavily Mineralized

Bone tissue is composed of cells (10% by weight), a mineralized phase (hydroxyapatite crystals, representing 60% of the total tissue) and an organic matrix (30%). ***Thus, except for its cells, bone is a biphasic structure composed of an organic and an inorganic matrix.***

The **mineralized matrix** consists of poorly crystalline hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$. Because of its net negative

charge, it can neutralize substantial amounts of acid. Other important ions in bone are carbonate, citrate, fluoride, chloride, sodium, magnesium, potassium and strontium.

The **organic matrix** consists of 88% type I collagen, 10% other proteins and 1%–2% lipids and glycosaminoglycans. ***Thus, type I collagen basically defines the organic matrix.*** Other proteins include:

- **Osteocalcin** is produced by osteoblasts. Blood levels of this protein are a useful marker of bone formation.
- **Osteopontin** and **sialoprotein** are bone matrix proteins containing the amino acid sequence *Arg-Gly-Asp*, which is recognized by **integrins**. Thus, osteopontin and bone sialoprotein probably help anchor cells to the bone matrix.

The Cells of the Bone Are Responsible for Maintaining Its Structure

There are four types of cells in bone tissue, each of which has specific functions related to the formation, resorption and remodeling of bone:

OSTEOPROGENITOR CELL: The osteoprogenitor cell, which differentiates ultimately into osteoblasts and osteocytes, is itself derived from a primitive stem cell. The stem cell can develop into adipocytes, myoblasts, fibroblasts or osteoblasts. Osteoprogenitor cells are found in marrow, periosteum and all supporting structures within the marrow cavity. They are not readily recognized by light microscopy as they are small, nonspecific, stellate or spindle-shaped cells. In response to an appropriate signal, the osteoprogenitor cell gives rise to an osteoblast. Osteoblast commitment and differentiation are controlled by complex activities involving signal transduction and transcriptional regulation of gene expression (e.g., Wnt signaling pathway, Runx2 and bone morphogenic proteins).

OSTEOBLAST: Osteoblasts are the protein-synthesizing cells that produce and mineralize bone tissue. They are derived from mesenchymal progenitors that also give rise to chondrocytes, myocytes, adipocytes and fibroblasts. These large mononuclear and polygonal cells are arrayed in a line along the bone surface (Fig. 30-3A). Underlying the layer of osteoblasts is a thin, eosinophilic zone of organic bone matrix that has not yet been mineralized, called **osteoid**. The time from the deposition of osteoid to its mineralization is known as the **mineralization lag time** (approximately 12 days). The protein synthetic capacity of osteoblasts is reflected in its abundant endoplasmic reticulum, prominent Golgi apparatus and mitochondria with calcium-containing granules.

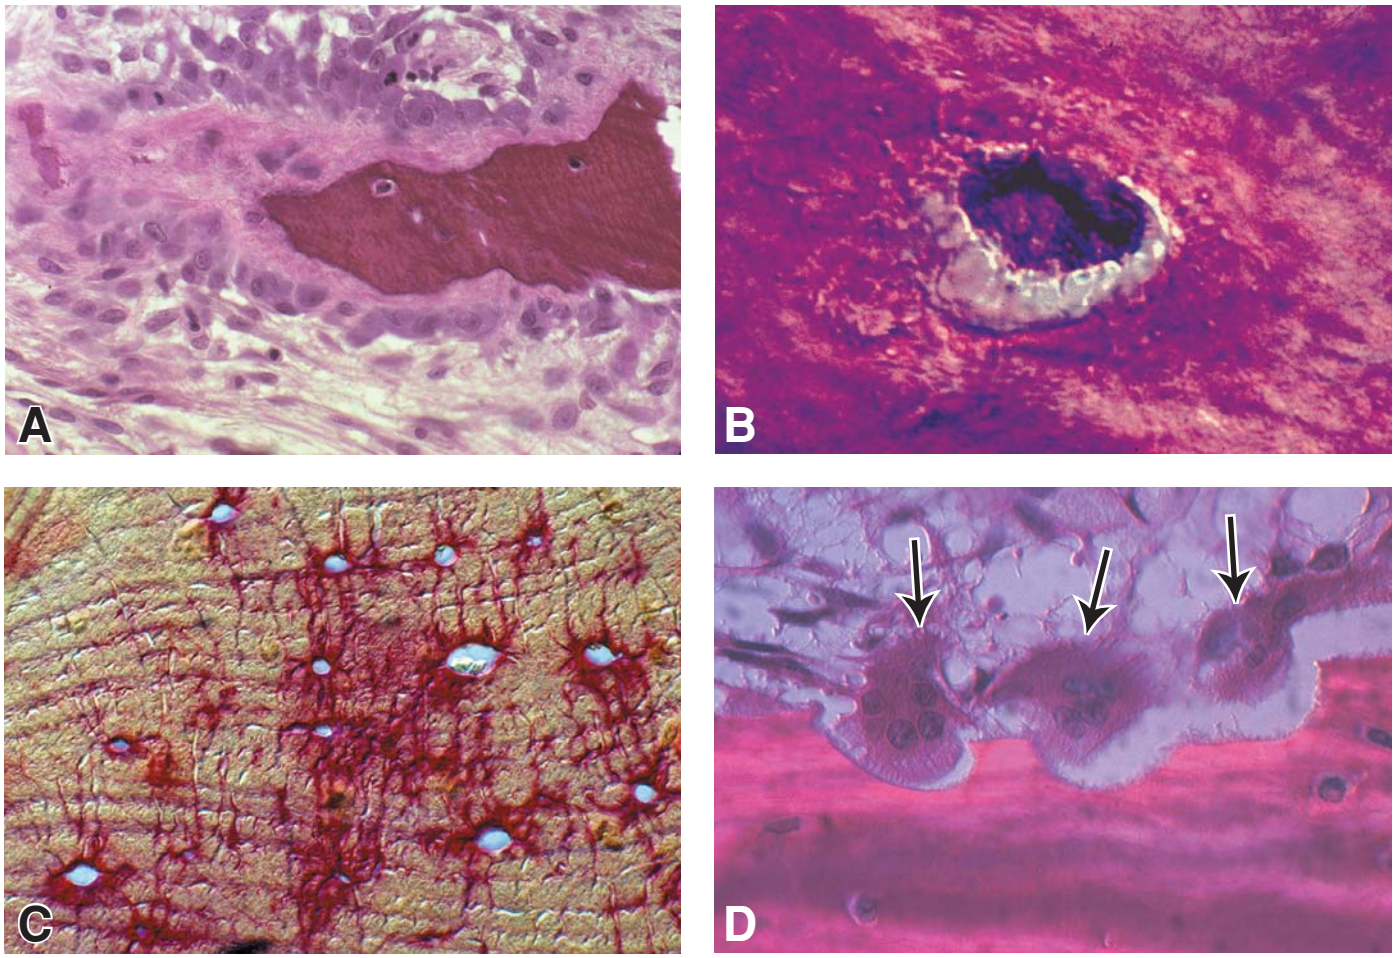

FIGURE 30-3. The cells of bones. A. A **developing bone spicule** demonstrates a prominent layer of plump osteoblasts lining the pink osteoid seam. The dark purple layer beneath the osteoid seam is mineralized bone. **B. Osteocytes.** Osteocytes represent trapped osteoblasts surrounded by bone matrix. The space surrounding the cell is called a **lacuna**. At this power, a few cytoplasmic extensions of the cell can be seen extending into narrow channels in the bone, called **canaliculi. C.** The extensive **intercommunication of osteocyte processes** via their canalicular network in cortical bone is visible in this section. **D. Osteoclasts.** These are multinucleated giant cells (*arrows*) found on bone surfaces within small scalloped reabsorption pits, called **Howship lacunae**.

Cytoplasmic processes that extend into the osteoid contact cells embedded in the matrix called **osteocytes**. The syncytium of osteocytes and osteoblasts probably prevents bone calcium (99% of the body's calcium) from equilibrating with the general extracellular space. When an osteoblast is inactive, it flattens on the surface of bone tissue. It contains alkaline phosphatase, manufactures osteocalcin and expresses parathyroid hormone (PTH) receptors. Collagenase secreted by osteoblasts may also facilitate osteoclastic activity. Finally, a number of growth factors, including transforming growth factor-β (TGF-β), insulin-like growth factor-I (IGF-I), IGF-2, platelet-derived growth factor (PDGF), interleukin-1 (IL-1), fibroblast growth factor (FGF) and tumor necrosis factor-α (TNF-α), are produced by osteoblasts and are important in regulating bone growth and differentiation. Furthermore, the osteoblast possesses surface receptors for various hormones (e.g., PTH, vitamin D, estrogen, glucocorticoids, etc.), as well as for cytokines and growth factors. ***The osteoblast ultimately controls the activation, maturation and differentiation of the osteoclast through a paracrine cell signaling mechanism (see Osteoclast below).***

OSTEOCYTE: The osteocyte is an osteoblast that is completely embedded in bone matrix and is isolated in a lacuna (Fig. 30-3B). Osteocytes deposit small quantities of bone around lacunae, but with time, they lose the capacity for protein synthesis. They have small hyperchromatic nuclei and numerous processes that extend through bony canals called **canaliculi,** which communicate with those from other osteocytes and osteoblasts (Fig. 30-3C). ***The osteocytes may be the bone cells that recognize and respond to mechanical forces and are important regulators of bone remodeling.***

OSTEOCLAST: Osteoclasts are the exclusive bone-resorptive cells. They are of hematopoietic origin, being members of the monocyte/macrophage family. Three major factors are required for osteoclastogenesis: (1) TNF-related receptor RANK (receptor activator for nuclear factor-κB [NFκB]), (2) RANK ligand (RANKL) and (3) macrophage colony-stimulating factor (M-CSF). RANK is expressed by osteoclast precursors. RANKL and M-CSF are produced by osteoblasts and stromal cells. Binding of RANKL to RANK activates NFκB signaling, which leads to increased osteoclastogenesis. M-CSF is required for the survival of cells of macrophage/osteoclast lineage. **Osteoprotegerin,** another protein produced by osteoblasts and also a member of the TNF family, blocks the interaction between RANK and RANKL and consequently inhibits osteoclastogenesis.

Osteoclasts are multinucleated cells that contain many lysosomes and are rich in hydrolytic enzymes. They are found in small depressions on bone surfaces called **Howship lacunae** (Fig. 30-3D). By electron microscopy, they form a polarized ruffled plasmalemmal membrane (Fig. 30-4) when the cell is in contact with and is actively degrading bone. Osteoclastic resorption is a multistep process that involves attachment of the cell to bone by integrins. A tight gasket-like seal isolates an extracellular compartment that forms between bone and the osteoclast ruffled membrane. A proton pump then acidifies this compartment to a pH of 4.5, in effect creating a giant extracellular lysosome. This proton-rich environment mobilizes bone mineral, thus exposing the organic bone matrix to degradation by lysosomal enzymes. Degraded fragments of bone are transported to the opposite side of the osteoclasts and then released to the extracellular space.

Although the machinery of an osteoclast is superbly suited for bone resorption, it functions only if the matrix is mineralized. ***In fact, any bone that is lined by osteoid or unmineralized cartilage is protected from osteoclastic activity.*** In rickets (see below), the growth plate does not calcify normally; it thus grows without osteoclastic resorption and becomes very thick.

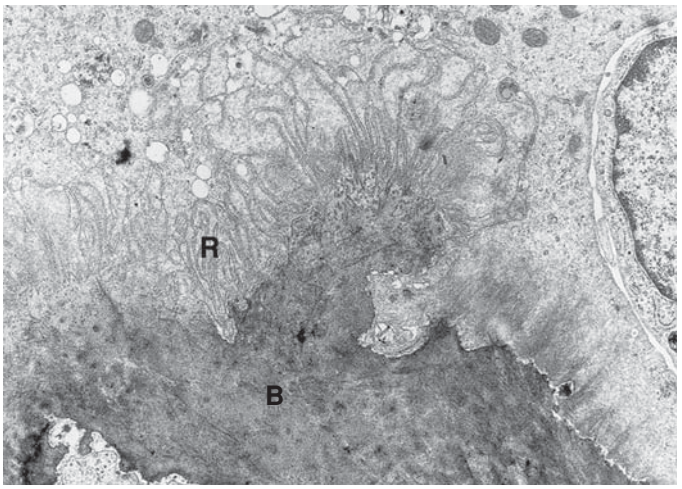

FIGURE 30-4. Osteoclast. An electron micrograph shows the ruffled membrane (*R*), which consists of a complex infolding of the plasma membrane juxtaposed to bone (*B*).

Constant bone remodeling is a normal part of skeletal maintenance (Fig. 30-5). It is initiated by activation of the cytokine receptor RANK on osteoclasts. Soluble factors released during bone resorption and PTH aid in recruitment of osteoblasts to the site and their activation to form new bone. Osteoclasts possess receptors for **calcitonin,** which inhibits osteoclast activity. ***Thus, bone remodeling involves***

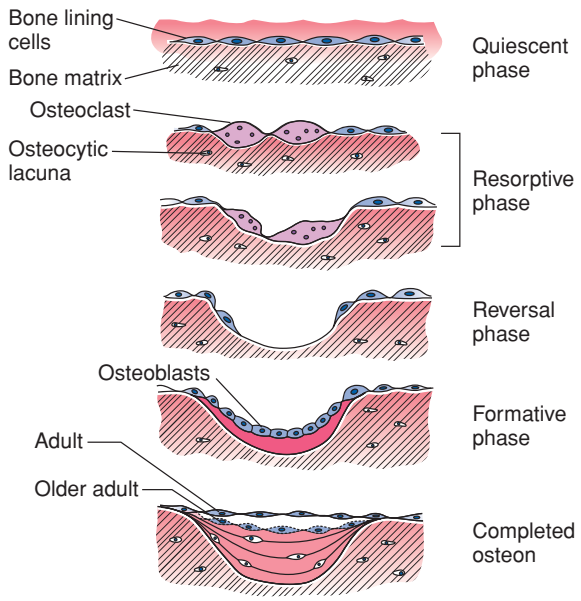

FIGURE 30-5. Bone-remodeling sequence. Bone remodeling is initiated by the appearance of osteoclasts on a bone surface previously lined by fusiform cells. After development of a resorption bay, osteoclasts are replaced by osteoblasts, which deposit new bone. The bone loss that attends aging (senile osteoporosis) is due to incomplete filling of resorption bays.

replacing old bone with newly formed bone via the functional coupling of osteoclasts and osteoblasts, called the bone-remodeling unit. Bone remodeling enables bone to adapt to mechanical stress, maintain its strength and regulate calcium homeostasis.

There Are Two Types of Bone Tissue: Lamellar Bone and Woven Bone

Both may be mineralized or unmineralized. Unmineralized bone is called **osteoid**.

Lamellar Bone

Lamellar bone is made slowly and is highly organized. As the stronger bone tissue, it forms the adult skeleton. ***Anything other than lamellar bone in the adult skeleton is abnormal.*** Lamellar bone is defined by (1) a parallel arrangement of type I collagen fibers, (2) few osteocytes in the matrix and (3) uniform osteocytes in lacunae parallel to the long axis of the collagen fibers. There are four types of lamellar bone (Fig. 30-6):

- **Circumferential bone** forms the outer periosteal and inner endosteal lamellar envelopes of the cortex.
- **Concentric lamellar bone** is arranged around the Haversian canals. In two dimensions, concentric lamellar bone and its Haversian artery and vein constitute the **osteon** (Fig. 30-1). In three dimensions, osteons make up the **Haversian system**. These cylinders of bone around Haversian canals run parallel to the long axis of the cortex and are the strongest bone made. The osteons form only if there is appropriate stress. Thus, a paralyzed limb has a cortex composed exclusively of poorly formed Haversian systems and circumferential lamellar bone.
- **Interstitial lamellar bone** represents remnants of either circumferential or concentric lamellar bone that have been remodeled and are wedged between the osteons.
- **Trabecular lamellar bone** forms the coarse cancellous bone of the medullary cavity. It exhibits plates of lamellar bone perforated by marrow spaces.

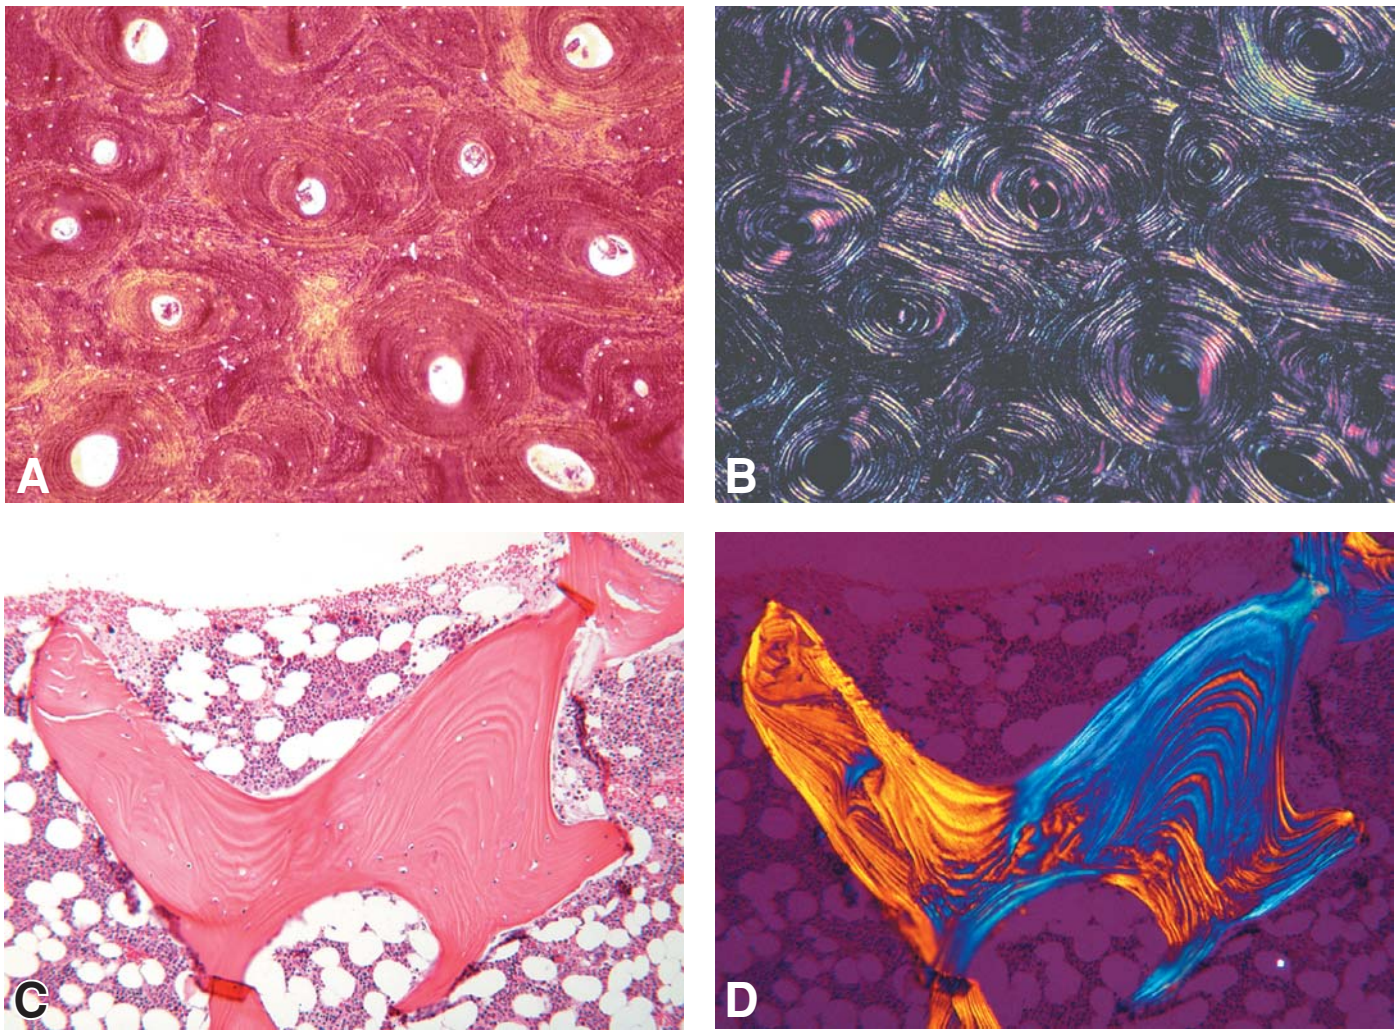

FIGURE 30-6. Cortical lamellar bone. A. Lamellae of the compacta (cortex) are arranged concentrically about Haversian canals. **B.** The same field in polarized light shows the alternating light and dark layered arrangement of the collagen fibers. **C. Lamellae of the spongiosa** in a single mature trabecula are shown in a bright field view. **D.** Polarized light demonstrates that the lamellae are arranged in light and dark layers, but these layers are in long plates rather than in a concentric arrangement.

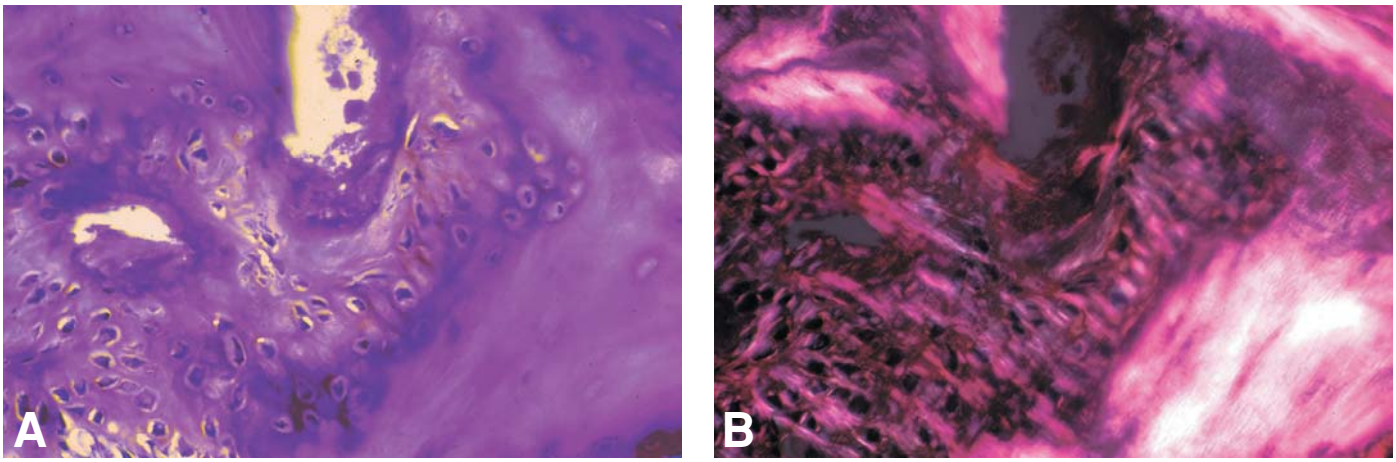

FIGURE 30-7. Woven bone. A. In this section, the woven bone constitutes early fracture repair. Note that in the area of new bone, there are many osteocytes that vary in size but are mainly large with prominent lacunae (compare with area of lamellar bone at *lower right*). **B.** This is the same section viewed in polarized light. Note that the collagen fibers are disposed in a pattern resembling the loose fiber pattern of coarsely woven burlap.

Woven Bone

Woven bone is identified by (1) an irregular arrangement of type I collagen fibers, hence the term ***woven;*** (2) numerous osteocytes in the matrix; and (3) variation in osteocyte size and shape (Fig. 30-7A,B).

Woven bone is deposited more rapidly than lamellar bone. It is haphazardly arranged and of low tensile strength, serving as a temporary scaffolding for support. It is not surprising that woven bone is found in the developing fetus, in areas surrounding tumors and infections and as part of a healing fracture. ***Its presence in the adult skeleton is always abnormal and indicates that reactive tissue has been produced in response to some stress in the bone.***

Cartilage, Unlike Bone, Contains No Blood Vessels, Nerves or Lymphatics

Cartilage may be focally calcified to provide some internal strength in the appropriate areas.

Cartilage Matrix

Like bone, cartilage may be viewed as an organic and inorganic biphasic material. The inorganic phase is composed of calcium hydroxyapatite crystals, equivalent to those found in bone matrix. However, the organic matrix is quite different from that of bone. Essentially, cartilage is a hyperhydrated structure, with water forming some 80% of its weight. The remaining 20% is composed principally of two types of macromolecules, type II collagen and proteoglycans. The water content is extremely important in the function of articular cartilage as it enhances the resilience and lubrication of the joint. Proteoglycans are complex macromolecules composed of a central linear protein core, to which long side arms of polysaccharides, called **glycosaminoglycans,** are attached. These molecules are polyanionic because of the regular presence of carboxyl groups and sulfates along the molecules. Cartilage glycosaminoglycans comprise three long-chain, unbranched, repeating, polydimeric saccharides: chondroitin-4-sulfate, chondroitin-6-sulfate and keratan sulfate. The chondroitin sulfates are the most abundant, accounting for 55%–90% of the cartilage matrix, depending on the age of the tissue.

Types of Cartilage

There are three types of cartilage:

- **Hyaline cartilage:** This is the prototypic cartilage, constituting the articular cartilage of joints; cartilaginous anlage of developing bones; growth plates; costochondral cartilages; cartilages of the trachea, bronchi and larynx; and nasal cartilages. Hyaline cartilage is the most common cartilage in tumors, in fracture callus and in areas of relative avascularity.
- **Fibrocartilage:** This tissue is essentially hyaline cartilage that contains numerous type I collagen fibers for tensile and structural strength. It is found in the annulus fibrosus of the intervertebral disk, tendinous and ligamentous insertions, menisci, symphysis pubis and insertions of joint capsules. Fibrocartilage may also occur in a fracture callus.
- **Elastic cartilage** is found in the epiglottis, in the arytenoid cartilages of the larynx and in the external ear.

Chondrocytes

Chondrocytes are derived from primitive mesenchymal cells that are similar to the precursors of bone cells. The chondroblast gives rise to the chondrocyte. Activation of SOX9 transcription factor is essential for chondrocyte formation, and SOX9 is expressed in cartilaginous neoplasms. As in bone, the cell that resorbs calcified cartilage is the osteoclast.

BONE FORMATION AND GROWTH

Bone tissue grows only by appositional growth, defined as deposition of new matrix on a preexisting surface by adjacent surface osteoblasts. By contrast, virtually all other tissues, especially cartilage, increase by interstitial cell proliferation within the matrix as well as by appositional growth.

Bone development in the fetus follows a stereotyped sequence. Most of the skeleton (except the calvaria and

clavicles) develops from cartilage anlagen present during fetal development. This cartilage is eventually resorbed and replaced by bone by **endochondral ossification**. Development of bone can be illustrated by using a limb as an example.

The Process of Primary Ossification Follows a Defined Temporal Sequence

1. **Cartilage anlage:** By 5 weeks of gestation, a thin layer of mesenchymal cells forms between the ectoderm and endoderm of the limb bud and condenses into a core of hyaline cartilage. This cartilaginous anlage is the precursor of the future long bone of that limb. The fibrous capsule of the cartilage anlage is called a **perichondrium**. The width of the cartilaginous anlage is increased by appositional growth of chondroblasts, which deposit cartilage matrix on the internal surface of the perichondrium. At the same time, the anlage increases in length by both appositional and interstitial growth of the chondrocytes. At this stage, the long "bone" is actually composed of cartilage.
2. **The primary center of ossification:** The vascular bed increases, and the perichondrium deposits woven bone on the surface of the cartilage core at the midportion of the future bone. This circumferential sleeve of woven bone is the primary center of ossification, because it is the first bone tissue to be formed. The perichondrium then becomes **periosteum** (Fig. 30-8A).
3. **Cylinderization:** Within the cartilaginous anlage, chondrocytes form proliferating columns, which eventually undergo focal calcification. Calcification is the signal for osteoclastic resorption and invasion of vessels into the cartilaginous mass. Thus, the earliest endochondral ossification occurs after the cartilage is hollowed out from the center of the anlage. This "cavitation" of the cartilaginous core forms the future marrow space. The progressive hollowing of the diaphysis is **cylinderization**.
4. **Primary spongiosum:** The swollen, hypertrophied chondrocytes within the central cartilage begin to die. Capillary invasion increases. The surfaces of the calcified cartilage cores become enveloped by woven bone laid down by osteoblasts, which arrive through the pluripotential mesenchymal tissue that enters with the capillaries. This cartilaginous core, surrounded by woven bone, is called **primary spongiosum,** or **primary trabecula.** It is the first bone formed after the replacement of cartilage.

Cavitation continues along the future diaphysis toward each end of the bone. Meanwhile, the bone enlarges in width by appositional bone growth from the ever-increasing periosteal sleeve, which makes additional woven bone for the future cortex.

In Secondary Ossification, Cartilage Is Stimulated and Transformed into Bone

Programmed events similar to those in the primary spongiosum take place in the cartilaginous ends of the future bone. Resting (reserve) cartilage is stimulated to become columns of proliferating cartilage, which then progress to hypertrophied chondrocytes and, eventually, calcified cartilage.

1. **The secondary center of ossification** (Fig. 30-8B): Also called the **epiphyseal center of ossification,** this structure is formed at the ends of the bone when cartilage is resorbed. The centrifugal enlargement of the secondary ossification is called **hemispherization** and occurs simultaneously with the longitudinal development of the marrow cavity of the diaphysis.
2. **Formation of the growth plate:** As the bony ends expand during hemispherization and cylinderization occurs in the future diaphysis, a zone of cartilage is trapped between the end of the bone and the diaphysis. This cartilage is destined to be the **growth plate** (Fig. 30-9A), which is a layer of modified cartilage between the diaphysis and epiphysis. Its structure is essentially unchanged from early fetal life to skeletal maturity. ***The growth plate controls the longitudinal growth of bones and ultimately determines adult height.***
3. **Structure of the growth plate:** The chondrocytes of the growth plate are arranged in vertical rows, which, in three

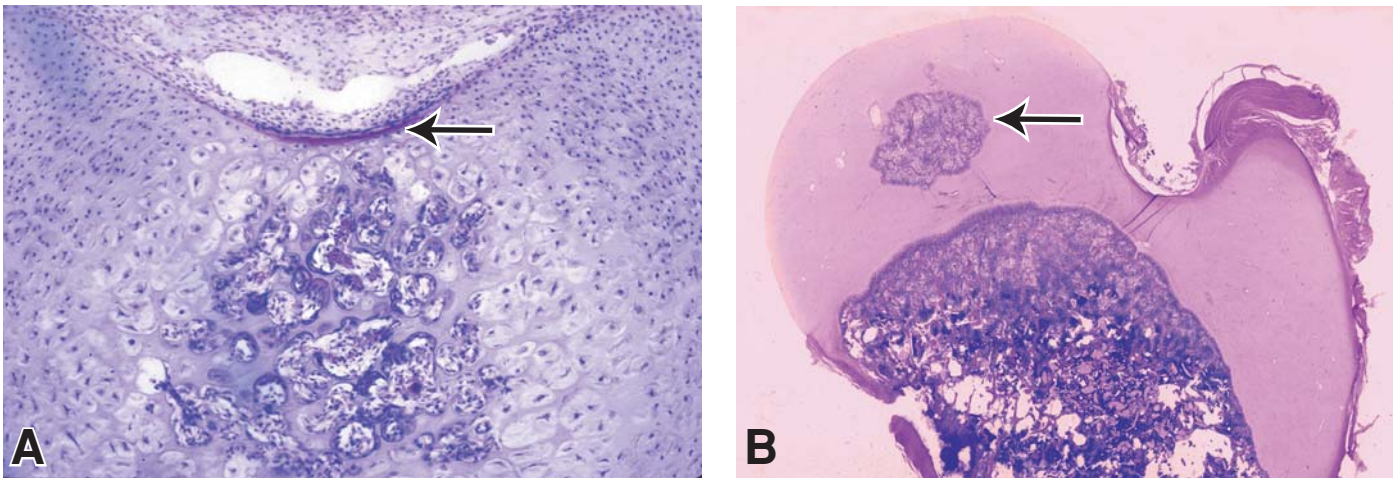

FIGURE 30-8. Primary ossification. A. This section of a short tubular bone demonstrates the first true bone tissue deposited on the outside of the midshaft of the cartilage model along with very early hollowing of the center of the cartilage model to form mixed spicules of cartilage and bone (primary spongiosa). **B.** The **secondary ossification center** is demonstrated in this femoral head.

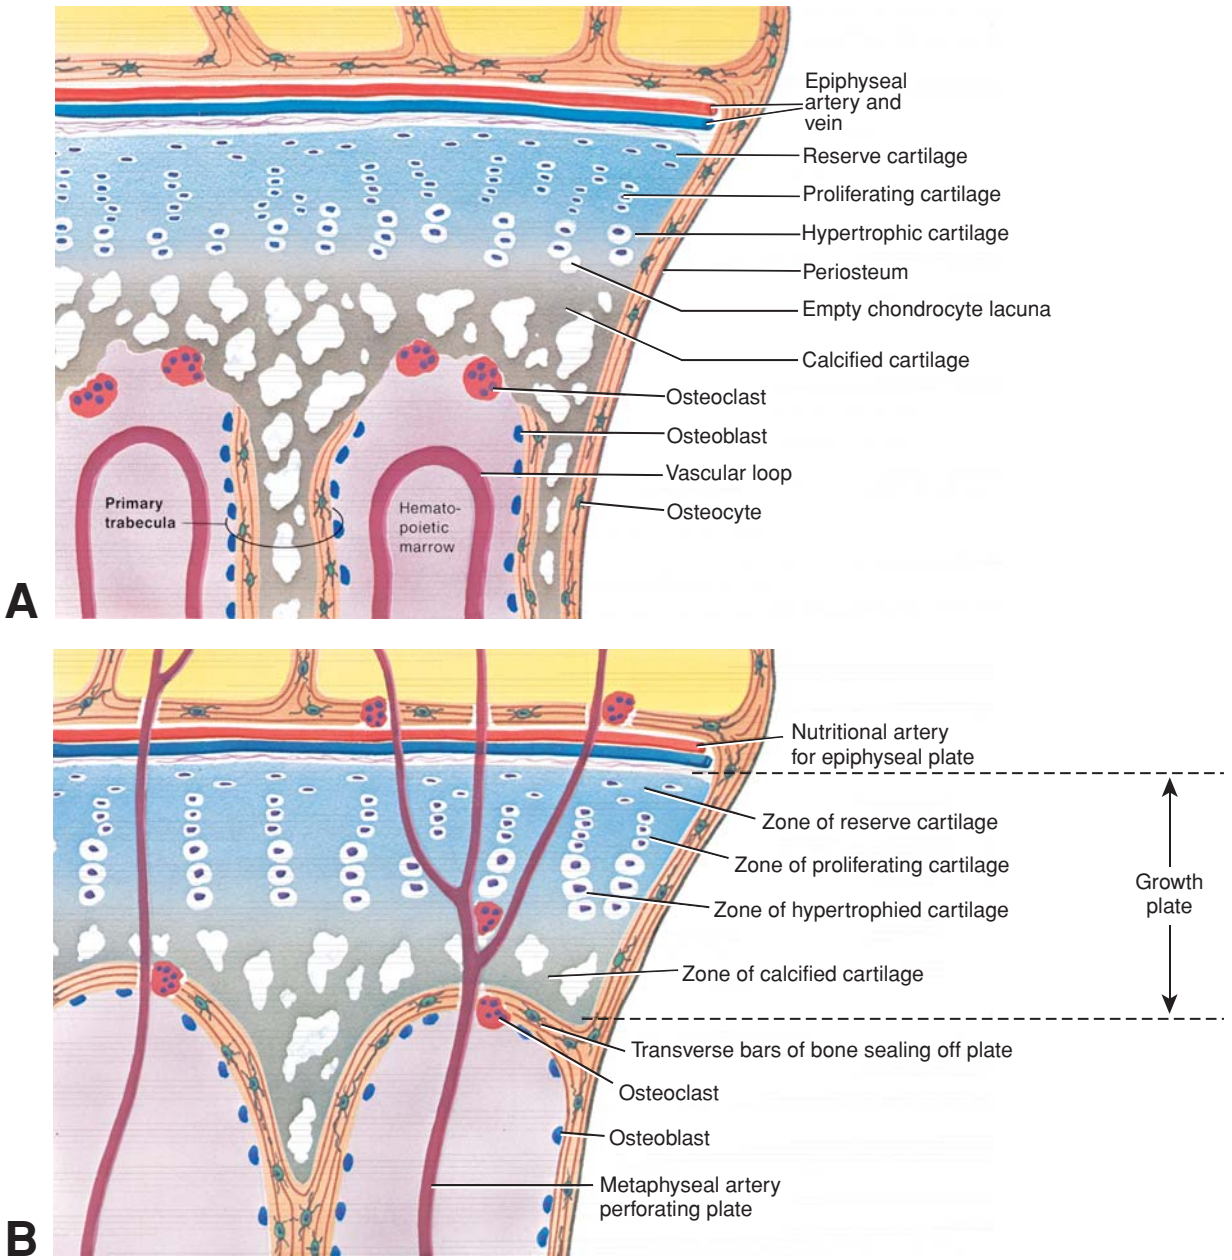

FIGURE 30-9. Anatomy of the epiphyseal growth plate. A. Normal growing epiphyseal plate. The epiphysis is separated from the epiphyseal plate by transverse plates of bone that seal the plate so that it grows only toward the metaphysis. The various zones of cartilage are illustrated. As the calcified cartilage migrates toward the metaphysis, the chondrocytes die, and the lacunae are empty. At the interface of the epiphyseal plate and the metaphysis, osteoclasts bore into the calcified cartilage, accompanied by a capillary loop from the metaphyseal vessels. Osteoblasts follow the osteoclasts and lay down woven bone on the cartilage core, thereby forming the primary spongiosum or primary trabeculae. **B. Normal closure.** The epiphyseal cartilage has ceased to grow, and metaphyseal vessels penetrate the cartilage plate. Transverse bars of bone separate the plate from the metaphysis.

dimensions, are really helices. Viewed longitudinally, the growth plate, proceeding from epiphysis to metaphysis, is divided into zones (Figs. 30-2B and 30-9).

- **The reserve (resting) zone** is supplied by epiphyseal arteries and has small chondrocytes and very little matrix. An additional peripheral zone, known as the **zone of Ranvier,** lies directly under the perichondrium.
- **The proliferative zone** is the next deeper zone, in which active proliferation of chondrocytes occurs both longitudinally and transversely, although the main growth thrust is longitudinal. In a very active growth plate, proliferative zones account for over half the thickness of the growth plate.
- **The hypertrophic zone** is next and demonstrates a substantial increase in chondrocyte size. The intercellular matrix is prominent, and a dense zone, the **territorial matrix,** surrounds chondrocytes.
- **The zone of calcification** is the cartilaginous zone closest to the metaphysis, where the matrix becomes mineralized.
- **The zone of ossification** is the area where a coating of bone is laid down on the surface of the calcified

cartilage. Capillaries grow into the calcified cartilage and give access to osteoclasts, which resorb much of the calcified matrix. Residual vertical walls of calcified cartilage act as scaffolding for the deposition of bone.

The molecular mechanisms governing endochondral growth are beginning to be understood. Parathyroid hormone–related protein (PTHrP) is secreted from perichondrial cells and chondrocytes and maintains chondrocyte proliferation. PTHrP deficiency leads to severe growth retardation and distorted growth plates. The developmental regulator Indian hedgehog (Ihh) is also involved in growth plate maturation by acting in conjunction with PTHrP. A third major factor involved in growth plate regulation is FGF. FGF receptor-3 (FGFR3) is expressed on proliferating chondrocytes, and its activation leads to inhibition of growth plate proliferation. Mutations of FGFR3 are associated with growth arrest (e.g., achondroplasia or other forms of dwarfism) or growth acceleration.

Formation of the Metaphysis Is Called Funnelization

It occurs at the ring of Delacroix, a periosteal cuff of bone surrounding the epiphyseal cartilage. A wave of periosteal osteoclasts resorbs the cortex, so that a fluted or funnel shape begins to appear. At the same time, endosteal osteoblastic bone is deposited to keep pace with, and offset, some of the osteoclastic resorption. The net result is the funnel or fluted shape of the bone.

The Growth Plate Is Normally Obliterated at a Specific Age for Each Bone

Closure of the growth plate (Fig. 30-9B) is induced by sex hormones and occurs earlier in girls than in boys. Renewal of chondrocytes slows and ultimately ceases. The entire plate is eventually replaced by bone. In some people, a transverse bony plate representing the site of closure can be seen on radiography.

DISORDERS OF THE GROWTH PLATE

Cretinism Leads to Defective Cartilage Maturation

Cretinism results from **maternal iodine deficiency** (see Chapter 27) and has profound effects on the skeleton. Thyroid hormone plays a role in regulating chondrocytes, osteoblasts and osteoclasts through production of cytokines and other factors involved in bone development and growth. Linear growth is severely impaired, resulting in dwarfism, with limbs disproportionately short in relation to the trunk. Delayed closure of the fontanelles of the skull causes an unusually large head. There is a delay in closure of the epiphyses, as well as radiologic stippling of these zones. Shedding of deciduous teeth and eruption of permanent teeth are retarded.

PATHOLOGY: In cretinism, chondrocytes do not follow the orderly endochondral sequence. Instead, maturation of the hypertrophied zone is retarded, and the zone of proliferative cartilage is narrow. Endochondral ossification, therefore, does not proceed appropriately, and transverse bars of bone in the metaphysis seal off the growth plate. Although growth plates may remain open, the failure of endochondral ossification produces severe dwarfism. The misshapen epiphyses seen on radiography reflect incomplete penetration of the secondary centers of ossification of the epiphysis.

Morquio Syndrome Features Mucopolysaccharide Deposition in Chondrocytes

Many of the mucopolysaccharidoses (see Chapter 6) involve skeletal deformities, attributable to deposition of mucopolysaccharides (glycosaminoglycans) in developing bones. An example is Morquio syndrome (mucopolysaccharidosis type IV), which leads to a particularly severe form of dwarfism, in addition to dental defects, mental retardation, corneal opacities and increased urinary excretion of keratan sulfate.

Achondroplasia Is an Inherited Dwarfism Caused by Arrest of the Growth Plate

Achondroplasia refers to a syndrome of short-limbed dwarfism and macrocephaly and represents a failure of normal epiphyseal cartilage formation. It is the most common genetic form of dwarfism (1 in 15,000 live births) and is inherited as an autosomal dominant trait. Most cases represent new mutations. The mean adult height in achondroplasia is 131 cm (51 inches) in men and 125 cm (49 inches) in women. Achondroplastic dwarfs have normal mentation and average life spans. However, some patients develop severe kyphoscoliosis and its complications.

MOLECULAR PATHOGENESIS: Achondroplasia is caused by an **activating** mutation in FGFR3 encoded on chromosome 4(p16.3). The mutation constitutively inhibits chondrocyte differentiation and proliferation, which retards growth plate development.

PATHOLOGY: The growth plate in achondroplasia is greatly thinned, and the zone of proliferative cartilage is either absent or extensively attenuated (Fig. 30-10). The zone of provisional calcification, if present, undergoes endochondral ossification, but at a greatly reduced rate. A transverse bar of bone often seals off the growth plate, thus preventing further bone formation and causing dwarfism. Interestingly, the secondary centers of ossification and the articular cartilage are normal. Because intramembranous ossification is undisturbed, the periosteum functions normally and the bones become very short and thick. For the same reasons, the head of the dwarf appears unusually large, compared with the bones formed from the cartilage of the face. The spine is of normal length, but limbs are abnormally short.

Scurvy Results from Dietary Deficiency of Vitamin C

MOLECULAR PATHOGENESIS AND PATHOLOGY: Hydroxyproline and hydroxylysine are important in stabilizing the helical structure of collagen and in cross-linking the tropocollagen fibers into the proper molecular structure of collagen. Vitamin C is a cofactor in hydroxylation of proline and lysine. The skeletal changes of scurvy reflect the lack of osteoblastic function. Woven bone is not formed because osteoblasts cannot produce and normally cross-link

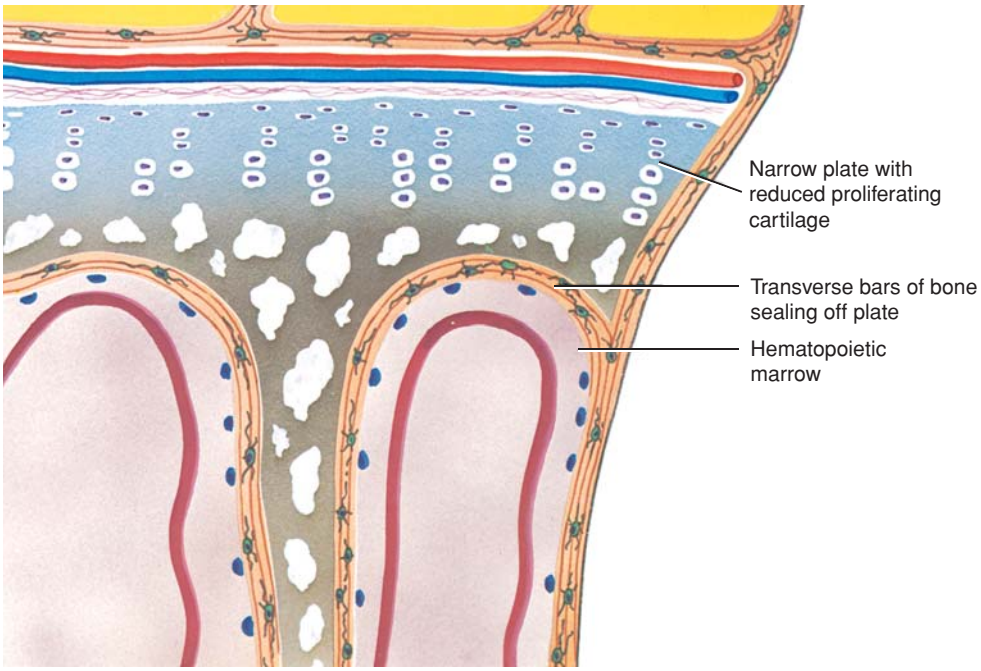

FIGURE 30-10. The epiphyseal growth plate of an achondroplastic dwarf. In achondroplasia, the epiphyseal plate is reduced in thickness, and the zones of proliferating cartilage are attenuated. Osteoclastic activity is inconspicuous, and the interface between the plate and the metaphysis is often sealed by transverse bars of bone that prevent further endochondral ossification. As a result, the bones are shortened.

collagen. Chondrocytes at the growth plate continue to grow. The zone of calcified cartilage may actually become more prominent, because it is more heavily calcified. Osteoclasts resorb this zone, but the primary spongiosum does not form properly, and there is irregular vascular perforation of the cartilage plate.

CLINICAL FEATURES: Today, scurvy is a rare disease (see Chapter 8). Wound healing and bone growth are impaired in patients with scurvy. Furthermore, the basement membrane of capillaries is damaged by this condition and widespread capillary bleeding is common. Subperiosteal bleeding may occur, leading to joint and muscle pain.

Asymmetric Cartilage Growth Causes Spinal Disorders and Tumors

Asymmetric cartilage growth, such as occurs in patients with knock-knees and bowed legs, develops when one part of the growth plate, either medial or lateral, grows faster than the other. Most cases are hereditary, but mechanical forces such as trauma near the growth plate may stimulate one side to grow faster or in an asymmetric fashion. Aside from the cosmetic appearance, these conditions may require correction to prevent future incongruity, eventual loss of articular cartilage and joint destruction.

Scoliosis and Kyphosis

Scoliosis *is an abnormal lateral curvature of the spine, usually affecting adolescent girls.* **Kyphosis** *refers to an abnormal anteroposterior curvature.* When both conditions are present, the term **kyphoscoliosis** is used.

ETIOLOGIC FACTORS: A vertebral body grows in length (height) from the endplates of the vertebrae, which correspond to the growth plates of long tubular bones. As in tubular bones, vertebral bodies increase in width by appositional bone growth from the periosteum. In scoliosis, for unknown reasons, one portion of the endplate grows faster than the other, producing lateral curvature of the spine.

CLINICAL FEATURES: The treatment is appropriate stress on the vertebral body through use of braces or internal fixation to straighten the spine. If kyphoscoliosis is severe, the patient may eventually develop chronic pulmonary disease, cor pulmonale and joint problems, particularly involving the hip.

Hemihypertrophy

Hemihypertrophy describes several conditions in which one limb's growth plate is stimulated to undergo rapid and prolonged endochondral ossification. That limb becomes much longer than the contralateral one. Infection in the metaphyseal area may stimulate the growth plate to grow rapidly. An arteriovenous malformation may also cause one growth plate to grow faster than its counterpart, as may fractures and tumors near the growth plate. In some cases, hemihypertrophy is part of an inherited syndrome. Children with isolated hemihypertrophy are at increased risk for neoplasms.

MODELING ABNORMALITIES

Osteopetrosis Is Characterized by Abnormally Dense Bone

Osteopetrosis, *also known as* **marble bone disease** *or* **Albers-Schönberg disease,** ***is a heterogeneous group of rare inherited disorders in which skeletal mass is increased as a result of abnormally dense bone.*** The most common autosomal recessive form is a severe, sometimes fatal disease affecting infants and children. Death of infants with this severe variant is attributable to marked anemia, cranial nerve entrapment, hydrocephalus and infection. A more benign

form, transmitted as an autosomal dominant trait and seen in adulthood or adolescence, is associated with mild anemia or no symptoms at all.

MOLECULAR PATHOGENESIS: ***The sclerotic skeleton of osteopetrosis is the result of failed osteoclastic bone resorption.*** The disease is caused by mutations in genes that govern osteoclast formation or function. The most common mutations cause defects in bone acidification, which is necessary for osteoclastic bone resorption. These include mutations in the *TCIRG1* gene (osteoclast proton pump; autosomal dominant); the *CLCN7* gene (osteoclast chloride channel; autosomal recessive); and the **carbonic anhydrase II** gene, autosomal recessive. Other mutations that cause osteopetrosis involve transcription factors or cytokines necessary for the osteoclast differentiation.

PATHOLOGY: Because osteoclast function is arrested, osteopetrosis is characterized by (1) retention of the primary spongiosum with its cartilage cores, (2) lack of funnelization of the metaphysis and (3) a thickened cortex. The result is short, block-like, radiodense bones, hence the term **marble bone disease** (Fig. 30-11A). These bones are extremely radiopaque and weigh two to three times more than normal bone. However, they are basically weak because their structure is intrinsically disorganized and cannot remodel along lines of stress. The mineralized cartilage is also weak and friable, so that the bones in osteopetrosis fracture easily. Grossly, bones in osteopetrosis are widened in the metaphysis and diaphysis, causing the characteristic "Erlenmeyer flask" deformity (Fig. 30-11A,B). Histologically, the bone tissue is extremely irregular, and almost all areas contain a cartilage core (Fig. 30-11C). The marrow spaces become obliterated. Depending on the mutation, osteoclasts may be absent, present in normal numbers or even abundant. In the case of osteopetrosis characterized by normal or increased numbers of osteoclasts, the molecular defect lies in a gene involved in the function of osteoclasts, rather than in their formation.

CLINICAL FEATURES: Suppression of hematopoiesis in osteopetrosis is due to replacement of the marrow by sheets of abnormal osteoclasts or extensive fibrosis. Marrow suppression in patients with the malignant form of osteopetrosis may be sufficiently severe to lead to severe anemia or pancytopenia. To compensate for loss of marrow hematopoiesis, extramedullary hematopoiesis occurs in the liver, spleen and lymph nodes, and these structures are enlarged. Narrowing of neural foramina causes cranial nerve involvement, and subsequent strangulation of nerves leads to blindness and deafness. Osteopetrosis can be treated by bone marrow transplantation, which gives rise to a new clone of functional osteoclasts.

Progressive Diaphyseal Dysplasia Features Thickened Long Bones

Progressive diaphyseal dysplasia (Camurati-Engelmann disease) is an autosomal dominant disorder of children in which cylinderization does not proceed appropriately, resulting in symmetric thickening and increased diameter of the diaphyses of long bones. It is due to increased bone formation linked to a mutation in the propeptide of TGF-β. The disease particularly affects the femur, tibia, fibula, radius and ulna. Patients have pain over the affected areas, fatigue, muscle wasting, atrophy and gait abnormalities.

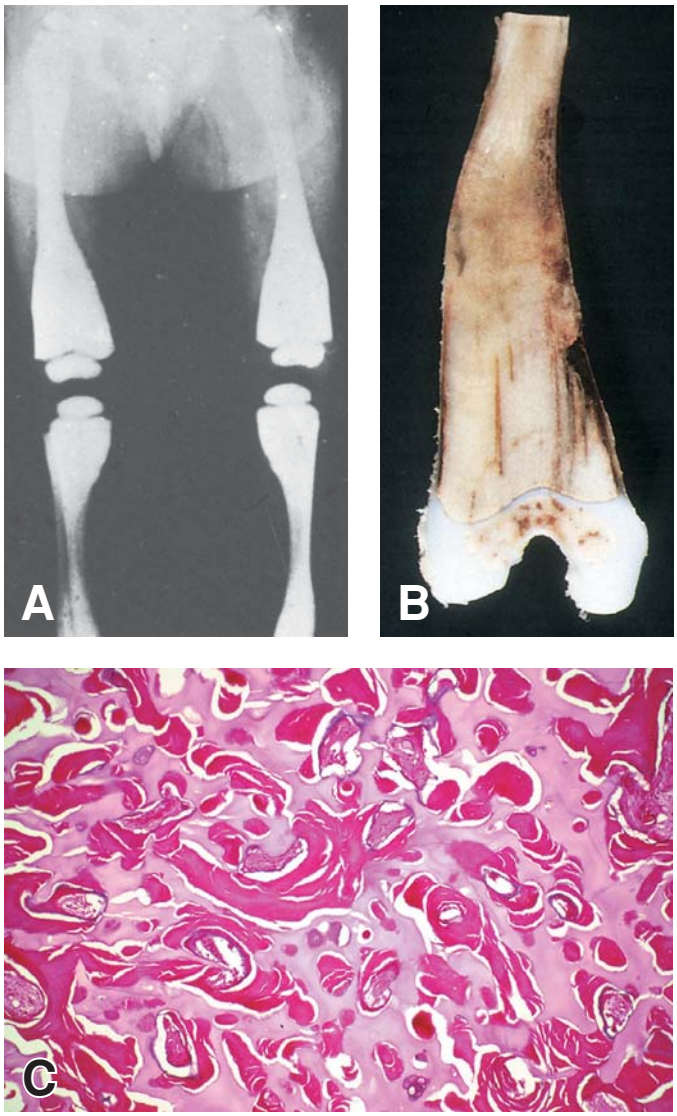

FIGURE 30-11. Osteopetrosis. A. A radiograph of a child shows markedly misshapen and dense bones of the lower extremities, characteristic of "marble bone disease." **B.** A gross specimen of the femur shows obliteration of the marrow space by dense bone. **C.** A photomicrograph of the bone of a child with autosomal recessive osteopetrosis demonstrates disorganization of bony trabeculae by retention of primary spongiosa (mixed spicules) and further obliteration of the marrow space by secondary spongiosa. The result is complete disorganization of the trabeculae and absence of marrow.

DELAYED MATURATION OF BONE

Osteogenesis Imperfecta Is Characterized by Abnormal Type I Collagen

Osteogenesis imperfecta (OI) refers to a group of mainly autosomal dominant, heritable disorders of connective tissue, caused by mutations in the gene for type I collagen, affecting the skeleton, joints, ears, ligaments, teeth, sclerae

and skin (see Chapter 6). There are four well-characterized types of OI, each different genetic structurally and clinically.

MOLECULAR PATHOGENESIS: The pathogenesis of OI involves mutations of *COL1A1* and *COL1A2* genes, which encode the α_1- and α_2-chains of type I procollagen, the major structural protein of bone. These genes are in chromosome 17 (17q21.3–q22) and chromosome 7 (7q21.3–q22), respectively. A point mutation that affects a glycine residue in either *COL1A1* or *COL1A2* is the most typical abnormality found in OI. While *COL1A1* mutations are seen in all types of OI, mutations of *COL1A2* are found in types II, III and IV OI. Mutations of *COL1A1* affect three fourths of the type I collagen molecules, with half of the molecules containing one abnormal pro–α_1-chain and one quarter containing two abnormal pro–α_1-chains. By contrast, mutations in *COL1A2* affect only half of the synthesized collagen molecules. The resulting phenotype will range from mild to lethal depending on which gene is affected, the location in the collagen triple helix at which the substitution occurs and which amino acid is substituted for glycine.

Osteogenesis Imperfecta Type I

OI type I is the mildest phenotype. It is inherited as an autosomal dominant trait, characterized by multiple fractures after birth, blue sclera and hearing abnormalities. In some patients, abnormalities of the teeth are also conspicuous (dentinogenesis imperfecta).

PATHOLOGY AND CLINICAL FEATURES: Initial fractures usually occur after the infant begins to sit and walk. There may be hundreds of fractures a year with minor movement or trauma. On radiologic examination, bones are extremely thin, delicate and abnormally curved (Fig. 30-12A). The collagen has reduced tensile strength and bone mineralization is abnormal. The combination of these abnormalities accounts for the brittleness of OI bone. In OI, insufficient bone is formed, leading to decreased cortical thickness and reduced trabecular bone. When a fracture occurs, the fracture callus may be extensive enough to resemble a tumor (Fig. 30-12B). As the child grows, fractures tend to decrease in severity and frequency, and stature is generally unaffected.

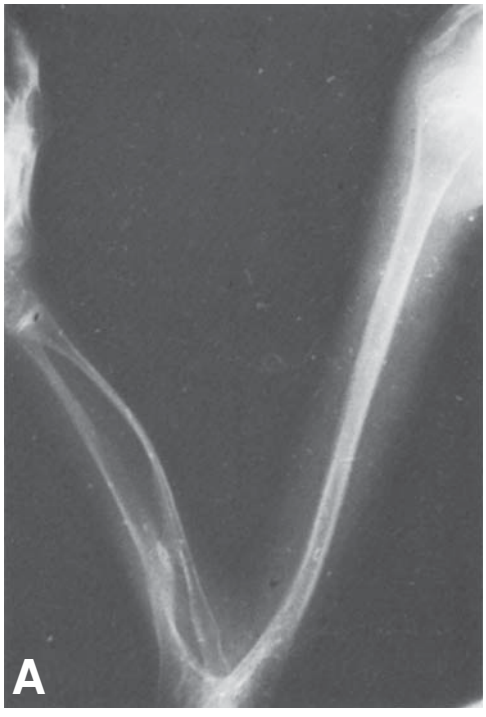
The sclerae are very thin, with a blue color attributable to the underlying choroid. Progressive hearing loss, which develops to total deafness in adulthood, results from fusion of the auditory ossicles. The joint laxity associated with the condition eventually leads to kyphoscoliosis and flat feet. Because of hypoplasia of the dentine and pulp, the teeth are misshapen and bluish yellow.

Osteogenesis Imperfecta Type II

OI type II is a lethal, autosomal dominant, perinatal disease. Affected infants are stillborn or die within a few days after birth, in a sense being crushed to death. They are markedly short in stature, with severe limb deformities. Almost all bones sustain fractures during delivery or during uterine contractions in labor. As in OI type I, sclerae are blue.

Osteogenesis Imperfecta Type III

OI type III is the progressive, most severely deforming type of disease and is characterized by many bone fractures, growth retardation and severe skeletal deformities. Inheritance is usually autosomal dominant, although (rarely) autosomal recessive forms are reported. Fractures are present at birth, but bones are less fragile than in the type II form. These patients eventually develop severe shortening of their stature because of progressive bone fractures and severe kyphoscoliosis. Although sclerae may be blue at birth, they become white shortly thereafter. Dental abnormalities are common.



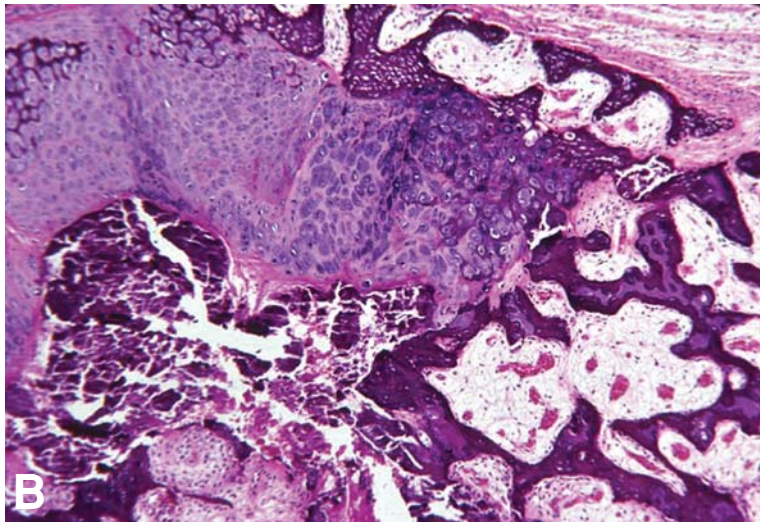


FIGURE 30-12. Osteogenesis imperfecta. A. A radiograph illustrates the markedly thin and attenuated humerus and bones of the forearm. There is a fracture callus in the proximal ulna. **B.** A photomicrograph of the fracture callus with prominent cartilage (*upper left*). The cortex is thin and composed of hypercellular woven bone.

Osteogenesis Imperfecta Type IV

OI type IV is similar to type I except that sclerae are normal. The condition is heterogeneous in presentation, and there may or may not be dental disease. In this disorder, abnormal cross-linkages of collagen result in thin, delicate and weak collagen fibrils. This inappropriate collagen does not allow the bone cortex to mature, so that at birth the cortex of the bone resembles that of a fetus. The cortex is composed of woven bone and small areas of lamellar bone. Over a period of years, the cortex matures, but this may not occur until adolescence or even later. In any event, the frequency of fractures tends to decrease over a long period. These patients are vigorously treated with orthopedic devices, including rods inserted into the medullary cavities to prevent the dwarfing effect of multiple fractures.

Additional types of OI (types V, VI, VII and VIII) have recently been identified from within the heterogeneous type IV group, based on distinct clinical, genetic and bone histologic features.

There is no single treatment for OI. Osteoprogenitor cells for bone marrow transplantation, growth factors, bisphosphonates and gene therapy to improve collagen synthesis have been undergoing clinical trials in an attempt to modify the course and severity of the disease. Because exuberant fracture callus occurs, it is not surprising that rare cases of OI have been interpreted as osteosarcoma.

FRACTURE

The most common bone lesion is a fracture, which is defined as a discontinuity of the bone. A force perpendicular to the long axis of the bone results in a **transverse fracture.** A force along the long axis of the bone yields a **compression fracture**. Torsional force results in **spiral fractures,** and combined tension and compression shear forces cause angulation and displacement of the fractured ends.

A force powerful enough to fracture a bone also injures adjacent soft tissues. In this situation, there is often (1) extensive muscle necrosis; (2) hemorrhage because of shearing of capillary beds and larger vessels of soft tissues; (3) tearing of tendinous insertions and ligamentous attachments; and (4) even nerve damage, caused by stretching or direct tearing of the nerve.

Fracture Healing Is Divided into Inflammatory, Reparative and Remodeling Phases

The duration of each phase (Fig. 30-13) depends on the patient's age, the site of fracture, the patient's overall health and nutritional status and the extent of soft tissue injury. Local factors, such as vascular supply and mechanical forces at the site, also play a role in healing. ***In repairing a bone fracture, anything other than formation of bone tissue at the fracture site represents incomplete healing.***

PATHOLOGY:

The Inflammatory Phase

In the first 1–2 days after a fracture, rupture of blood vessels in the periosteum and adjacent muscle and soft tissue leads to extensive hemorrhage. Extensive bone necrosis at the fracture site also occurs because of disruption of large vessels in the bone and interruption of cortical vessels (i.e., Volkmann and Haversian canals). ***Dead bone is characterized by the absence of osteocytes and empty osteocyte lacunae.***

In 2–5 days, the hemorrhage forms a large clot, which must be resorbed so that the fracture can heal. Neovascularization begins to occur peripherally to this blood clot. By the end of the first week, most of the clot is organized by invasion of blood vessels and early fibrosis.

The earliest bone, which is invariably woven bone, is formed after 7 days. ***This corresponds to the "scar" of bone.*** Since bone formation requires a good blood supply, woven bone spicules begin to appear at the periphery of the clot. Pluripotential mesenchymal cells from the soft tissue and within the bone marrow give rise to the osteoblasts that synthesize woven bone. In most fractures, cartilage also is formed and is eventually resorbed by endochondral ossification. Granulation tissue containing bone or cartilage is called a **callus**. Woven bone also forms inside the marrow cavity at the edge of the blood clot because vascular tissue is also present in that location.

The Reparative Phase

The reparative phase follows the first week after a fracture and may last for months, depending on the degree of movement and the fixation of the fracture. By this time, acute inflammation has dissipated. Pluripotential cells differentiate into fibroblasts and osteoblasts. Repair proceeds from the periphery toward the center of the fracture site and accomplishes two objectives: (1) to organize and resorb the blood clot and, more importantly, (2) to neovascularize construction of the callus, which will eventually bridge the fracture site. Events leading to repair are as follows:

1. Armies of osteoclasts within the Haversian canals form **cutting cones** that bore into the cortex toward the fracture site. A new vessel accompanies the cutting cone, supplying nutrients to these cells and providing more pluripotential cells for cell renewal.
2. At the same time, the external callus, which is found on the surface of the bone and is formed from the periosteum and the soft tissue mesenchymal cells, continues to grow toward the fracture site.
3. Simultaneously, an endosteal or internal callus forms within the medullary cavity and grows outward toward the fracture site.
4. The cortical cutting cones reach the fracture site and the ends of the fractured bone begin to appear beveled and smooth, as the site is remodeled by osteoclasts.
5. The same is true of the endosteal surface of the cortex, as the internal callus works its way to the fracture site.
6. Where there are large areas of cartilage, new blood vessels invade the calcified cartilage, after which the endochondral sequence duplicates the normal formation of bone at the growth plate.

The Remodeling Phase

Several weeks after a fracture, the ingrowth of callus has sealed the bone ends and remodeling begins. In this phase, the bone is reorganized so that the original cortex is restored. Occasionally, the bone is strong enough to qualify as a clinically healed fracture, but biologically, the fracture may not

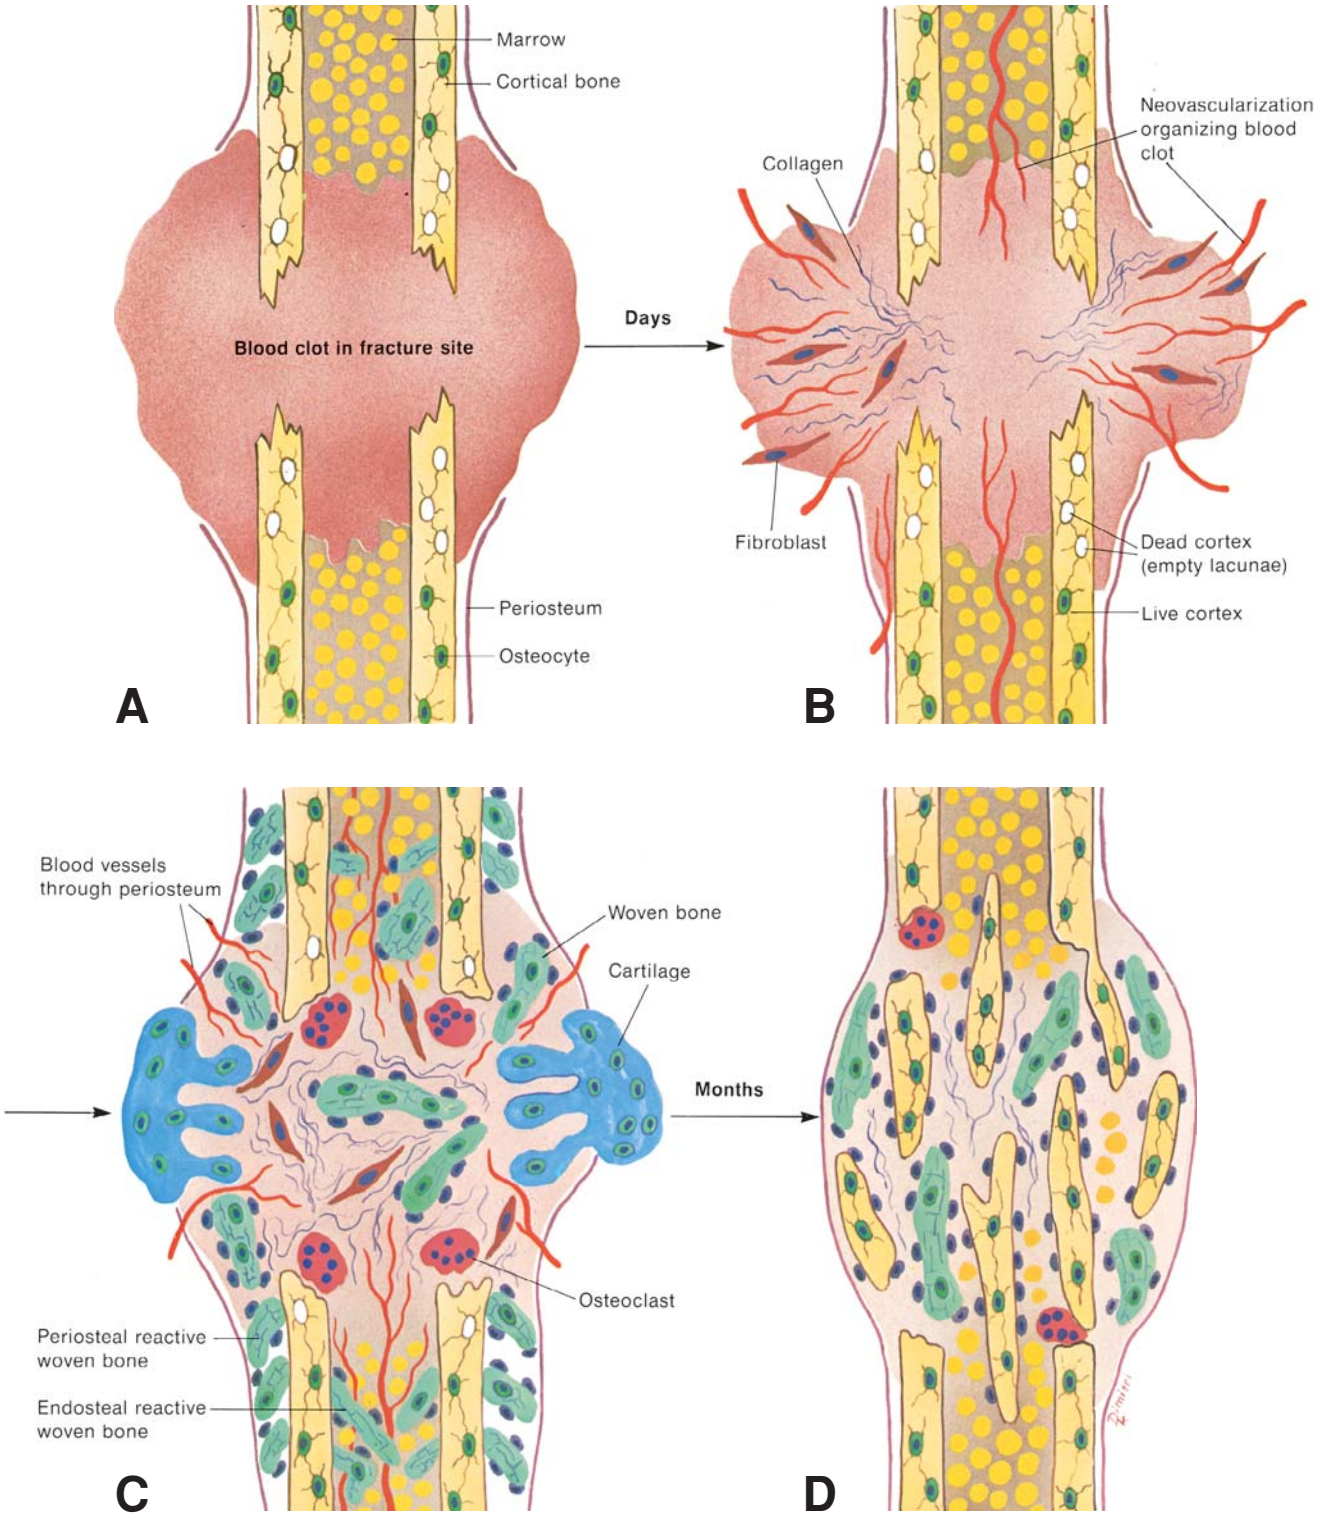

FIGURE 30-13. Healing of a fracture. A. Soon after a fracture is sustained, an extensive blood clot forms in the subperiosteum and soft tissue, as well as in the marrow cavity. The bone at the fracture site is jagged. **B.** The **inflammatory phase** of fracture healing is characterized by neovascularization and beginning organization of the blood clot. Because the osteocytes in the fracture site are dead, the lacunae are empty. The osteocytes of the cortex are necrotic well beyond the fracture site, owing to the traumatic interruption of the perforating arteries from the periosteum. **C.** The **reparative phase** of fracture healing is characterized by the formation of a callus of cartilage and woven bone near the fracture site. The jagged edges of the original cortex have been remodeled and eroded by osteoclasts. The marrow space has been revascularized and contains reactive woven bone, as does the periosteal area. **D.** In the **remodeling phase,** during which the cortex is revitalized, the reactive bone may be lamellar or woven. The new bone is organized along stress lines and mechanical forces. Extensive osteoclastic and osteoblastic cellular activity is maintained.

be truly healed and may continue to undergo remodeling for years. For instance, the callus of rib fractures may remain throughout life because the continual respiratory movement of the ribs shears blood vessels and preserves extensive cartilage callus. In a child, in whom the growth plates are still open, normal modeling of growing bone overtakes the callus, so that a fracture may not be recognizable in later life. Similarly, normal modeling in a child may correct the angulation of a bone at a fracture site. If a fracture is near the growth plate, differential growth rates of the growth plate also correct the angulation. In an adult, however, because the plates are closed, angulation often requires correction with external or internal devices.

Special Considerations

There are unusual nuances to fracture healing that deserve mention.

PRIMARY HEALING: A fracture does not necessarily result in bone displacement and soft tissue injury. For example, a drill hole in the bone cortex or a controlled fracture, such as an osteotomy created with a fine saw during orthopedic surgery, does not displace bone. In this situation, there is almost no soft tissue reaction and callus formation because the bone is rigidly fixed. The fracture callus grows directly into the fracture site by a process called **primary healing**. This results in rapid reconstitution of the cortex, including restoration of the Haversian systems. Similarly, if a fracture site is held in rigid alignment by metal screws and plates, there is also little external callus. The cortical cutting cones will then be prominent and will heal the fracture site quickly.

NONUNION: Failure of a fracture to heal is called **nonunion**. Causes of nonunion include interposition of soft tissues at the fracture site, excessive motion, infection, poor blood supply and other factors mentioned above. Continued movement at the unhealed fracture site may also lead to **pseudoarthrosis,** a condition in which tissue similar to that in the joint is formed. Pluripotential cells become histologically indistinguishable from synovial cells, secrete synovial fluid and form a joint-like structure. In such cases, the fracture never heals and the abnormal tissue must be removed surgically for the fracture to heal properly.

Stress Fractures Result from Microfractures

In these fractures, also known as* fatigue *or* march fractures*, repeated microfractures eventually result in a true fracture through the bone cortex.

ETIOLOGIC FACTORS: A stress fracture occurs in bones in which the cortex has few osteons and forms only when stress is applied to the cortex. If the ill-prepared cortex (e.g., in the fifth metatarsal) undergoes repeated mechanical stress (e.g., from jogging, skiing or ballet dancing), the bone produces cutting cones in an attempt to implant osteons. If the stress continues and microfractures accumulate, periosteal and endosteal calluses develop to strengthen the bone while active remodeling takes place. An actual fracture occurs as the last event if the stresses are continually applied during remodeling.

CLINICAL FEATURES: Stress fractures produce pain and swelling over the affected bone. ***At the site of a future stress fracture, a callus forms before a fracture occurs.*** When the actual fracture takes place, the pain becomes more severe. In the early stages of this condition, before the actual fracture, the radiologic appearance may resemble that of a tumor. A biopsy will show that the cortex is riddled with cutting cones for remodeling, which is also seen in the reactive bone at the edge of an invasive tumor.

OSTEONECROSIS (AVASCULAR NECROSIS, ASEPTIC NECROSIS)

Osteonecrosis refers to the death of bone and marrow in the absence of infection (Fig. 30-14). Causes of

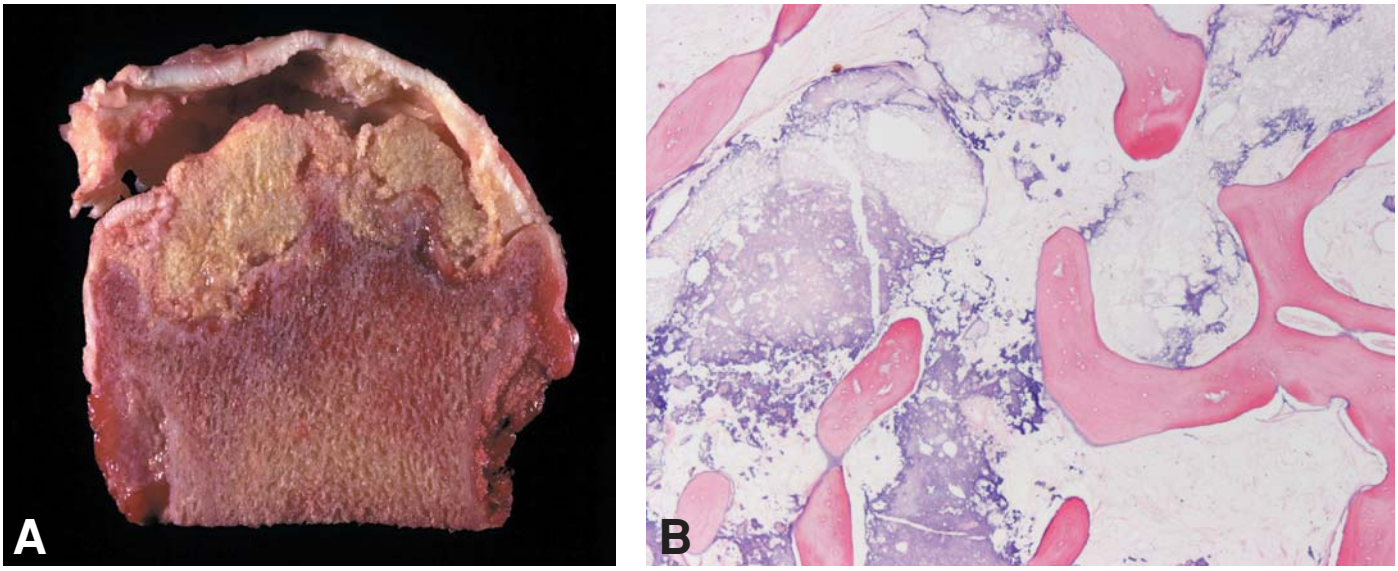

FIGURE 30-14. Osteonecrosis of the head of the femur. A coronal section shows a circumscribed area of subchondral infarction with partial detachment of the overlying articular cartilage and subarticular bone. **B.** Microscopically, the necrotic bone is characterized by empty lacunae and the necrotic marrow shows dystrophic calcification.

TABLE 30-1
CAUSES OF OSTEONECROSIS

Trauma, including fracture and surgery
Emboli, producing focal bone infarction
Systemic diseases, such as polycythemia, lupus erythematosus, Gaucher disease, sickle cell disease and gout
Radiation, either internal or external
Corticosteroid administration
Specific focal bone necrosis at various sites—for instance, in the head of the femur (Legg-Calvé-Perthes disease) or in the navicular bone (Köhler disease)
Organ transplantation, particularly renal, in patients with persistent hyperparathyroidism
Osteochondritis dissecans, a condition of unknown etiology in which a piece of articular cartilage and subchondral bone breaks off into a joint. It is thought that a focal area of bone necrosis occurs and eventually detaches.
Autografts and allografts
Thrombosis of local vessels secondary to the pressure of adjacent tumors or other space-occupying lesions
Idiopathic factors, as in the high incidence of osteonecrosis of the head and the femur in alcoholics. Necrotic bone heals differently in the cortex and in the underlying coarse cancellous bone.

osteonecrosis are listed in Table 30-1. Necrotic bone heals differently in the cortex than in the underlying coarse cancellous bone.

PATHOLOGY: Osteonecrosis is characterized by death of bone and marrow. The necrotic bone has empty lacunae lacking osteocyte nuclei, and the marrow displays dystrophic calcification (Fig. 30-14B). Necrotic coarse cancellous bone heals by **creeping substitution,** in which the necrotic marrow is replaced by invading or creeping neovascular tissue, which provides the pluripotential cells needed for bone remodeling. Although necrotic bony trabeculae may be resorbed directly by osteoclastic activity, they are more commonly surrounded by new woven or lamellar bone generated by the osteoblastic activity of granulation tissue. Eventually, the sandwich composed of necrotic bone in the center and surrounding viable bone is remodeled by osteoclastic activity, and new bone is laid down through intramembranous bone formation.

Necrotic cortical bone is healed by a cutting cone. The cutting cone, as discussed above, forms by way of preexisting vascular channels in the cortex. The appropriate signals reach this vascular channel and stimulate neovascularization by surrounding pluripotential mesenchymal tissue. Osteoclasts make their way into the necrotic compact cortical bone, with osteoblasts trailing behind. As a result, tunnels bore their way into the necrotic cortex, leading to new bone formation. This is a slow process, and the bone is often laid down de novo as lamellar bone.

Legg-Calvé-Perthes disease is osteonecrosis in the femoral head in children; **idiopathic osteonecrosis** occurs in a similar location in adults. In both conditions, collapse of the femoral head may create joint incongruity and eventual severe osteoarthritis. Collapse of the subchondral bone results from several mechanisms:

- Necrotic bone may sustain stress fractures and compaction over a long period.
- The portion peripheral to the necrotic bone may undergo neovascularization. On radiologic examination, there is a lucent area surrounding the necrotic zone.
- The rigid articular cartilage and subchondral bone may actually crack as the subchondral necrotic zone collapses, producing a fracture.

A radiograph in avascular necrosis often shows the necrotic zone to be radiodense because of (1) relative osteoporosis in the surrounding viable bone compared with the unchanged necrotic bone; (2) addition of new bone through creeping substitution; (3) formation of calcium soaps, which arise as a result of the necrosis of marrow fat; and (4) actual compaction of the preexisting dead bone. Focal end-arterial vascular insufficiency may precede these events, as the necrotic zone tends to be wedge shaped.

REACTIVE BONE FORMATION

Reactive bone is intramembranous bone formed in response to stress on bone or soft tissue. Conditions such as tumors, infections, trauma or generalized or focal disease can stimulate bone formation.

PATHOLOGY: The periosteum may respond with a so-called **sunburst** pattern (Fig. 30-15), as seen with certain tumors, or progressive layering of the periosteum, which yields an **onionskin pattern** of the cortex. The endosteal or the marrow surface may produce new bone, so that on radiologic studies, the cortex appears to be thickened, and the coarse cancellous bone is denser.

Reactive bone may be either woven or lamellar, depending on the rates of deposition of the reactive bone. Around an indolent infection, as in chronic osteomyelitis, reactive bone may be laid down de novo as lamellar bone from the periosteum. In this case, the bone has time to respond to the persistent stress. Similarly, a benign tumor may cause a lamellar bone reaction. By contrast, a rapidly enlarging tumor is more likely to promote woven bone. Invariably, reactive bone is of the intramembranous type, because it is derived from the periosteum or the endosteal tissue of the marrow.

Heterotopic Ossification Is Bone Formation outside the Skeletal System

Heterotopic ossification (HO) is formation of reactive bone (woven or lamellar) in extraskeletal sites such as the skin, subcutaneous tissue, skeletal muscle and fibroconnective tissue around joints. HO is not associated with any metabolic disease, reflected in the fact that patients have normal serum calcium and phosphorous levels. HO occurs in five major clinical settings: genetic, posttraumatic, neurogenic, postsurgical and as distinctive reactive lesions such as **myositis ossificans**. A genetic disorder known as **fibrodysplasia**

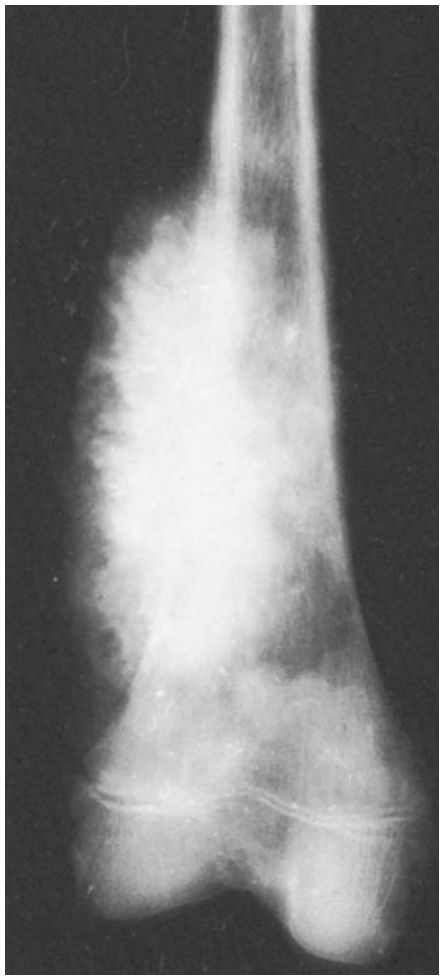

FIGURE 30-15. Reactive bone formation. A radiograph of a resected femur bearing an osteosarcoma shows a sunburst pattern of hyperdense new bone in the distal diaphysis and metaphysis. This radiodensity is due to woven bone produced by the sarcoma and the periosteal reaction of the host bone. The epiphyseal plate is represented as a transverse lucent line that separates the metaphysis from the epiphysis. The radiating radiodense bone extends beyond the periosteum into the soft tissues, obscuring the underlying bone architecture.

ossificans progressiva is characterized by massive deposits of bone around multiple joints. HO may form in hematomas or skeletal muscle after trauma. Neurogenic HO occurs in muscle and periarticular fibrous tissue at multiple sites in patients with head trauma, spinal cord injury or prolonged coma. HO can also form in periarticular soft tissue following joint surgery.

Heterotopic Calcification Is Deposition of Calcium Salts in Soft Tissues

Radiologically, heterotopic ossification and heterotopic calcification are usually distinctive. Bone formation is characterized by a spicular or trabeculated pattern, but heterotopic calcification has an irregular, splotchy, amorphous appearance. Heterotopic calcification tends to occur in necrotic soft tissue or in cartilage and on radiography is usually denser than bone. Heterotopic calcification appears in two forms:

- **Metastatic calcification** occurs when there is an increase in the calcium–phosphorus product. Thus, hypercalcemic states or hyperphosphatemic conditions predispose normal soft tissues to calcification.
- **Dystrophic calcification** is seen in abnormal or damaged soft tissues (e.g., tumors), degenerative diseases such as arteriosclerosis and areas subjected to trauma. In addition, loss of neurologic function, as seen in quadriplegia and hemiplegia, predisposes the affected parts to soft tissue calcification.

Myositis Ossificans Is Formation of Reactive Bone in Muscle after Injury

Myositis ossificans is a distinctive form of heterotopic ossification that affects young people and, although it is entirely benign, often mimics a malignant neoplasm. It is a self-limited process and carries an excellent prognosis. Spontaneous regression has been observed. No treatment is required once the diagnosis is established.

ETIOLOGIC FACTORS: The lesion typically results from blunt trauma to the muscle and soft tissues, usually of the lower limb. However, some cases occur spontaneously. Peripheral neovascularization and fibrosis at the site of damaged tissue, together with associated hemorrhage, leads in a short time to bone spicule formation. These changes are similar to those that occur at the initial hematoma in a healing fracture. Because myositis ossificans often occurs near a bone such as the femur or tibia, it may be misdiagnosed on radiography as a malignant bone-forming tumor.

PATHOLOGY: Histologically, woven bone is formed within granulation tissue and reactive fibrous tissue (Fig. 30-16B). The center of an early lesion of myositis ossificans is characterized by proliferating fibroblasts and more peripheral osteoblastic cells that begin to form woven bone. The fibroblasts are often cytologically atypical and show abundant mitoses, a histologic appearance that also resembles a malignant tumor. ***The key feature that distinguishes myositis ossificans from a neoplasm is that the bone matures peripherally, but in the center of the lesion it is immature or not formed at all.*** The phenomenon of peripheral maturity with central immaturity, the **zonation effect**, clearly indicates a reactive process. In a well-developed lesion, this phenomenon may be seen radiographically (Fig. 30-16A). A neoplasm has an opposite zonation effect; the most mature tissue of the tumor is located centrally.

The growth pattern of myositis ossificans reflects the ingrowth of neovascular tissue from the periphery into the center of the damaged area. In the late stages, the lesion may contain cartilage and even lamellar bone. Thus, in a well-developed lesion, it may mimic a sesamoid bone in the soft tissue.

INFECTIONS

Osteomyelitis is Inflammation of Bone Secondary to Bacterial Infection

Any infectious agent may be responsible, but the most common pathogens are *Staphylococcus* sp. (60%–80%). Other organisms, such as *Escherichia coli, Neisseria gonorrhoeae,*

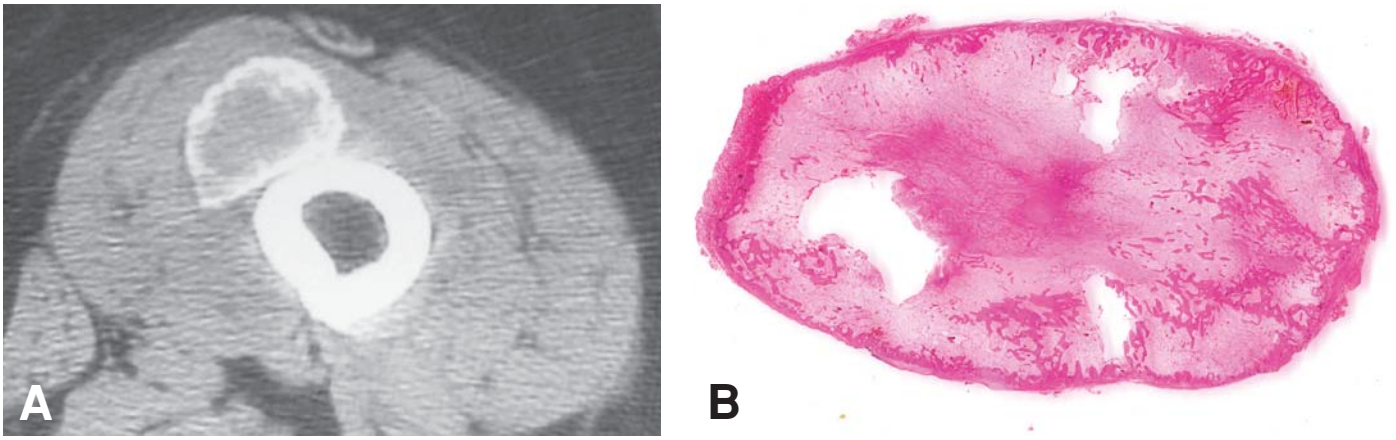

FIGURE 30-16. Myositis ossificans circumscripta. A. Computed tomography scan of the thigh shows an axial view of an ovoid, intramuscular mass adjacent to the femoral cortex with a radiolucent center and ossification that becomes denser at the periphery. **B.** The mass at low-power magnification with woven bone at the periphery and fibrous tissue in the center.

Haemophilus influenzae and *Salmonella* sp., are also seen. The organisms gain entry either via the bloodstream or by direct introduction into the bone.

Direct Penetration

Infection by direct penetration or extension of bacteria is now the most common cause of osteomyelitis in the United States. Bacterial organisms are introduced directly into bone by penetrating wounds, open fractures or surgery. Staphylococci and streptococci are still commonly incriminated, but in 25% of postoperative infections, anaerobic organisms are detected. Rarely, a gram-negative organism may seed a hip after a urologic or gastrointestinal surgical procedure or instrumentation.

Hematogenous Osteomyelitis

Infectious organisms may reach the bone from a focus elsewhere in the body through the bloodstream. Often the focus itself (e.g., a skin pustule or infected teeth and gums) poses little threat.

The most common sites affected by hematogenous osteomyelitis are the metaphyses of the long bones, such as in the knee, ankle and hip. The infection principally affects boys aged 5–15 years, but it is occasionally seen in older age groups as well. Drug addicts may develop hematogenous osteomyelitis from infected needles.

ETIOLOGIC FACTORS AND PATHOLOGY: Hematogenous osteomyelitis primarily affects the metaphyseal area because of the unique vascular supply in this region (Fig. 30-17). Normally, arterioles enter the calcified portion of the growth plate, form a loop, and then drain into the medullary cavity without establishing a capillary bed. This loop system permits slowing and sludging of blood flow, thus allowing bacteria enough time to penetrate blood vessel walls and establish infective foci within the marrow. If the organism is virulent and continues to proliferate, it creates increased pressure on the adjacent thin-walled vessels because they lie in a closed space, the marrow cavity. Such pressure further compromises the vascular supply in this region and produces bone necrosis. The necrotic areas coalesce into an avascular zone, and so facilitate further bacterial proliferation.

If infection is not contained, pus and bacteria extend into the endosteal vascular channels that supply the cortex and spread throughout the Volkmann and Haversian canals of the cortex. Eventually, pus forms underneath the periosteum, shearing off the perforating arteries of the periosteum and further devitalizing the cortex. The pus flows between the periosteum and the cortex, isolating more bone from its blood supply, and may even invade the joint. Eventually, pus penetrates the periosteum and the skin to form a draining sinus (Fig. 30-17D and 30-18B). A sinus tract that extends from the cloaca (see below) to the skin may become epithelialized by epidermis that grows into the sinus tract. When this occurs, the sinus tract invariably remains open, continually draining pus, necrotic bone and bacteria.

Periosteal new bone formation and reactive bone formation in the marrow tend to wall off the infection. At the same time, osteoclastic activity resorbs bone. If the infection is virulent, this attempt to contain it is overwhelmed and it races through the bone, with virtually no bone formation but extensive bone necrosis. More commonly, pluripotential cells modulate into osteoblasts in an attempt to wall off the infection. Several lesions may develop:

- **Cloaca** is the hole formed in the bone during the formation of a draining sinus.
- **Sequestrum** is a fragment of necrotic bone that is embedded in the pus.
- **Brodie abscess** consists of reactive bone from the periosteum and the endosteum, which surrounds and contains the infection.
- **Involucrum** refers to a lesion in which periosteal new bone formation forms a sheath around the necrotic sequestrum. An involucrum that involves an entire bone may exist for several years before a patient seeks medical attention.

In very young children (1 year old or younger) afflicted with osteomyelitis, the adjacent joint is often involved (septic arthritis). This occurs because the periosteum is loosely attached to the cortex, and the metaphyseal vessels penetrate the open growth plate to join the epiphyseal vessels,

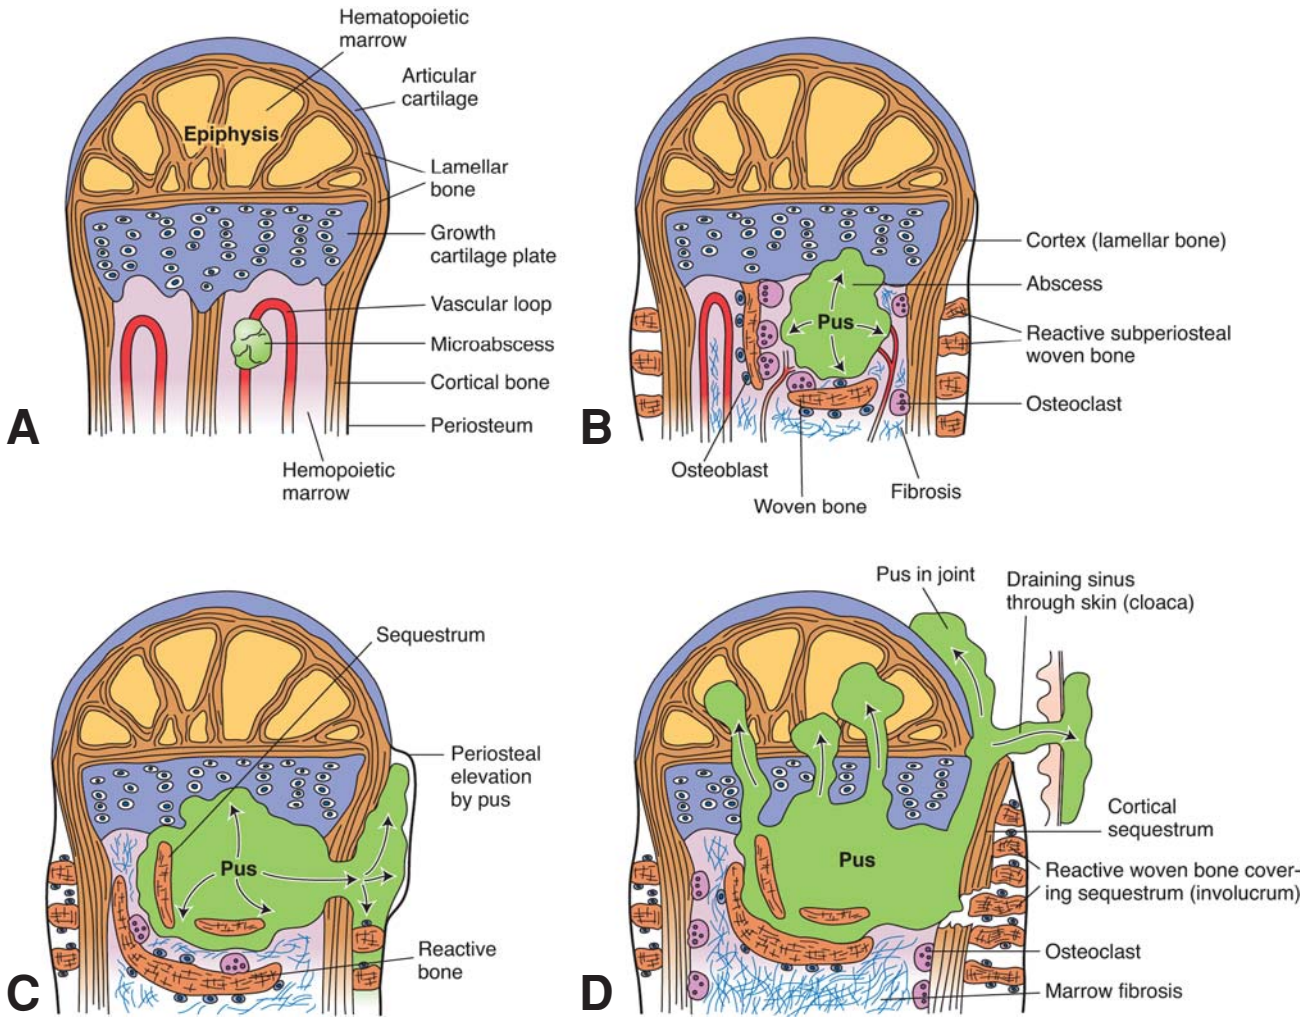

FIGURE 30-17. Pathogenesis of hematogenous osteomyelitis. A. The epiphysis, metaphysis and growth plate are normal. A small, septic microabscess is forming at the capillary loop. **B.** Expansion of the septic focus stimulates resorption of adjacent bony trabeculae. **Woven bone** begins to surround this focus. The abscess expands into the cartilage and stimulates reactive bone formation by the periosteum. **C.** The **abscess,** which continues to expand through the cortex into the subperiosteal tissue, shears off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of the cortex. **D.** The extension of this process into the joint space, the epiphysis and the skin produces a **draining sinus.** The necrotic bone is called a **sequestrum.** The viable bone surrounding a sequestrum is termed the **involucrum.**

allowing the infectious organisms to reach the subchondral bone. From the age of 1 year to puberty, subperiosteal abscesses are common. Spread of infection to adjacent joints and subchondral bone regions also occur in adults.

Vertebral Osteomyelitis

In adults, osteomyelitis frequently involves vertebral bodies (Fig. 30-19). The intervertebral disk is not a barrier to bacterial osteomyelitis, particularly staphylococcal infection. Infections directly traverse the disk and travel from one vertebra to the next. Some investigators consider that the intervertebral disk is actually the primary source of infection, so-called diskitis. The disk expands with pus and is eventually destroyed as the pus bores into adjacent vertebral bodies.

Half or more of cases of vertebral osteomyelitis are caused by *Staphylococcus aureus.* Twenty percent involve *E. coli* and other enteric organisms, often originating from the urinary tract. *Salmonella* sp. are also seen in the vertebral bodies, as are *Brucella* sp. Predisposing factors are intravenous drug abuse, upper urinary tract infections, urologic procedures and hematogenous spread of organisms from other sites. Back pain, with point tenderness over the area of infection, is associated with low-grade fever and an increased sedimentation rate.

Occasionally, a paravertebral abscess draining the bone may "point" and emerge in the groin or elsewhere. Vertebral osteomyelitis may lead to (1) vertebral collapse and paravertebral abscesses; (2) spinal epidural abscesses, with cord compression from the abscess or from displaced fragments of the infected bone; and (3) compression fractures of the vertebral body, leading to neurologic deficits.

Complications

The complications of osteomyelitis include:

- **Septicemia:** Dissemination of organisms through the bloodstream may occur as a result of bone infection. It is unusual for osteomyelitis to result from septicemia.

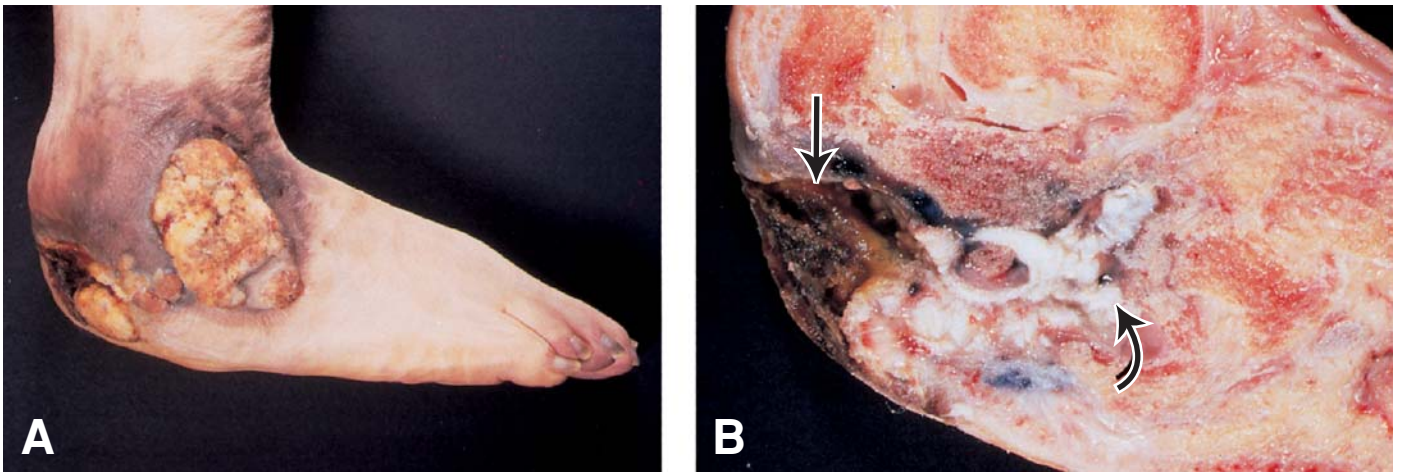

FIGURE 30-18. Chronic osteomyelitis. A. In this patient with chronic osteomyelitis, the skin overlying the infected bone is ulcerated and a draining sinus (*dark area*) is evident over the heel. **B.** After amputation of the foot, a sagittal section shows a draining sinus (*straight arrow*) that connects the infected bone with the surface of the ulcerated skin. The white tissue (*curved arrow*) is invasive squamous cell carcinoma, which arose in the skin.

- **Acute bacterial arthritis:** Joint infection is secondary to osteomyelitis at all ages and represents a medical emergency. Direct digestion of cartilage by inflammatory cells destroys the articular cartilage and produces osteoarthritis. Rapid intervention to prevent this complication is mandatory.
- **Pathologic fractures:** Osteomyelitis may lead to fractures, which heal poorly and may require surgical drainage.
- **Squamous cell carcinoma:** This cancer develops in the bone or the sinus tract of long-standing chronic osteomyelitis, often years after the initial infection. In such cases, squamous tissue arises from the epithelialization of the sinus tract and eventually undergoes malignant transformation (Fig. 30-18B).
- **Amyloidosis:** Amyloidosis used to be a common consequence of chronic osteomyelitis but is now rare in industrialized countries.
- **Chronic osteomyelitis:** Chronic osteomyelitis (Fig. 30-18) may follow acute osteomyelitis. It is difficult to treat, especially if it involves the entire bone, because necrotic bone or sequestra function as foreign bodies in avascular areas, and antibiotics do not reach the bacteria. Chronic osteomyelitis is, therefore, treated symptomatically with surgery or antibiotics for the duration of the patient's life.

CLINICAL FEATURES: Hematogenous osteomyelitis in children occurs as a sudden illness, with fever and systemic toxicity, or as a subacute illness in which local manifestations predominate. Swelling, erythema and tenderness over the involved bone are characteristic. The leukocyte count is often conspicuously increased, but it is normal in so many cases that absence of leukocytosis does not rule out the disease. Erythrocyte sedimentation rate and C-reactive protein are usually elevated but are not specific. Radiologic workup including radiography, computed tomography (CT), magnetic resonance imaging (MRI) and bone scan are very helpful. Bone biopsy is necessary for a definitive diagnosis, since it provides material for histologic examination, microbiological culture and antibiotic sensitivity.

The treatment depends on the stage of the infection. Early osteomyelitis is treated with intravenous antibiotics for 6 or more weeks. Surgery is used to drain and decompress

FIGURE 30-19. Osteomyelitis of the vertebral body. A. Bacterial osteomyelitis expands from one vertebral body to the next by direct invasion of the intervertebral disk and may actually push posteriorly into the spinal canal. The sequence of events in the marrow cavity is similar to that in a long bone. **B.** In **tuberculous osteomyelitis,** the bone is destroyed by resorption of bony trabeculae, which results in mechanical collapse of the vertebrae and extrusion of the intervertebral disk. Tuberculous organisms cannot penetrate the intervertebral disk directly; rather, they extend from one vertebra to the next after mechanical forces destroy and extrude the intervertebral disk.

FIGURE 30-20. Tuberculous spondylitis (Pott disease). A vertebral body is almost completely replaced by tuberculous tissue. Note the preservation of the intervertebral disks.

the infection within the bone or to drain abscesses that do not respond to antibiotic therapy. In long-standing, chronic osteomyelitis, antibiotics alone are not curative and extensive surgical debridement of necrotic bone is often required.

Tuberculosis of Bone Represents Spread from a Primary Focus Elsewhere

Tuberculosis of bone usually originates in the lungs or lymph nodes (see Chapter 9). When the bone infection is caused by the rare bovine type of tubercle bacillus, the initial focus is often in the gut or tonsils. The mycobacteria spread to the bone hematogenously, and only rarely is there direct spread from the lungs or lymph nodes.

Tuberculous Spondylitis (Pott Disease)

Tuberculous spondylitis (i.e., infection of the spine) is a feared complication of childhood tuberculosis. The disease affects vertebral bodies, sparing the lamina, spines and adjacent vertebrae (Figs. 30-19B and 30-20). Thoracic vertebrae are usually affected, especially the 11th thoracic vertebra. The lumbar and cervical vertebrae are less often involved. As a result of currently available effective antibiotic treatment, Pott disease is now rare.

PATHOLOGY: The pathology in tuberculous spondylitis is similar to tuberculosis at other sites. The granulomas first produce caseous necrosis of the bone marrow, which leads to slow resorption of bony trabeculae and, occasionally, to cystic spaces in the bone. Since there is little or no reactive bone formation, affected vertebrae tend to collapse, leading to kyphosis and scoliosis. The intervertebral disk is crushed and destroyed by the compression fracture, rather than by invasion of organisms. The typical "hunchback" of bygone days was often the victim of Pott disease.

If the infection ruptures into the soft tissue anteriorly, pus and necrotic debris drain along the spinal ligaments and form a **cold abscess** (i.e., an abscess lacking acute inflammation). A **psoas abscess** (Fig. 30-19B), which forms near the lower lumbar vertebrae and dissects along the pelvis to emerge through the skin of the inguinal region as a draining sinus, may be the first manifestation of tuberculous spondylitis. Paraplegia results from vascular insufficiency of the spinal nerves, rather than from direct pressure.

Tuberculous Arthritis

Hematogenous spread of tuberculosis may bring organisms to the joint capsule, synovium or intracapsular portion of the bone. Tuberculosis induces granulomas in synovial tissue, which then becomes edematous and papillary and may fill the entire joint space. Massive destruction of the articular cartilage results from undermining granulation tissue in the bone. The destroyed joint is replaced by bone, an effect that produces an immovable joint **(bony ankylosis)**.

Tuberculous Osteomyelitis of the Long Bones

Infection of long bones is the least common bone manifestation of tuberculosis. This infection occurs near the joint, where it also produces arthritis. For unknown reasons, the greater trochanter of the femur is a common site for this disease.

Syphilis of Bone Is Today Rare

Syphilis causes a slowly progressive, chronic, inflammatory disease of bone, characterized by granulomas, necrosis and marked reactive bone formation. It may be acquired through sexual contact or transmitted transplacentally from mother to fetus (see Chapter 9). The bone changes in syphilis depend on the patient's age, endosteal and periosteal changes and the presence or absence of gummas.

Congenital Syphilis

PATHOLOGY: Bone involvement in congenital syphilis may appear as early as the fifth month of gestation and is fully developed at birth. Spirochetes are ubiquitous in the epiphysis and periosteum, where they produce osteochondritis (epiphysitis) and periostitis, respectively (Fig. 30-21). In severe disease, an epiphysis may

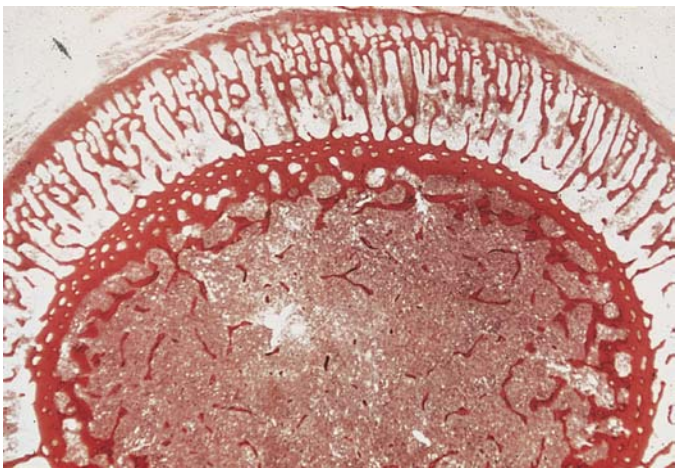

FIGURE 30-21. Congenital syphilis of bone. A cross-section of a tubular bone infected by syphilis shows marked periosteal new bone formation. The medullary cavity is filled with a lymphoplasmacytic infiltrate that replaces the normal marrow fat. The cortex is irregularly destroyed by osteoclastic resorption, a process that stimulates periosteal new bone formation.

become dislocated, leaving the child with a functionless limb **(pseudoparalysis of Parrot)**.

The knee is most often affected by congenital syphilis. The growth plate is irregularly widened and displays a yellow discoloration. After the zone of calcified cartilage is destroyed, a sea of lymphocytes, plasma cells and spirochetes fills the marrow spaces. Because the periosteum is stimulated to produce reactive new bone, the thickness of the cortex may actually be doubled. The inflammatory infiltrate permeates the cortex through the Volkmann and Haversian canals and settles in the elevated periosteum. Ultimately, as the affected bones grow, they become short and deformed.

Acquired Syphilis

Acquired syphilis in adults produces lesions of the bone early in the tertiary stage, 2–5 years after inoculation of the organisms. Periostitis is predominant because the growth plates have already closed. The bones most commonly affected are the tibia, nose, palate and skull. Tibial lesions are marked by periostitis, with deposition of new bone on the medial and anterior aspects of the shaft, which leads to the **saber shin** deformity. The skull thickness also increases because of periosteal stimulation.

Gumma formation is seen most often in tertiary syphilis. Bone adjacent to gummas is slowly replaced by fibrous marrow. Ultimately, perforations occur through the cortex. The markedly irregular, thickened periosteal surfaces, which are perforated by pits and serpiginous ulcerations, are characteristic of syphilis. Lysis and collapse of nasal and palatal bones produce the classic **saddle nose**—perforation, destruction and collapse of the nasal septum (see Chapter 29).

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH) is a generic term (previously referred to as **histiocytosis X**) for three entities characterized by proliferation of Langerhans cells in various tissues: (1) **eosinophilic granuloma,** a localized form; (2) **Hand-Schüller-Christian disease,** a disseminated variant; and (3) **Letterer-Siwe disease,** a fulminant and often fatal generalized disease (see Chapter 26). Studies of X-chromosome inactivation have shown that LCH is a clonal proliferative disease.

PATHOLOGY: The histologic appearance of the bones in all three variants of LCH is identical and is characterized by collections of large, histiocytic cells with pale, eosinophilic cytoplasm and convoluted or grooved nuclei (see Figs. 12-68 and 30-76). By immunohistochemistry, the histiocytic cells stain with CD1a, Langerin and S-100 protein. By electron microscopy these cells have the typical racquet-shaped, tubular structures, **"**Birbeck granules**,"** which are seen in normal Langerhans cells of the skin (see Fig. 30-76, inset). There are many eosinophils throughout these lesions, occasionally forming collections called "eosinophilic abscesses." Multinucleated **osteoclastic** giant cells are often observed, as are chronic inflammatory cells and neutrophils.

The lesions of LCH may occur anywhere in the body, including bones, skin, brain, lungs, lymph nodes, liver and spleen. Radiologic findings in the bones in all three diseases are identical. The lesions may occur in the metaphysis or diaphysis of long bones, or in a flat bone, especially in the skull (Fig. 30-22). They are punched-out lytic defects, with virtually no reactive bone. Such lesions may precipitate fractures and periosteal callus formation.

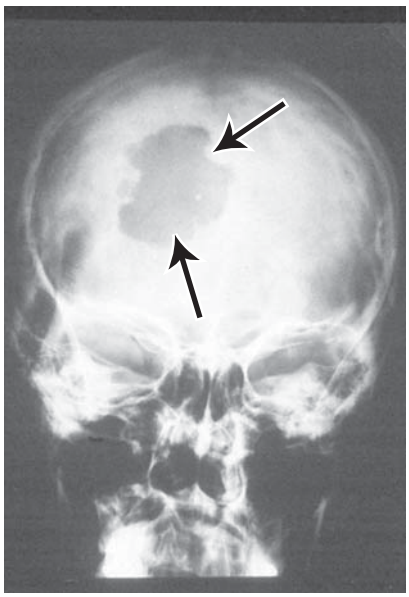

FIGURE 30-22. Eosinophilic granuloma. A radiograph of the skull shows a large, lytic lesion (*arrows*).

Eosinophilic Granuloma Is a Self-Limited Disease

Eosinophilic granuloma, in either its solitary or multiple varieties, accounts for 70% of all cases of LCH. It is usually seen in the first two decades of life but occasionally occurs in older individuals. There are typically one or two lytic areas in bones of the axial or appendicular skeleton (Fig. 30-22) or the vertebrae. These lesions may cause mild pain or may be incidental findings on routine chest radiographs. Foci of disease in the lower thoracic or upper lumbar vertebrae may lead to collapse and pathologic fractures. Eventual recovery is the rule.

Hand-Schüller-Christian Disease Is a Multiorgan Disease of Childhood

Hand-Schüller-Christian disease occurs in children 2–5 years old and represents some 20% of all cases of LCH. The lesions are more widespread than in eosinophilic granuloma. Radiolucent bony lesions characterize the disorder, most frequently in the calvaria, ribs, pelvis and scapulae. Involvement of the jaw bone results in loss of teeth, evident radiologically as "floating teeth." Infiltration of the retroorbital space causes exophthalmos; infiltration of the hypothalamic stalk by Langerhans cells brings about diabetes insipidus. One fifth of patients have lymphadenopathy and lung infiltrates.

Crusty, red, weepy skin lesions occur at the hairline and on the extensor surfaces of the extremities, the abdomen and occasionally the soles of the feet. Deafness results from involvement of the external auditory canal and mastoid air cells. One third of affected patients have disease in the liver and spleen, and 40% have bone lesions, half of which involve

the skull. Thus, the classic triad of Hand-Schüller-Christian disease, namely, **(1) radiolucent lesions of the skull, (2) diabetes insipidus and (3) exophthalmos,** occurs in only one third of patients.

Letterer-Siwe Disease Is an Aggressive, Potentially Fatal Disease of Infants

Letterer-Siwe disease accounts for 10% of cases of LCH. Affected children fail to thrive and become cachectic. Multiple organ involvement culminates in massive hepatosplenomegaly, lymphadenopathy, anemia, leukopenia and thrombocytopenia. Widely scattered, seborrheic skin lesions, which are often hemorrhagic, are usual. Bone lesions are not prominent initially, but progressive marrow replacement and pulmonary infiltration occasionally cause death.

CLINICAL FEATURES: Eosinophilic granuloma is a self-limited disease, and most lesions disappear if left alone. A bone lesion may have to be curetted and packed with bone chips. Sometimes biopsy itself is enough to stimulate repair of the lytic lesion. A collapsed vertebra may actually reconstitute itself over time. Hand-Schüller-Christian disease may require radiation therapy for some bone and retro-orbital lesions. Diabetes insipidus seems to be irreversible, despite irradiation of the pituitary region. Drugs such as corticosteroids, cyclophosphamide and tumoricidal agents may also be used to treat Hand-Schüller-Christian disease. Aggressive chemotherapy for Letterer-Siwe disease seems to improve the prognosis.

Metabolic Bone Diseases

Metabolic bone diseases are defined as disorders of metabolism that result in secondary structural effects on the skeleton, including diminished bone mass due to decreased synthesis or increased destruction, reduced bone mineralization or both. Because metabolic bone diseases are systemic, a biopsy of any bone should reveal the abnormality, even though severity may differ in various parts of the skeleton (Fig. 30-23).

OSTEOPOROSIS

Osteoporosis is a metabolic bone disease in which normally mineralized bone is decreased in mass to the point that it no longer provides adequate mechanical support. Although osteoporosis reflects a number of causes, it is always characterized by loss of skeletal mass. Remaining bone has a normal ratio of mineralized to nonmineralized (i.e., osteoid) matrix. Bone loss and eventually fractures are the hallmarks of osteoporosis, regardless of the underlying causes (Fig. 30-24). The etiology for bone loss is diverse but includes menopause, smoking, vitamin D deficiency, low body mass index, hypogonadism, a sedentary lifestyle and glucocorticoid therapy.

EPIDEMIOLOGY: Osteoporosis and its complications are huge public health problems that are expected to expand as life expectancy increases. Bone mass normally peaks between the ages of 25 and 35 and begins to decline in the fifth or sixth decade. Bone loss with age occurs in all races, but because of higher peak bone mass, blacks are less prone to osteoporosis than are Asians and whites. Bone loss during normal aging in women has been divided into two phases: menopause and aging. The latter affects men as well as women. At a certain point, the loss of bone suffices to justify the label **osteoporosis** and renders weight-bearing bones susceptible to fractures. The most common fractures occur in the neck and intertrochanteric region of the femur (**hip fracture;** Fig. 30-24), vertebral bodies and distal radius **(Colles fracture)**. In whites in the United States, 15% of people have had a hip fracture by the age of 80 years and 25% by age 90. Women have twice the risk of hip fracture as men, although among blacks and some Asian populations, the incidence is equal among the sexes. Compared with other osteoporotic fractures, hip fractures incur the greatest morbidity, mortality (up to 20% within a year) and direct medical costs. The female predominance of 8:1 is particularly striking for vertebral fractures. A subset of women in the early postmenopausal years is at particular risk of vertebral fractures, which are rare in middle-aged men. The propensity of men to sustain hip fractures as opposed to vertebral ones also reflects factors other than bone mass, such as loss of proprioception.

ETIOLOGIC FACTORS AND MOLECULAR PATHOGENESIS: ***Regardless of the cause of osteoporosis, it always reflects enhanced bone resorption relative to formation.*** Thus, this family of diseases should be viewed in the context of the remodeling cycle. Bone resorption and bone formation exist simultaneously. All osteoblasts and osteoclasts belong to a unique temporary structure, known as the **basic multicellular unit** (BMU or **bone-remodeling unit**). The BMU is responsible for bone remodeling throughout life. Individuals younger than 35 or 40 years completely replace bone resorbed during the remodeling cycle. With age, less bone is replaced in resorption bays than is removed, leading to a small deficit at each remodeling site. Given the thousands of remodeling sites in the skeleton, net bone loss, even in a short time, can be substantial.

Osteoporosis is classified as either primary or secondary. **Primary osteoporosis,** by far the more common variety, is of uncertain origin and occurs principally in postmenopausal women (type 1) and elderly people of both sexes (type 2). **Secondary osteoporosis** is a disorder associated with a defined cause, including a variety of endocrine and genetic abnormalities.

Type 1 primary osteoporosis is due to an absolute increase in osteoclast activity. Since osteoclasts initiate bone remodeling, the number of remodeling sites increases in this state of enhanced osteoclast formation, a phenomenon known as **increased activation frequency**.

The increase in osteoclasts in the early postmenopausal skeleton is a direct result of estrogen withdrawal. The effects of lack of estrogen are not, however, targeted directly to the osteoclast, but rather to cells derived from marrow stroma, which secrete cytokines that recruit osteoclasts. These cytokines, which are believed to be estrogen sensitive, include IL-1 and IL-6, TNF and M-CSF.

Type 2 primary osteoporosis, also called **senile osteoporosis,** has a more complex pathogenesis than type 1. Type 2 osteoporosis generally appears after age 70 and reflects decreased

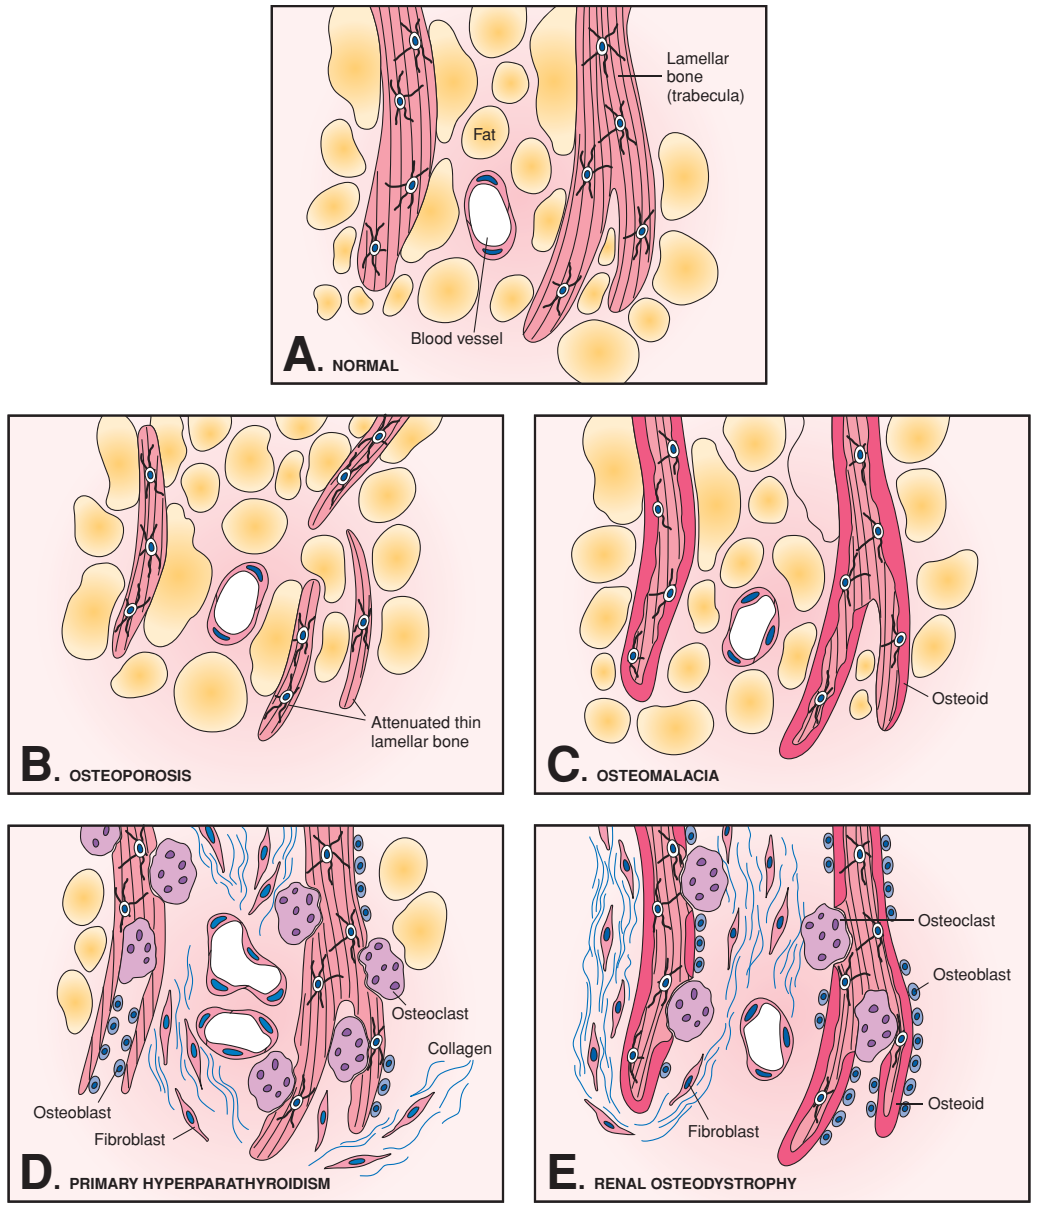

FIGURE 30-23. Metabolic bone diseases. A. Normal trabecular bone and fatty marrow. The trabecular bone is lamellar and contains evenly distributed osteocytes. **B. Osteoporosis.** The lamellar bone trabeculae are discontinuous and thin. **C. Osteomalacia.** The lamellar bone trabeculae have abnormal amounts of nonmineralized bone (osteoid). These osteoid seams are thickened and cover a larger than normal area of the trabecular bone surface. **D. Primary hyperparathyroidism.** The lamellar bone trabeculae are actively resorbed by numerous osteoclasts that bore into each trabecula. The appearance of osteoclasts dissecting into the trabeculae, a process termed **dissecting osteitis,** is diagnostic of hyperparathyroidism. Osteoblastic activity also is pronounced. The marrow is replaced by fibrous tissue adjacent to the trabeculae. **E. Renal osteodystrophy.** The morphologic appearance is similar to that of primary hyperparathyroidism, except that prominent osteoid covers the trabeculae. Osteoclasts do not resorb unmineralized bone, and wherever an osteoid seam is lacking, osteoclasts bore into the trabeculae. Osteoblastic activity is also prominent.

osteoblast function. Thus, although osteoclast activity is no longer increased, the number of osteoblasts and amount of bone produced per cell are insufficient to replace bone removed in the resorptive phase of the remodeling cycle.

Primary Osteoporosis Is Caused by a Number of Factors

Primary osteoporosis has been linked to a number of factors that influence peak bone mass and the rate of bone loss:

- **Genetic factors:** Environmental factors and an individual's genotype both play a role in determining peak bone mass and risk of osteoporosis. The development of clinically significant osteoporosis is related, in largest part, to the maximal amount of bone in a given person, referred to as the **peak bone mass**. In general, peak bone mass is greater in men than in women and in blacks than in whites or Asians. There is a higher concordance of peak bone mass in monozygotic than in dizygotic twins. Women of reproductive age whose mothers have postmenopausal

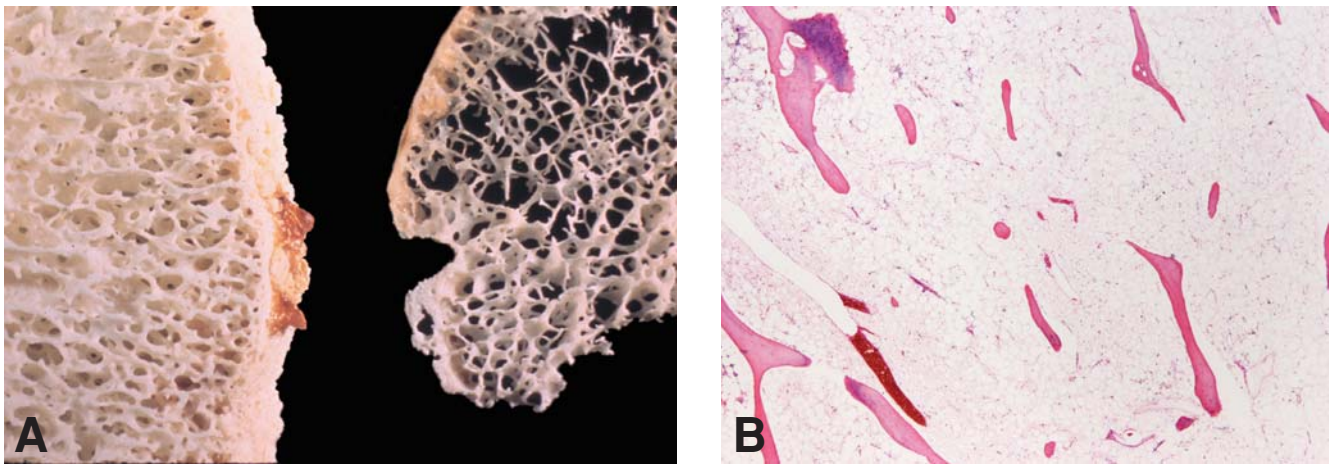

FIGURE 30-24. Osteoporosis. A. Femoral head of an 82-year-old female with osteoporosis and a femoral neck fracture (*right*) compared with a normal control cut to the same thickness (*left*). **B.** Microscopically, there is reduction in the size and thickness of bone trabeculae and loss of connectivity.

osteoporosis exhibit a lower bone mineral density (BMD) than do women in the general population. BMD is the most commonly used index for defining and studying osteoporosis. Genetic factors are thought to play an important role in regulating BMD. In fact, genetic variations explain as much as 70% of the variance in BMD. Sequence variance in the vitamin D receptor (VDR), *Col1A1* collagen gene, estrogen receptor-α (ESR1), IL-6 and low-density lipoprotein (LDL) receptor–related protein-5 (LRP5) are significantly associated with differences in BMD. Furthermore, VDR and IL-6 interact with environmental and hormonal factors (e.g., calcium intake, estrogen) to modulate BMD.

- **Calcium intake:** The average calcium intake of postmenopausal women in the United States is below the recommended value of 800 mg/day. However, whether this apparent shortfall contributes to development of osteoporosis is controversial, in view of a number of studies to the contrary. Nevertheless, it has been recommended that both premenopausal and postmenopausal women increase the intake of calcium and vitamin D.
- **Calcium absorption and vitamin D:** Calcium absorption by the intestine decreases with age. Because calcium absorption is largely under the control of vitamin D, attention has been directed to the role of this steroid hormone in osteoporosis. Compared with controls, people with osteoporosis have lower circulating levels of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], the active form of vitamin D that promotes calcium absorption in the intestine. This decrease has been attributed to age-related decreases in 1α-hydroxylase activity in the kidney, the enzyme that catalyzes formation of 1,25$(OH)_2$D. The lower 1α-hydroxylase activity has been attributed to diminished stimulation of the enzyme by PTH, as well as an age-related decrease in responses of renal tubules to PTH. Interestingly, giving estrogens to postmenopausal women with osteoporosis increases both circulating 1,25$(OH)_2$D and calcium absorption. It has been suggested that decreased 1α-hydroxylase activity in the kidney may stimulate PTH secretion, and so contribute to bone resorption.
- **Exercise:** Physical activity is necessary to maintain bone mass, and athletes often have increased bone mass. By contrast, immobilization of a bone (e.g., prolonged bed rest, application of a cast) elicits accelerated bone loss. The weightlessness of space flight results in severe bone loss (33% of trabecular bone mass in 25 weeks). Yet vigorous exercise in this setting does not seem to increase bone mass substantially or prevent osteoporosis.
- **Environmental factors:** Cigarette smoking in women has been correlated with an increased incidence of osteoporosis. It is possible that the decreased level of active estrogens produced by smoking is responsible for this effect.

In summary, the two major determinants of primary osteoporosis are estrogen deficiency in postmenopausal women and the aging process in both sexes. The possible mechanisms for these effects are summarized in Fig. 30-25.

PATHOLOGY: ***The ratio of osteoid to mineralized bone is normal in individuals with osteoporosis.*** Because of the abundance of cancellous bone in the spine, osteoporotic changes are generally most conspicuous there. In vertebral body fractures caused by osteoporosis, the vertebra is deformed, with anterior wedging and collapse. If the vertebral body is not fractured, there is a general outline of both endplates, with a virtual absence of cancellous bone.

Osteoporosis is characterized histologically by decreased thickness of the cortex and reduction in the number and size of trabeculae of the coarse cancellous bone (Fig. 30-24). Although senile osteoporosis tends to feature reduced trabecular thickness, postmenopausal osteoporosis exhibits disrupted connections between trabeculae. The loss of trabecular connectivity, which is attended by diminished biomechanical strength and ultimately provokes fracture, is due to perforation of trabeculae by resorbing osteoclasts in remodeling sites. In histologic sections, the loss of connectivity results in the appearance of "isolated" islands of bone (Figs. 30-23B and 30-24B).

CLINICAL FEATURES: Postmenopausal osteoporosis is usually recognizable within 10 years after onset of the menopause; senile osteoporosis generally becomes symptomatic after age 70 years. Until recently, most patients were unaware of their disease until they had a fracture of a vertebra, hip or other bone. However, the use of sensitive screening techniques permits early

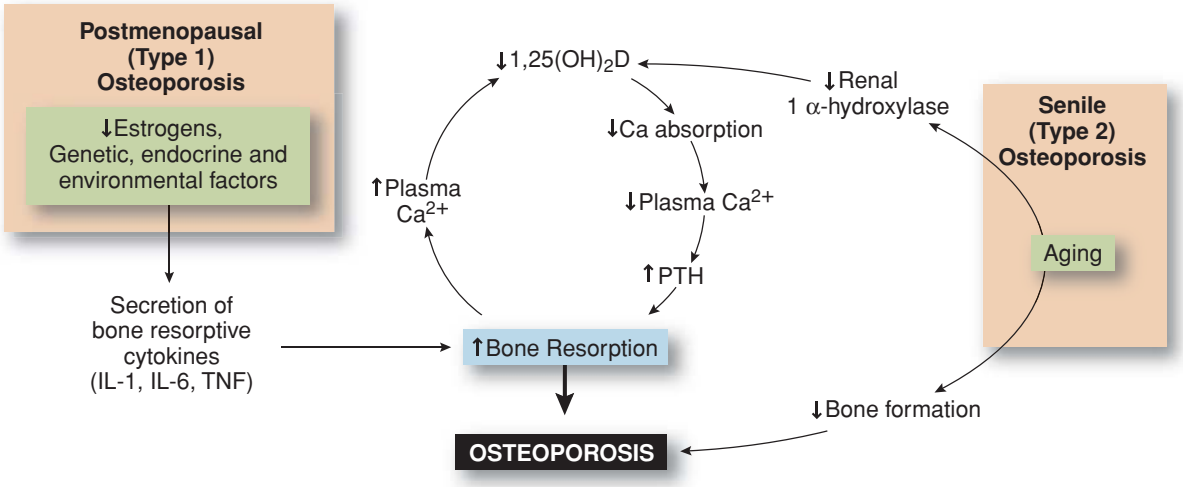

FIGURE 30-25. Pathogenesis of primary osteoporosis. Ca^{2+} = calcium; *IL* = interleukin; *PTH* = parathyroid hormone; *TNF* = tumor necrosis factor.

diagnosis. Vertebral body compression fractures often occur after trivial trauma or may even follow lifting a heavy object. With each compression fracture, the patient becomes shorter and develops kyphosis **(dowager's hump)**. Serum calcium and phosphorus levels remain normal.

Estrogen therapy is an effective yet controversial means of preventing postmenopausal osteoporosis. Because hormone treatment carries with it increased risks of breast and endometrial cancers, other bone-specific antiosteoporotic drugs have been developed. **Bisphosphonates** are currently the most popular therapeutic agents used. All successful antiosteoporotic agents thus far developed block or slow the rate of bone resorption but do not stimulate bone formation. Thus, the drugs may prevent disease progression but cannot cure a patient who already has osteoporosis. Dietary calcium supplementation in elderly patients reduces the risk of osteoporotic fractures by half.

Secondary Osteoporosis Reflects Extraosseous Metabolic Disorders

ETIOLOGIC FACTORS AND MOLECULAR PATHOGENESIS: Causes of secondary osteoporosis include adverse effects of drug therapy, endocrine abnormalities, eating disorders, immobilization, marrow-related conditions, diseases of the gastrointestinal or biliary tracts, renal insufficiency and cancer.

- **Endocrine conditions:** The most common form of secondary osteoporosis is iatrogenic and results from corticosteroid administration. Bone loss may also result from an excess of endogenous glucocorticoids, as in Cushing disease (see Chapter 27). Corticosteroids inhibit osteoblastic activity, thus reducing bone formation. They also impair vitamin D–dependent intestinal calcium absorption, an effect that leads to increased secretion of PTH and enhanced bone resorption.

  Estrogen is a key hormone for maintaining bone mass, and its deficiency is the major cause of age-related bone loss in both sexes; estrogen deficiency or a low level of bioavailable estrogen decreases bone mass in elderly males. Its role in bone metabolism is focused on the role of proinflammatory cytokines: IL-1, IL-6, TNF-α, RANKL, granulocyte-macrophage colony-stimulating factor (GM-CSF), M-CSF and prostaglandin E_2 (PGE_2). It is thought that these cytokines act upon both osteoclasts and osteoblasts via mediation by estrogen receptors.
- **Hyperparathyroidism** induces osteoclast recruitment and increased osteoclastic activity, resulting in secondary osteoporosis (see below). In both sexes, hyperparathyroidism secondary to calcium malabsorption increases remodeling, worsening the cortical thinning and porosity and predisposing to hip fractures.
- **Hyperthyroidism** increases osteoclastic activity and causes accelerated turnover of bone. Although thyrotoxicosis is associated with some secondary osteoporosis, bone loss is limited.
- **Hypogonadism** in both men and women is accompanied by osteoporosis. In women with primary gonadal failure (Turner syndrome) or with secondary amenorrhea as a result of pituitary disease, estrogen deficiency is likely the cause. Hypogonadal men (e.g., Klinefelter syndrome, hemochromatosis) are at risk of osteoporosis because of a deficiency of anabolic androgens. Similarly, hypogonadism contributes to bone loss in 25% of elderly males. There is evidence of decreased bone density in androgen deprivation therapy for prostatic cancer.
- **Hematologic malignancies:** A variety of hematologic cancers, particularly multiple myeloma, are accompanied by significant bone loss. The malignant plasma cells of multiple myeloma secrete osteoclast-activating factor, which is presumably responsible for secondary osteoporosis. Some leukemias and lymphomas are also associated with osteoporosis. Even in the absence of skeletal metastases, some neoplasms (e.g., squamous cell carcinoma of lung) are associated with severe hypercalcemia due to bone resorption. Osteoclastic activity is enhanced in these patients, owing to secretion of PTH-related protein by the tumor (paraneoplastic syndrome).
- **Malabsorption:** Gastrointestinal and hepatic diseases that cause malabsorption often contribute to osteoporosis, probably because of impaired absorption of calcium, phosphate and vitamin D.

- **Alcoholism:** Chronic alcohol abuse also has been linked to development of osteoporosis. Alcohol is a direct inhibitor of osteoblasts and may also inhibit calcium absorption.

OSTEOMALACIA AND RICKETS

Osteomalacia (soft bones) ***is a disorder of adults characterized by inadequate mineralization of newly formed bone matrix.*** **Rickets** ***refers to a similar disorder in children, in whom the growth plates (physes) are open.*** Thus, children with rickets manifest defective mineralization not only of bone (osteomalacia) but also of the cartilaginous matrix of the growth plate. Diverse conditions associated with osteomalacia and rickets include abnormalities in vitamin D metabolism, phosphate deficiency states and defects in the mineralization process itself.

Vitamin D Metabolism Influences Bone Mineralization

MOLECULAR PATHOGENESIS: Vitamin D is ingested in food or synthesized in the skin from 7-dehydrocholesterol under the influence of ultraviolet light (Fig. 30-26). The vitamin is first hydroxylated in the liver to form its major circulating metabolite, 25-hydroxyvitamin D, then hydroxylated again in proximal renal tubules to produce the active hormone $1,25(OH)_2D$. Exposure to sunlight provides sufficient vitamin D for bone growth and mineralization, even if there is an inadequate dietary source.

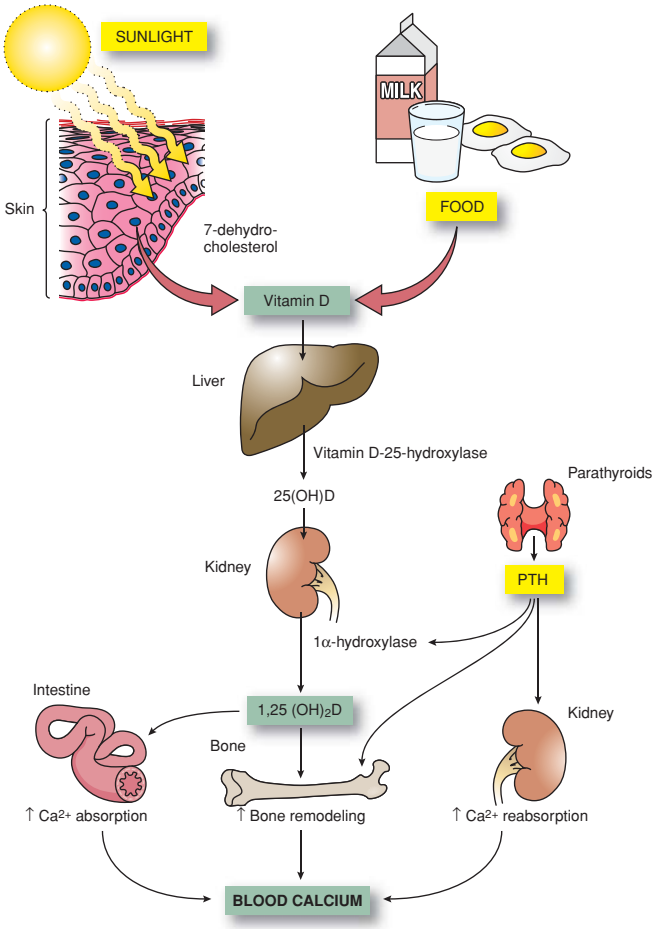

FIGURE 30-26. Metabolism of vitamin D and the regulation of blood calcium.

Receptors for $1,25(OH)_2D$ are present not only in classic targets, such as intestine, bone and kidney, but also in many other cell types. This hormone is a general inducer of differentiation, for example, influencing maturation of hematopoietic and dermal cells, as well as many cancers. In the intestine, $1,25(OH)_2D$ stimulates calcium and phosphate absorption. It is also essential for osteoclast maturation. Regardless of mechanism, $1,25(OH)_2D$, in concert with PTH, maintains blood calcium and phosphate at levels that are required for proper mineralization of bone. ***The key determinant of the formation of 1,25(OH)$_2$D is blood calcium concentration.*** Decreases in blood calcium stimulate release of PTH, which augments renal synthesis of $1,25(OH)_2D$.

Hypovitaminosis D can result from (1) inadequate exposure to sunlight, (2) deficient dietary intake or (3) defective intestinal absorption. There are also hereditary and acquired disorders of vitamin D metabolism.

Dietary Deficiency of Vitamin D and Inadequate Exposure to Sunlight Cause Rickets

Rickets plagued some 85% of children in the industrial cities of the United States and Europe from the 17th century through the 19th century. These children had insufficient sun exposure, and their dietary intake of vitamin D was inadequate to avert hypovitaminosis D. Use of vitamin D–rich cod liver oil and later fortification of milk and other foods with vitamin D effectively ended widespread rickets in Western countries. However, nutritional vitamin D deficiency remains a problem elsewhere in the world, in the neglected elderly and in food faddists.

Intestinal Malabsorption Decreases the Availability of Vitamin D

In industrialized countries, diseases associated with intestinal malabsorption cause osteomalacia more often than does poor nutrition. ***Intrinsic diseases of the small intestine, cholestatic disorders of the liver, biliary obstruction and chronic pancreatic insufficiency are the most frequent causes of osteomalacia in the United States.***

Malabsorption of vitamin D and calcium complicates a number of small-intestinal diseases, including celiac disease, Crohn disease, scleroderma and the postsurgical blind-loop syndrome. In obstructive jaundice, the lack of bile salts in the intestine impairs absorption of lipids and lipid-soluble substances, among which is fat-soluble vitamin D. Furthermore, hydroxylation of vitamin D is reduced in cases of severe liver damage. Oddly, biliary cirrhosis, a disease characterized by intestinal malabsorption and vitamin D deficiency, gives rise to osteoporosis rather than osteomalacia. Thus, vitamin D is essential not only for mineralization but also for the synthesis of bone collagen.

Disorders of Vitamin D Metabolism Are Inherited or Acquired

Vitamin D metabolism can be disturbed either by defective 1α-hydroxylation of vitamin D in the kidney or by

insensitivity of the target organ to $1,25(OH)_2D$. Two autosomal recessive diseases associated with rickets are together known as **vitamin D–dependent rickets**.

- **Vitamin D–dependent rickets type I** results from an inherited deficiency of renal 1α-hydroxylase activity. The clinical and biochemical changes of rickets appear during the first year of life, and these children exhibit hypocalcemia, hypophosphatemia and high levels of serum PTH and alkaline phosphatase. The disease is controlled by the administration of $1,25(OH)_2D$.
- **Vitamin D–dependent rickets type II** involves inherited mutations of the vitamin D receptor, so that end organs are insensitive to $1,25(OH)_2D$. The disease usually manifests early in life but may appear at any time up to adolescence. Serum concentrations of $1,25(OH)_2D$ are very high. Patients do not respond to $1,25(OH)_2D$ but are helped by repeated intravenous administration of calcium.
- **Acquired alterations in vitamin D metabolism** include defective renal 1α-hydroxylation and end-organ insensitivity. Some of the causes of impaired α-hydroxylation are hypoparathyroidism, tumor-induced osteomalacia, chronic renal diseases and osteomalacia of old age. Osteomalacia occasionally complicates the treatment of epilepsy with anticonvulsant drugs, particularly phenobarbital and phenytoin. It is believed that these drugs block the action of $1,25(OH)_2D$ on target organs.

Renal Disorders of Phosphate Metabolism Interfere with Vitamin D Metabolism

Both rickets and osteomalacia may result from impaired reabsorption of phosphate by the proximal renal tubules, with resulting hypophosphatemia.

MOLECULAR PATHOGENESIS:

X-LINKED HYPOPHOSPHATEMIA: This condition, also known as **vitamin D–resistant rickets** or **phosphate diabetes,** is the most common type of hereditary rickets and is inherited as a dominant trait. Mutations in the *PHEX* (phosphate-regulating) gene on the X chromosome (Xp22) impair transport of phosphate across the luminal membrane of proximal renal tubular cells. The gene product of *PHEX* is a protease that inactivates fibroblast growth factor-23 (FGF23). Increased levels of FGF23 produced renal phosphate wasting. Although renal phosphate wasting is central to the disease, osteoblast function is also impaired. In boys, florid rickets appears during childhood, but girls often suffer only hypophosphatemia. Treatment consists of lifelong administration of phosphate and $1,25(OH)_2D$. Microscopically, the bones of patients with X-linked hypophosphatemia show severe osteomalacia and wide osteoid seams. They also exhibit characteristic hypomineralized areas surrounding osteocytes, known as **halos**. The presence of these structures indicates that osteocytes are responsible for the terminal mineralization of bone.

FANCONI SYNDROMES: These inborn errors of metabolism are characterized by renal wastage of phosphate, glucose, bicarbonate and amino acids. They are all characterized by renal tubular acidosis and lead to rickets and osteomalacia. Fanconi syndromes include Wilson disease, tyrosinemia, galactosemia, glycogen storage disease and cystinosis. Renal tubular damage that leads to phosphate wastage may also be acquired, as in lead or mercury intoxication, amyloidosis and Bence-Jones proteinuria.

TUMOR-ASSOCIATED OSTEOMALACIA: This disorder is a phosphate-wasting syndrome that is associated with predominantly benign and occasionally malignant tumors of soft tissue and bone. The typical laboratory features are hypophosphatemia, hyperphosphaturia, low serum concentrations of $1,25\text{-}(OH)_2D$ and elevated serum alkaline phosphatase. Oncogenic osteomalacia mimics the clinical phenotype of X-linked hypophosphatemia and autosomal dominant hypophosphatemia. The paraneoplastic phosphaturic factors secreted by the tumor, known as **phosphatonins,** cause renal tubular phosphate wasting and prevent tubular conversion of 25-hydroxyvitamin D into $1,25(OH)_2D$. Phosphatonins thus appear to have the same effect as inherited mutations of the *PHEX* gene seen in X-linked hypophosphatemia. Removal of the primary tumor is often curative. FGF23 has been implicated as a phosphatonin. Overproduction of FGF23 by tumors results in renal phosphate wasting and tumor-associated osteomalacia.

PATHOLOGY:

OSTEOMALACIA: Osteomalacia, like osteoporosis, causes an osteopenic radiologic pattern. The only findings may be vertebral compression fractures and decreased bone thickness, as in osteoporosis. However, some specific findings may be seen in osteomalacia, including the pseudofractures of **Milkman-Looser syndrome.** These are radiolucent transverse defects that are most common on the concave side of a long bone, medial side of the neck of the femur, ischial and pubic rami, ribs and scapula.

Microscopically, defective mineralization in osteomalacia results in **exaggeration of osteoid seams,** both in thickness and in the proportion of trabecular surface covered (Figs. 30-23 and 30-27). Osteoid seams reflect a time lag between the deposition of collagen and the appearance of the calcium salt. Although adults add 1 μm of new matrix to the surfaces of bone every day, it requires approximately 10 days to mineralize this new bone. The normal thickness of osteoid seams, therefore, does not exceed 12 μm. Areas of pseudofracture display abundant osteoid and may function as stress points for true fractures. These areas do not evoke

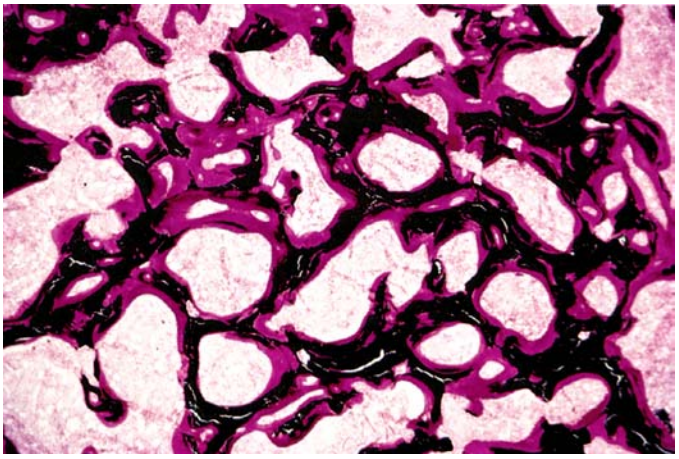

FIGURE 30-27. Osteomalacia. The surfaces of the bony trabeculae (*black*) are covered by a thicker than normal layer of osteoid (*red*) with the von Kossa stain, which colors calcified tissue black.

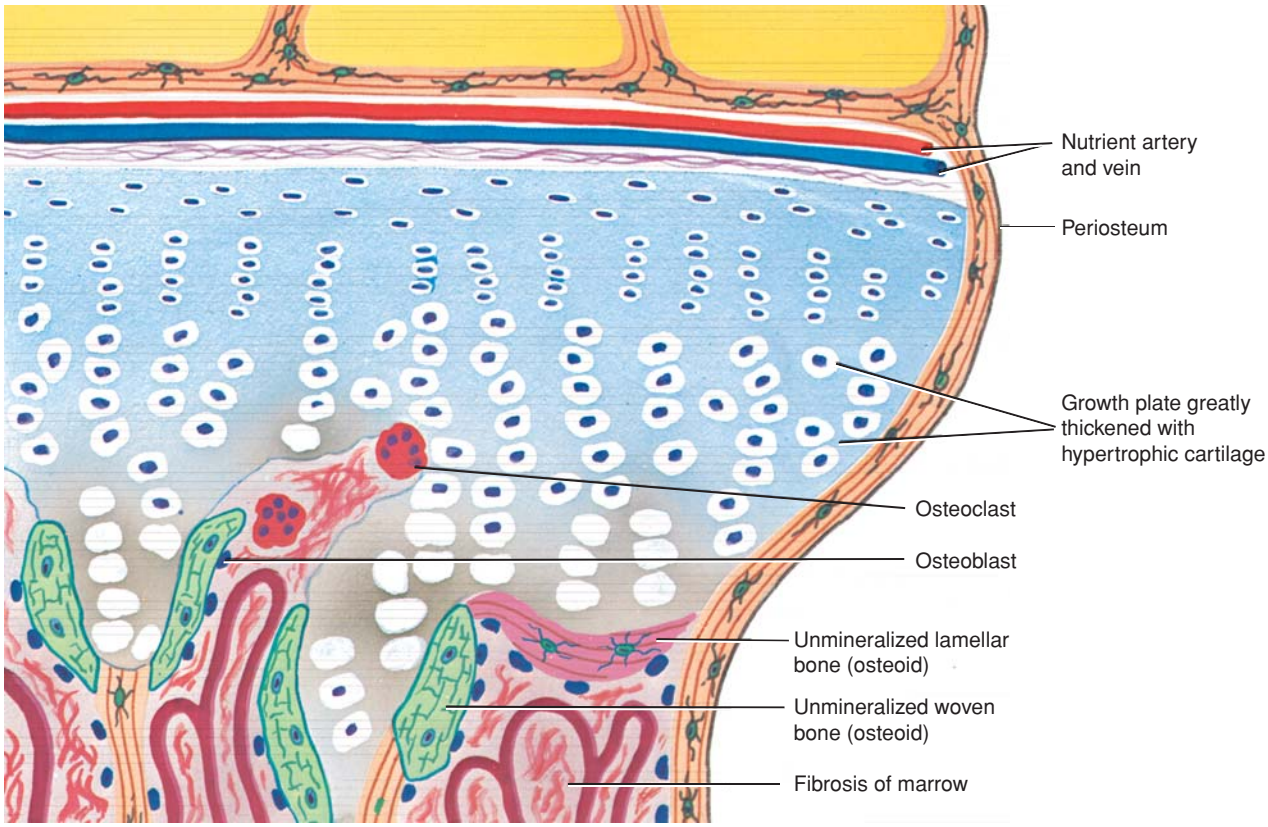

FIGURE 30-28. The growth plate in rickets. The growth plate is thickened and disorganized, with a large zone of hypertrophic cartilage cells. Irregular perforation of the cartilage plate by osteoclasts occurs because there is little calcified cartilage. The woven bone on the surface of some of the primary trabeculae is unmineralized and therefore easily fractured. Such microfractures often lead to hemorrhage at the interface between the plate and the metaphysis.

formation of callus and do not extend through the entire diameter of the bone.

RICKETS: Rickets is a disease of children and thus causes extensive changes at the physeal plate (Fig. 30-28), which does not become adequately mineralized. The calcified cartilage and zones of hypertrophy and proliferative cartilage continue to grow because osteoclastic activity does not resorb the poorly mineralized growth plate cartilage. As a consequence, the growth plate is conspicuously thickened, irregular and lobulated. Endochondral ossification proceeds very slowly and preferentially at the peripheral portions of the metaphysis. The result is a flared, cup-shaped epiphysis. The largest part of the primary spongiosum is composed of lamellar or woven bone that, importantly, remains unmineralized.

Microscopically, the growth plate exhibits striking changes. The resting zone is normal, but the zones of proliferating cartilage are greatly distorted. The ordered progression of helix-forming chondrocytes is lost and is replaced by a disorderly profusion of cells separated by small amounts of matrix. Resulting lobulated masses of proliferating and hypertrophied cartilage are associated with increasing width of the growth plate, which may be 5–15 times the normal width. The zone of provisional calcification is poorly defined, and only a minimal amount of primary spongiosum is formed. Masses of proliferating cartilage extend into the metaphyseal region, without any apparent vascular invasion and with little osteoclastic activity.

CLINICAL FEATURES:

OSTEOMALACIA: Clinical diagnosis of osteomalacia is often difficult. Patients have nonspecific complaints, such as muscle weakness or diffuse aches and pains. In mild forms of the disease, only slowly progressive changes in bone are seen, and many patients are totally asymptomatic for years. In advanced cases, poorly localized bone pain and tenderness are common, especially in the spine, pelvis and proximal parts of the extremities. In such cases, the diagnosis may be made only after an acute fracture, the most common sites being the femoral neck, pubic ramus, spine or ribs. Muscular weakness and hypotonia lead to a waddling gait in severe cases, and some patients are unable to walk.

RICKETS: Children with rickets are apathetic and irritable and have short attention spans. They are content to be sedentary, assuming a "Buddha-like" posture. They are short, with characteristic changes of bones and teeth. Flattening of the skull, prominent frontal bones **(frontal bossing)** and conspicuous suture lines are typical. Delayed dentition is associated with severe dental caries and enamel defects. The chest has the classic **rachitic rosary** (a grossly beaded appearance of the costochondral junctions due to enlargement of the costal cartilages) and indentations of the lower ribs at the insertion of the diaphragm (Harrison groove). **Pectus carinatum** ("pigeon breast") reflects an outward curvature of the sternum.

The overall musculature is weak, and abdominal weakness generates a "potbelly." The limbs are shortened and

deformed, with severe bowing of the arms and forearms and frequent fractures. The femoral head may dislocate from the growth plate (slipped capital femoral epiphysis).

PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is a metabolic bone disease characterized by generalized bone resorption due to inappropriate secretion of PTH. Early in the 20th century, bone disease in patients diagnosed with primary hyperparathyroidism was often advanced and crippling. Owing to screening of hospitalized patients for abnormalities of serum calcium, severe primary hyperparathyroidism is rarely encountered nowadays and clinically significant bone disease is unusual.

The histologic changes of primary hyperparathyroidism are known as **osteitis fibrosa**. This term applies to all circumstances of markedly accelerated bone remodeling and may be seen in Paget disease, in hyperthyroidism and even in some patients with postmenopausal osteoporosis.

ETIOLOGIC FACTORS: ***Some 90% of cases of primary hyperparathyroidism are caused by one or more parathyroid adenomas. Hyperplasia of all four glands accounts for only 10%.*** Because PTH promotes phosphate excretion in the urine and stimulates osteoclastic bone resorption, low serum phosphate and high serum calcium levels are characteristic. A familial type of primary hyperparathyroidism is associated with mutations in the calcium-sensing receptor (*CASR*) gene, located on chromosome 3 (3q13.3).

The effects of PTH are mediated by its effects on bone, kidney and (indirectly) intestine.

BONE: PTH mobilizes calcium from bone (the major reservoir of calcium in the body) by causing increased osteoclasis by extant osteoclasts and by recruitment of new osteoclasts from preosteoclastic mesenchymal cells. This action is indirect and is mediated by direct stimulation of osteoblasts by PTH. As a result, osteoblasts secrete RANKL, which then binds to RANK in osteoclasts and osteoclast precursors and results in bone resorption. Under physiologic circumstances, PTH secretion is shut down by increases in ionic calcium. At the same time, the osteoblast stimulation by PTH tends to cause balanced remodeling and does not result in a net loss of bone mass. By contrast, under pathologic conditions, the release of large amounts of PTH and continued RANKL secretion prevent osteoclast apoptosis, prolong osteoclast life and activation and induce a net loss of bone mass.

KIDNEY: PTH stimulates reabsorption of calcium by the thick ascending and granular portions of the distal renal tubules. It also enhances phosphate excretion in the proximal and distal tubules by directly inhibiting sodium-dependent phosphate transport. PTH also augments the activity of 1α-hydroxylase in the proximal tubules and stimulates production of $1,25(OH)_2D$.

INTESTINE: PTH does not act directly on the intestine, but rather enhances intestinal calcium absorption indirectly by increasing renal synthesis of $1,25(OH)_2D$.

PATHOLOGY: The histogenesis of osteitis fibrosa may be classified into three stages:

- **Early stage:** Initially osteoclasts are stimulated by the increased PTH levels to resorb bone. From the subperiosteal and endosteal surfaces, osteoclasts bore their way into the cortex as cutting cones. This process is called **dissecting osteitis** because each osteon is continually hollowed out by osteoclastic activity (Figs. 30-23 and 30-29A). At the same time, collagen fibers are laid down in the endosteal marrow and additional osteoclasts penetrate the bone. In contrast to myelofibrosis of hematologic origin, in which fibrous tissue is randomly distributed in the marrow space, the collagen of osteitis fibrosa is deposited adjacent to trabeculae. This observation suggests that the stromal cells depositing matrix material are osteoblast precursors.
- **Osteitis fibrosa:** In the second stage, the trabecular bone is resorbed and marrow is replaced by loose fibrosis, hemosiderin-laden macrophages, areas of hemorrhage from microfractures and reactive woven bone. These features constitute the "osteitis fibrosa" portion of the complex.
- **Osteitis fibrosa cystica:** As primary hyperparathyroidism progresses and hemorrhage continues, cystic degeneration ultimately occurs, evoking the final stage of the

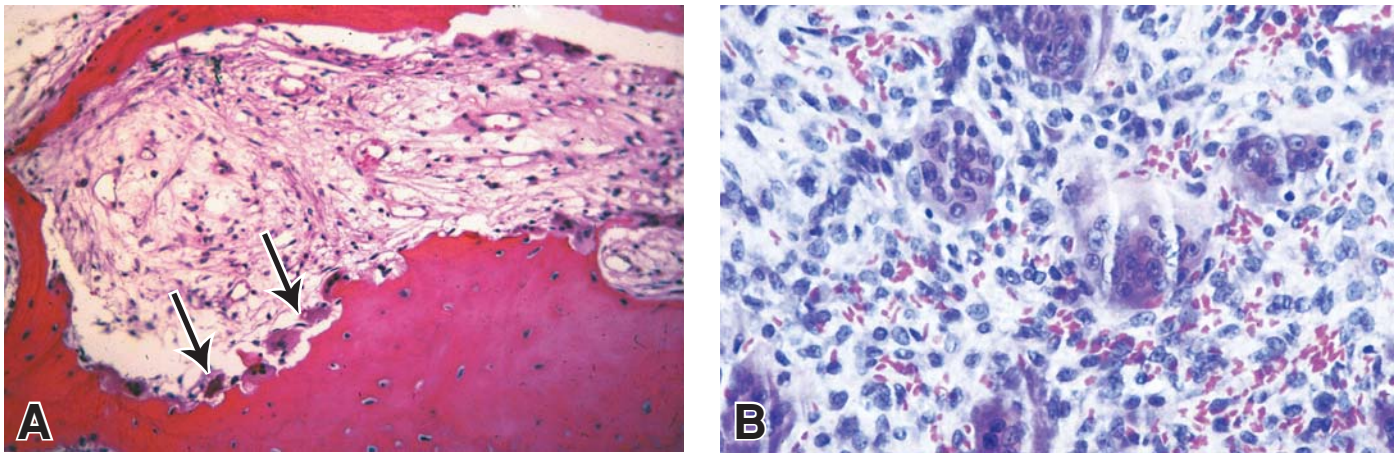

FIGURE 30-29. Primary hyperparathyroidism. A. Section through compact bone shows tunneling resorption of a Haversian canal. Numerous osteoclasts (*arrows*) and stromal fibrosis are evident. **B.** A section of tissue obtained from a "brown tumor" reveals numerous giant cells in a cellular fibrous stroma. Scattered erythrocytes are present throughout the tissue.

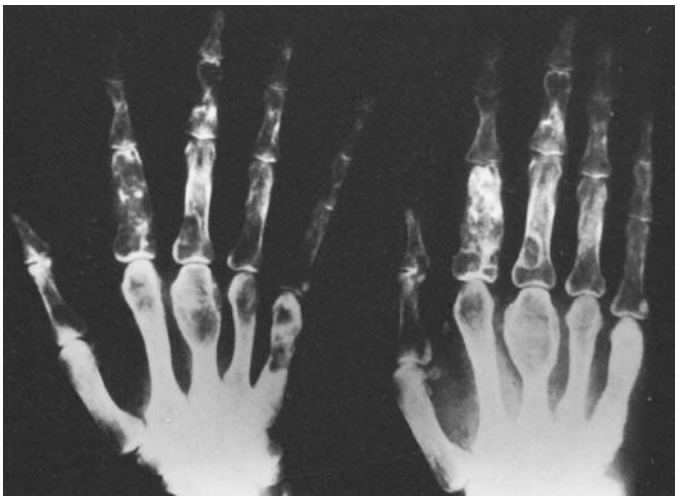

FIGURE 30-30. Primary hyperparathyroidism. A radiograph of the hands reveals bulbous swellings ("brown tumors") and numerous cavities, both representing bone resorption.

disease. The areas of fibrosis that contain reactive woven bone and hemosiderin-laden macrophages often display many osteoclastic giant cells. Because of its macroscopic appearance, this lesion has been dubbed **brown tumor** (Fig. 30-29B). This is not a neoplasm, but rather a repair reaction as an end stage of hyperparathyroidism.

The skeletal radiographs of most patients with primary hyperparathyroidism are normal. Some patients exhibit mottled bone cortices with an irregular frayed surface in the outer table of the skull, tufts of the terminal digits and shafts of the metacarpals (Fig. 30-30). A distinctive radiologic peculiarity, referred to as **subperiosteal bone resorption,** is evident in the subperiosteal outer surface of the cortex and reflects dissecting osteitis. Resorption around tooth sockets causes the lamina dura of the teeth to disappear, a well-known finding on radiography.

A classic feature of osteitis fibrosa cystica is the presence of multiple, localized, lytic lesions, which represent hemorrhagic cysts or masses of fibrous tissue. These eccentric and well-demarcated lesions are separated from the soft tissue by a periosteal shell of bone. The focal, tumor-like, lytic lesions always occur in the context of an abnormal skeleton produced by hyperparathyroidism. If a single lesion is examined in isolation, it may be mistaken for a primary giant cell neoplasm of bone.

CLINICAL FEATURES: The symptoms of primary hyperparathyroidism are related to the abnormality of calcium homeostasis and have been summarized as "stones, bones, moans and groans." The "stones" refer to kidney stones and the "bones" to the skeletal changes. The "moans" describe psychiatric depression and other abnormalities associated with hypercalcemia. The "groans" characterize the gastrointestinal irregularities associated with a high serum calcium level.

Primary hyperparathyroidism is treated by surgical removal of the parathyroid adenomas. If parathyroid hyperplasia is the cause of the disease, three and a half glands are usually removed. The remaining fragment suffices to ensure that the patient does not develop hypocalcemia. After surgery, the histologic appearance of the affected skeleton gradually normalizes.

RENAL OSTEODYSTROPHY

Renal osteodystrophy is a complex metabolic bone disease that occurs in the context of chronic renal failure. Severe renal osteodystrophy is most common in patients maintained on long-term dialysis, because they live long enough to develop conspicuous bone disease.

ETIOLOGIC FACTORS AND MOLECULAR PATHOGENESIS: The pathogenesis of renal osteodystrophy is similar to that of osteomalacia, with secondary hyperparathyroidism exerting its influence by way of osteoclastic bone resorption (Fig. 30-23). The development of renal osteodystrophy is summarized as follows:

1. In chronic renal disease, a reduced glomerular filtration rate leads to retention of phosphate, leading to **hyperphosphatemia**. High serum phosphate levels drive down the serum calcium levels.
2. Tubular injury reduces 1α-hydroxylase activity, with a resulting deficiency of $1,25(OH)_2D$.
3. Intestinal calcium absorption is, in turn, decreased, worsening the **hypocalcemia**.
4. Hypocalcemia stimulates **PTH production**. In fact, most patients with end-stage renal disease have substantial hyperparathyroidism. However, PTH does not effectively promote intestinal calcium absorption or renal tubular resorption of calcium because of failure to produce adequate $1,25(OH)_2D$.
5. Perhaps because of hyperparathyroidism and hyperphosphatemia, a substantial proportion of patients with end-stage renal disease have increased bone mass. Renal osteosclerosis is particularly prominent in vertebrae where, owing to alternating bands of radiopaque and normally dense bone, the lesion is named "rugger jersey spine."
6. Osteomalacia may result from the disturbances of the vitamin D pathway.

The **adynamic variant of renal osteodystrophy (ARO)** is characterized by arrested bone remodeling. More than 40% of adults who are treated with hemodialysis and more than 50% of those who are treated with peritoneal dialysis have bone biopsy evidence of ARO. Adynamic bone is characterized microscopically by an overall reduction in cellular activity in bone, with fewer or absent osteoblasts and osteoclasts. These changes can be due either to direct inhibitory effects of systemic factors on osteoblast function or to indirect changes in osteoblast activity mediated through PTH-dependent mechanisms. Old bone accumulates because it is not remodeled, thus causing structural compromise of the skeleton and increased tendency to fractures.

PATHOLOGY AND CLINICAL FEATURES: As a result of these effects of chronic renal failure, renal osteodystrophy is characterized by varying degrees of osteitis fibrosa, osteomalacia, osteosclerosis and adynamic bone disease (Fig. 30-31). Combinations of osteitis fibrosa and osteomalacia are particularly common. Hyperphosphatemic patients

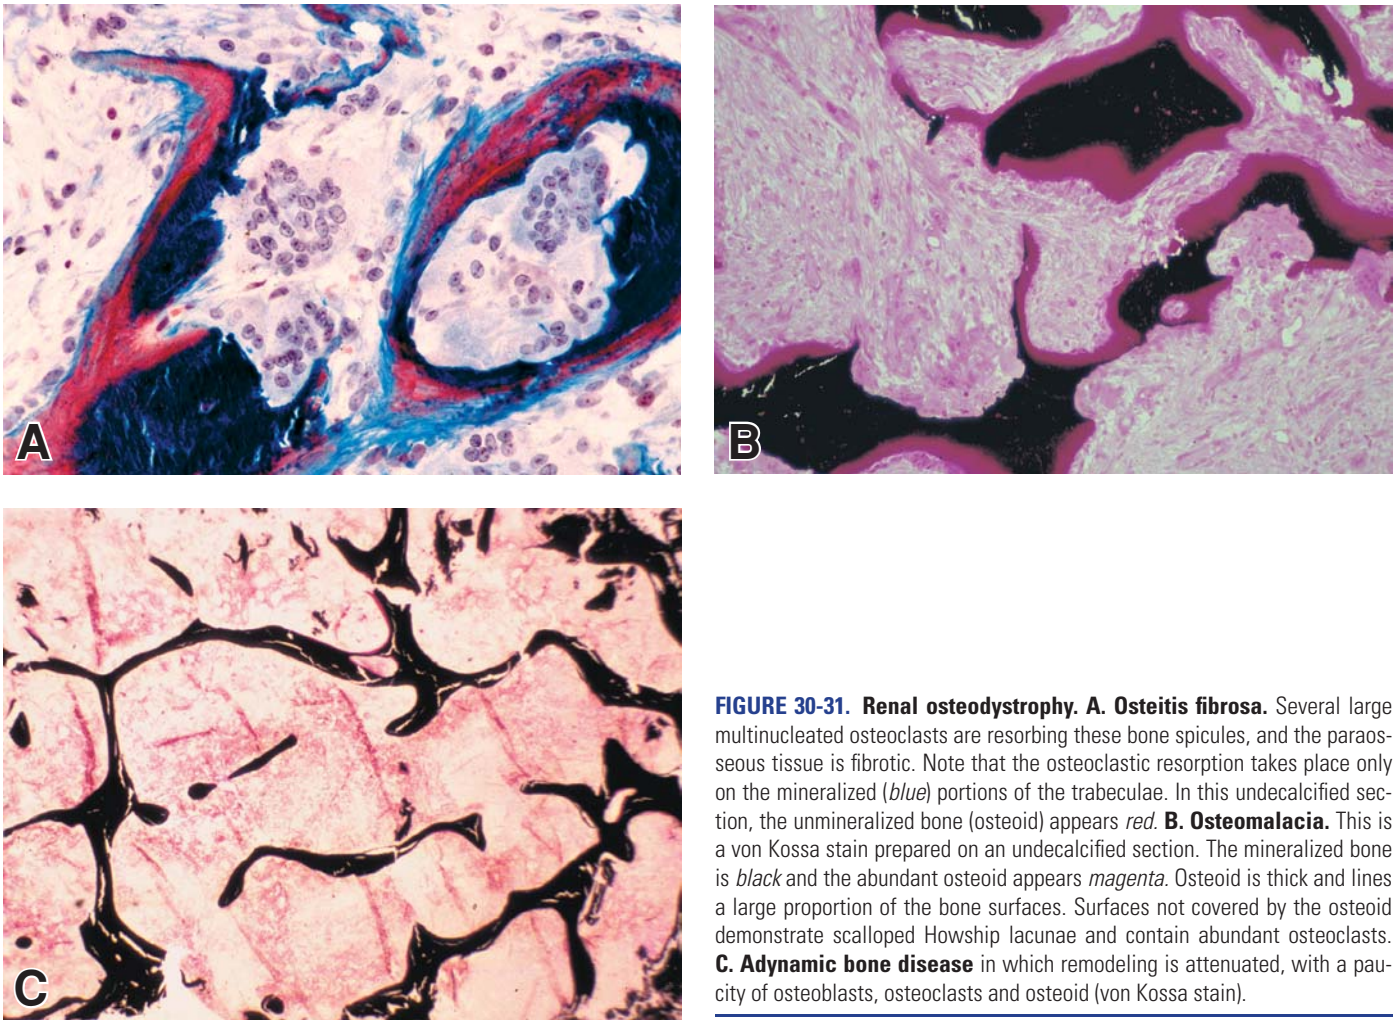

FIGURE 30-31. Renal osteodystrophy. A. Osteitis fibrosa. Several large multinucleated osteoclasts are resorbing these bone spicules, and the paraosseous tissue is fibrotic. Note that the osteoclastic resorption takes place only on the mineralized (*blue*) portions of the trabeculae. In this undecalcified section, the unmineralized bone (osteoid) appears *red*. **B. Osteomalacia.** This is a von Kossa stain prepared on an undecalcified section. The mineralized bone is *black* and the abundant osteoid appears *magenta*. Osteoid is thick and lines a large proportion of the bone surfaces. Surfaces not covered by the osteoid demonstrate scalloped Howship lacunae and contain abundant osteoclasts. **C. Adynamic bone disease** in which remodeling is attenuated, with a paucity of osteoblasts, osteoclasts and osteoid (von Kossa stain).

with terminal chronic renal disease may display metastatic calcification at various sites, including the eyes, skin, muscular coats of arteries and arterioles and periarticular soft tissues.

Management of renal osteodystrophy involves not only treatment of renal failure but also control of phosphate levels by appropriate drug therapy and infusions. Occasionally, parathyroidectomy is required to control hyperparathyroidism, and the administration of vitamin D may also be necessary.

PAGET DISEASE OF BONE

Paget disease is a chronic condition characterized by lesions of bone resulting from disordered remodeling, in which excessive bone resorption initially results in lytic lesions, to be followed by disorganized and excessive bone formation.

EPIDEMIOLOGY: Paget disease generally affects men and women older than 50 years. In predisposed populations, 3% of the elderly manifest the disease. The disorder has an unusual worldwide distribution, afflicting populations of the British Isles and following their migrations throughout the world. People of English descent living in the United States, Australia, New Zealand and Canada have a high incidence of the disease. Northern Europeans have more Paget disease than southern Europeans. The disorder is almost nonexistent in Asia and in the indigenous populations of Africa and South America. For unknown reasons, the incidence of Paget disease appears to have decreased worldwide over the last several decades.

MOLECULAR PATHOGENESIS: James Paget coined the term **osteitis deformans** for this disease over a century ago, but until recently its etiology has been obscure. Paget disease resembles a metabolic bone disease histologically and there is an increase in bone turnover in affected patients. However, its clinical tendency to involve one bone or only a few bones does not fulfill the definition of a metabolic disorder.

A hereditary predisposition has been suggested by reports of almost 100 families in whom Paget disease is transmitted as an autosomal dominant trait with incomplete penetrance that increases with age. There is evolving evidence that Paget disease and some related diseases are caused by mutations in genes encoding proteins in the RANK signaling pathway. Specifically, mutations in *Sequestosome 1* (*SQSTM1*) have been found in familial and sporadic forms of Paget disease. The *SQSTM1* gene encodes a protein, also known as p62, which may act as a scaffold protein in the RANK signaling pathway. It is currently unknown how this mutated protein leads to accelerated osteoclast activity. Inactivation of *SQSTM1* causes defects in RANKL-induced osteoclastogenesis, suggesting a significant role of p62 in osteoclast function.

Some evidence indicates that Paget disease is of viral origin. Virtually all patients exhibit nuclear inclusions consistent with the structure of a virus in osteoclasts and osteoclast precursors. These inclusions are not found in any other skeletal disease other than giant cell tumors of bone. They consist of microfilaments in a paracrystalline array and have been compared with the inclusions in the brains of patients with subacute sclerosing encephalitis (see Chapter 32). This similarity has suggested that a slow virus may be involved (Fig. 30-32). Support for this hypothesis has come from the finding that the marrow of Paget disease patients contains paramyxovirus nucleocapsid transcripts. Infection of osteoclast precursor cells with paramyxovirus can increase expression of RANK and so increase osteoclastic activity. In addition, paramyxoviruses stimulate osteoblasts to produce IL-6, which contributes to osteoclastogenesis. Although a viral etiology seems plausible, actual live viruses have not been isolated from pagetic bone, and it is difficult to explain monostotic bone involvement by a systemic viral infection.

Overall, Paget disease is characterized by localized increases in osteoclast formation that lead to bone resorption and associated osteoblastic activity. The increased osteoclastogenic nature of the bone microenvironment is mediated by increases in IL-6 and the RANK signaling pathway. These are perturbed in Paget disease as a result of genetic factors such as *SQSTM1* mutations and possibly a slow virus infection that may serve as a catalyst for developing the pagetic phenotype in genetically predisposed individuals. The result is uncoupling of the normal osteoclast/osteoblast remodeling unit.

PATHOLOGY: The lesions of Paget disease may be solitary (monostotic) or may involve multiple bones (polyostotic). They tend to localize to the bones of the axial skeleton, including the spine, skull and pelvis. The proximal femur and tibia may be involved in the polyostotic form of the disease. Solitary Paget disease rarely involves the humerus, but in polyostotic disease, lesions involving this bone are common.

Paget disease is an example of bone remodeling gone awry. The disease is triphasic:

1. **"Hot" or osteoclastic resorptive stage:** Radiologically, there is a characteristic, sharply defined, flame-shaped or wedge-shaped lysis of the cortex, which may mimic a tumor (Fig. 30-33A). Histologically, there is widespread **osteolysis** with marked osteoclastic resorption, marrow fibrosis and dilation of marrow sinusoids.
2. **Mixed stage of osteoblastic and osteoclastic activity:** By radiography, the bones are larger than normal. In fact, Paget disease is one of only two diseases that produce **larger than normal bones** (the other is fibrous dysplasia, discussed below). The cortex in the mixed phase is thickened, and the accentuation of the coarse cancellous bone makes the bone look heavy and enlarged (Fig. 30-33B,C). Involvement of vertebral bodies evokes a "picture frame" appearance (Fig. 30-33D), as cortices and endplates become greatly exaggerated compared to the coarse cancellous bone of the vertebral body. Although the bone is abnormal, the distorted, coarse cancellous bone and cortex still tend to align along stress lines. The pelvis is often thickened in the area of the acetabulum. Histologically, there is evidence of both increased osteoclastic and osteoblastic activity (Figs. 30-32 and 30-34B).

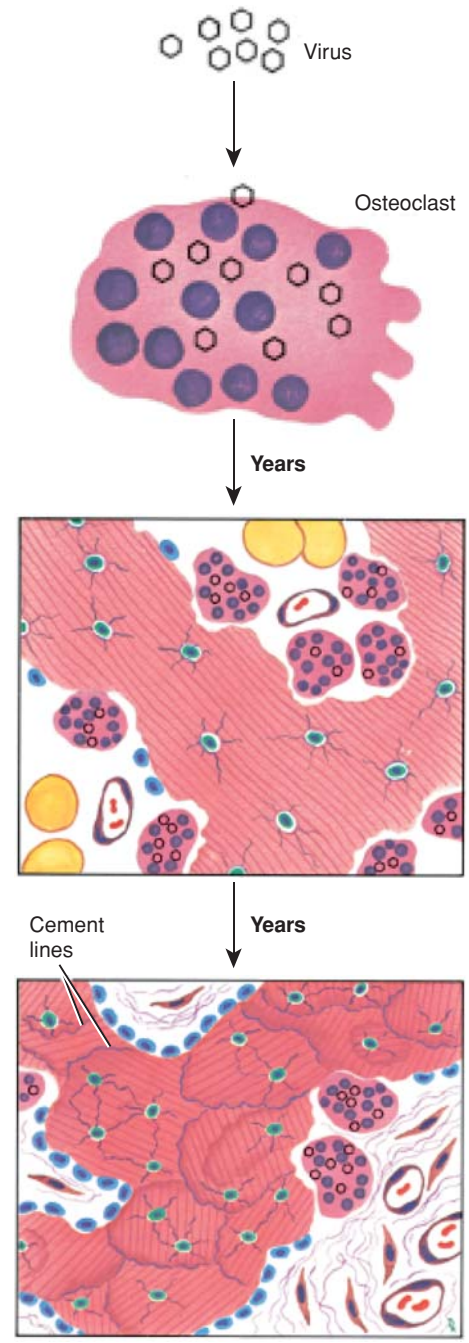

FIGURE 30-32. Hypothetical viral etiology of Paget disease of bone. A virus infects osteoclastic progenitors or osteoclasts in a genetically predisposed individual and stimulates osteoclastic activity, thereby leading to excessive resorption of bone. Over a period of years, the bone develops a characteristic mosaic pattern, produced by chaotically juxtaposed units of lamellar bone that form irregular cement lines. The adjacent marrow is often fibrotic, and there is a mixture of osteoclasts and osteoblasts on the surface of the bone.

3. **"Cold" or burnt-out stage:** This period is characterized histologically by little cellular activity and radiologically by thickened and disordered bones.

The disease need not progress through all three stages, and in polyostotic disease, various foci may appear in different stages.

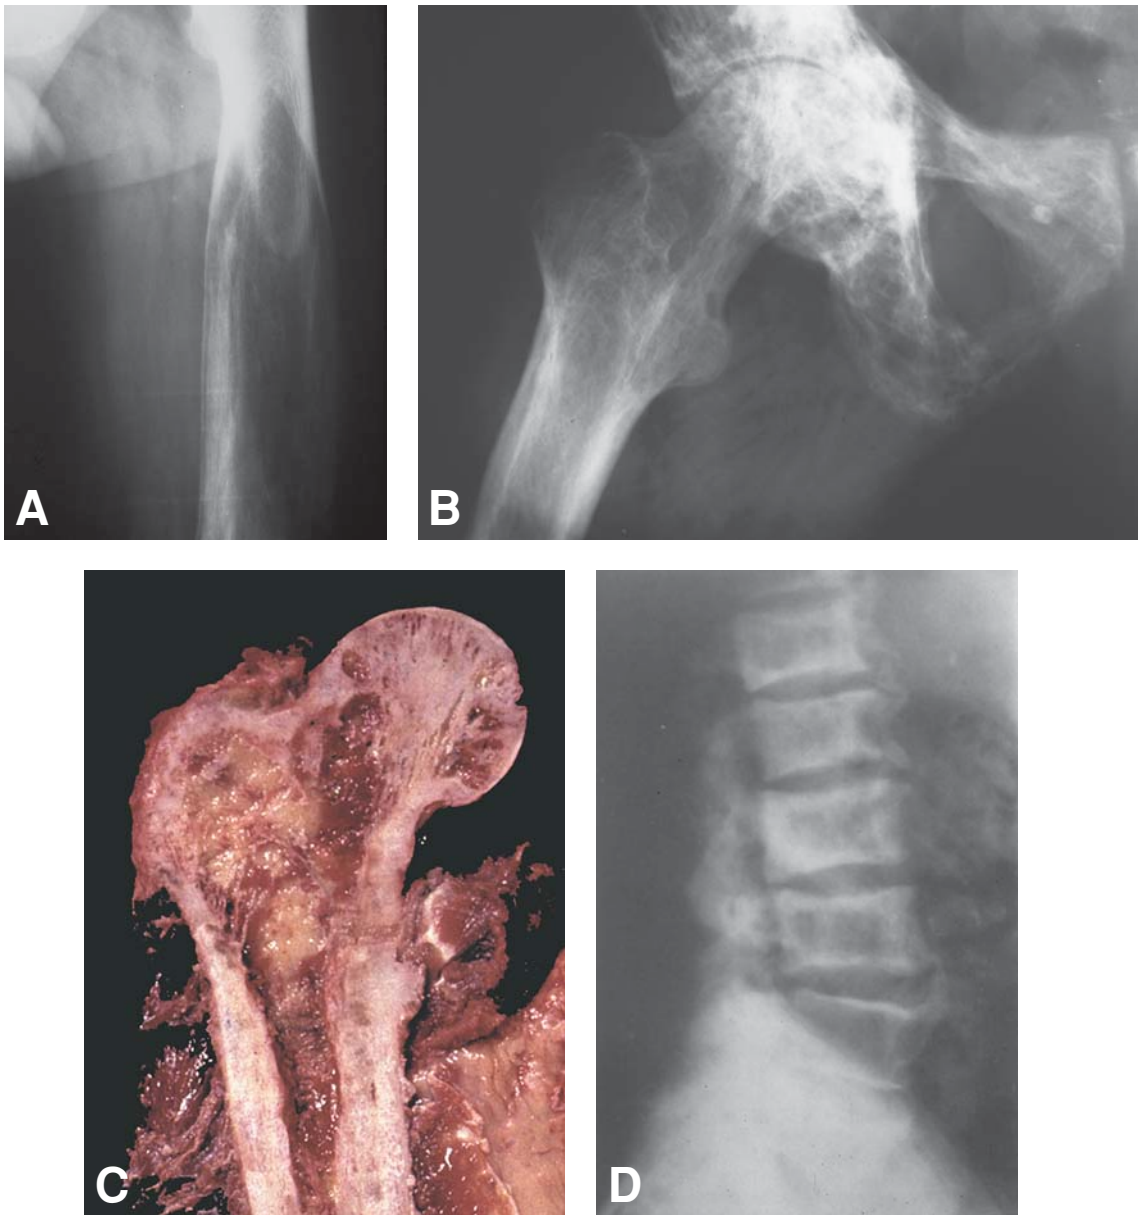

FIGURE 30-33. Paget disease. A. A radiograph of early Paget disease shows cortical dissolution, increased diameter of the diaphysis and an advancing, wedge-shaped area of cortical resorption ("flame sign"). Proximal to the edge of this wedge, the femur appears entirely normal. **B.** Later, Paget disease of the proximal femur and pelvis shows cortical disorganization and irregular coarse trabeculations. **C.** Gross specimen of proximal femur showing cortical thickening and coarse trabeculations of the femoral head and neck. **D.** Paget disease of the spine shows shortening and widening of the lumbar vertebral bodies. Their cortices and endplates are thickened and have a "picture frame" appearance.

The osteoclast is the pathologic cell of Paget disease, and its appearance is characteristic. While normal osteoclasts contain fewer than a dozen nuclei, those of Paget disease are huge and may have over 100 (Fig. 30-34B). Nuclei may contain intranuclear inclusions that contain virus-like particles (Fig. 30-34B,C).

Because active Paget disease is a disorder of accelerated remodeling, its histologic features are those of severe osteitis fibrosa. Numerous large osteoclasts, active osteoblasts and peritrabecular marrow fibrosis are encountered (Fig. 30-34B). The rapid remodeling occasions disruption of the trabecular architecture. Trabeculae are characteristically distorted and irregular, with a high surface-to-volume ratio. Bone collagen is often arranged in a woven rather than lamellar pattern.

With time, the lesions of Paget disease burn out and become inactive. The diagnostic hallmark of this stage is the abnormal arrangement of lamellar bone, in which islands of irregular bone formation resembling pieces of a jigsaw puzzle are separated by prominent irregular **cement lines** (Fig. 30-34A). The result is a **mosaic pattern** in the bone, which can be seen particularly well under polarized light. In the cortex of an affected bone, the osteons tend to be destroyed, and concentric lamellae are incomplete. Although the changes in lamellar bone are diagnostic, it is common to see woven bone as part of the pathologic process. In this

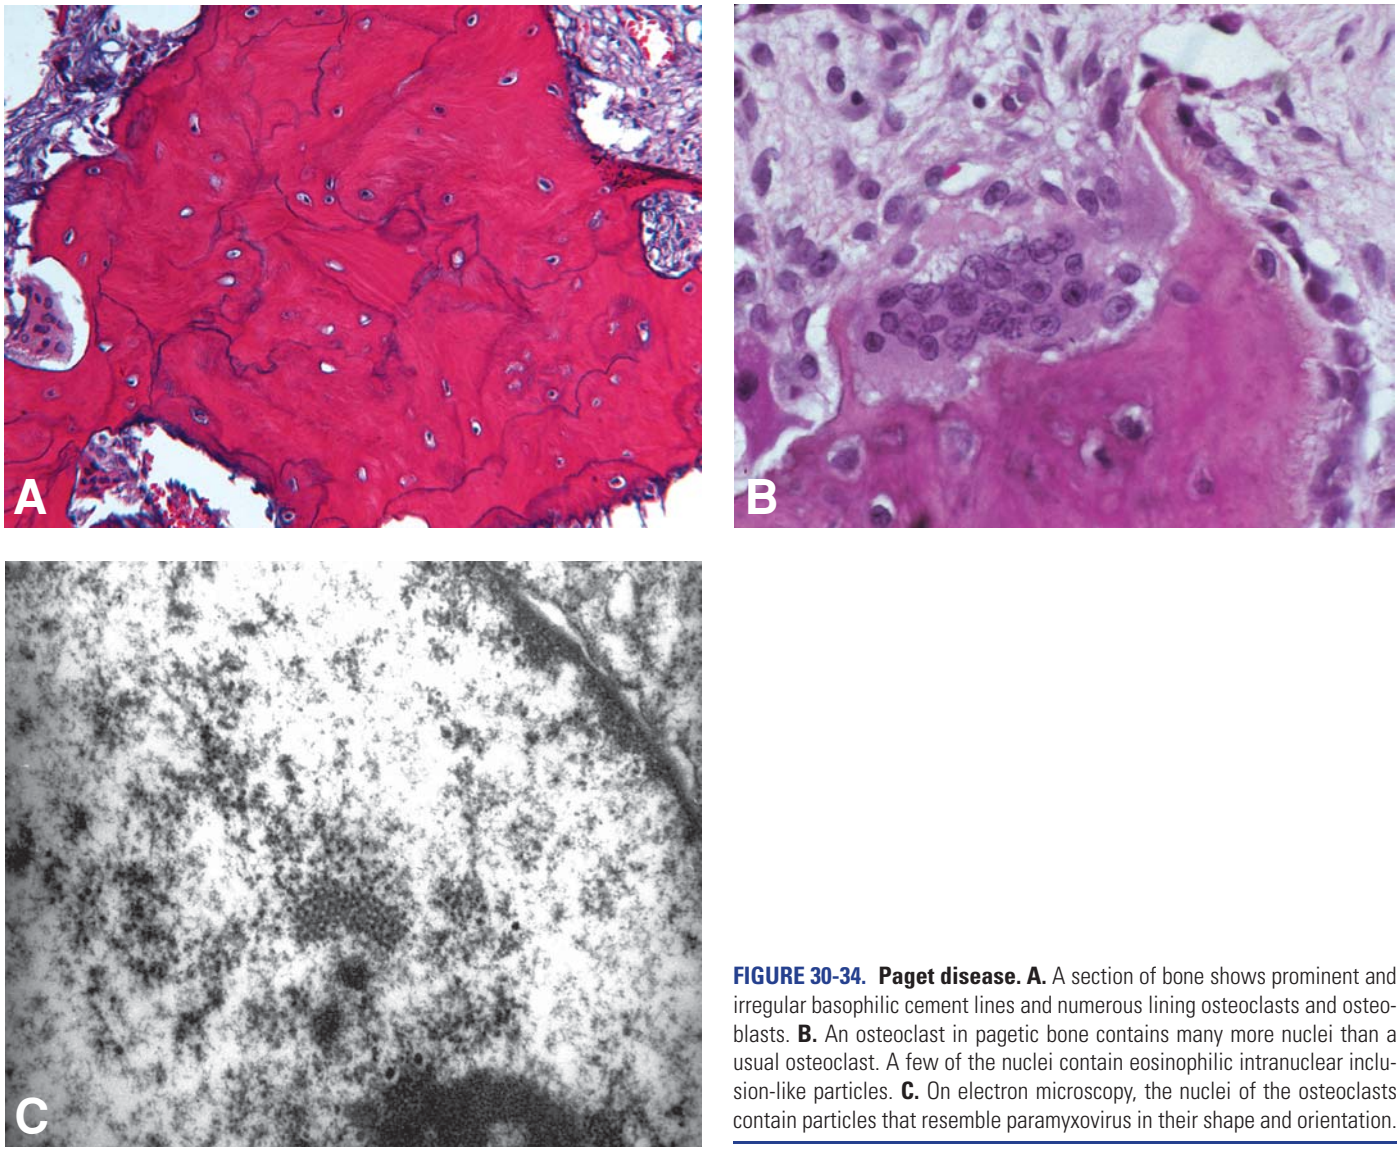

FIGURE 30-34. Paget disease. A. A section of bone shows prominent and irregular basophilic cement lines and numerous lining osteoclasts and osteoblasts. **B.** An osteoclast in pagetic bone contains many more nuclei than a usual osteoclast. A few of the nuclei contain eosinophilic intranuclear inclusion-like particles. **C.** On electron microscopy, the nuclei of the osteoclasts contain particles that resemble paramyxovirus in their shape and orientation.

situation, the woven bone is a reactive phenomenon, as in a microcallus, and represents a temporary bridge between islands of the mosaic bone of Paget disease.

CLINICAL FEATURES: The most common focal symptom of Paget disease is pain in the affected bone, although its cause is not clear. The pain may be related to microfractures, stimulation of free nerve endings by dilated blood vessels adjacent to the bones or weight bearing in weaker bones. The diagnosis is primarily made by radiologic findings and bone biopsy is seldom necessary.

SKULL: Involvement of the skull is particularly common. The skull exhibits localized lysis, called **osteoporosis circumscripta,** generally in the frontal and parietal bones. Alternatively, there may be thickening of the outer and inner tables, which is most pronounced in the frontal and occipital bones. The skull becomes very heavy and may collapse over the C1 vertebra, compressing the brain and spinal cord. Hearing loss follows involvement of the middle ear ossicles and bony impingement on the eighth cranial nerve at the foramen. **Platybasia** (flattening of the base of the skull) impinges on the foramen magnum, compressing the medulla and upper spinal cord.

The jaws may be grossly misshapen and the teeth may fall out. Often, facial bones increase in size, especially the maxillary bones, producing the so-called **leontiasis ossea** (lion-like face).

PAGETIC STEAL: Occasionally, patients feel lightheaded, due to so-called pagetic steal. In this situation, blood is shunted from the internal carotid system to the bones rather than directed to the brain.

FRACTURES AND ARTHRITIS: Fractures are common in Paget disease, the bones snapping transversely like a piece of chalk. Incomplete fractures without displacement are called **infractions**. Involvement of the pelvis engenders hip problems. The loss of subchondral bone compliance causes secondary osteoarthritis and destruction of the articular cartilage.

HIGH-OUTPUT CARDIAC FAILURE: With extensive Paget disease, blood flow to the bones and subcutaneous tissue increases remarkably, requiring increased cardiac output. In the presence of underlying cardiac disease, it may be severe enough to result in cardiac failure.

SARCOMATOUS CHANGE: Neoplastic transformation may occur in Paget disease, usually in the femur, humerus or pelvis. This complication occurs in less than 1% of all cases and usually arises in patients with severe polyostotic disease. However, the incidence of bone sarcoma is 1000 times higher than that in the general population. Interestingly, the skull and vertebrae, the bones most commonly involved by Paget disease, rarely undergo sarcomatous change. Sarcomas are usually osteogenic but may be fibrosarcoma or chondrosarcoma. Their prognosis is very poor.

Serum calcium and phosphorus levels in Paget disease are normal, even though bone turnover increases more than 20-fold. Hypercalcemia is rare, but does occur if a patient is immobilized. The collagen structure of bone in Paget disease is entirely normal, but because of the accelerated bone turnover, levels of collagen breakdown products (hydroxyproline and hydroxylysine) increase in the serum and urine. Hydroxyproline excretion may reach 1000 mg/day (normal, <40 mg). The serum alkaline phosphatase level is the most useful laboratory test in diagnosing Paget disease. It increases enormously and correlates with osteoblastic activity. The alkaline phosphatase levels are disproportionately high with skull involvement but tend to be lower when only the pelvis is affected. A sudden increase in the activity of serum alkaline phosphatase may reflect sarcomatous change within a lesion.

Fortunately, most patients with Paget disease are asymptomatic and require no treatment. Fractures, osteoarthritis and other orthopedic complications are treated symptomatically. Drugs directed at hindering the abnormal osteoclast hyperfunction, including calcitonin and bisphosphonates, are useful.

GIANT CELL TUMOR: Giant cell tumor may arise in Paget disease. It is not a neoplasm but rather a reactive phenomenon similar to the "brown tumor" of hyperparathyroidism. Giant cell tumor is an overshoot of osteoclastic activity with an associated fibroblastic response. Radiation therapy has been used in the treatment of giant cell tumor but has been abandoned owing to a high incidence of malignant transformation.

GAUCHER DISEASE

This autosomal recessive hereditary storage disease is discussed in Chapter 6. We consider here only its skeletal manifestations. These include:

- **Failure of remodeling:** This is the most common, and least problematic, skeletal abnormality. Flaring is absent and funnelization and cylinderization are abnormal, giving rise to an Erlenmeyer flask shape of the distal femur and proximal tibia.
- **Bone crisis:** This rare but very painful event results from acute infarction of a large segment of one or more bones, often after an acute viral illness. There is insufficient bone blood flow owing to marrow infiltration by Gaucher cells. It lasts about 2 weeks and then gradually improves.
- **Localized and diffuse bone loss:** Radiolucent lesions with overlying cortical thinning are usually asymptomatic unless a fracture occurs at the site. These lesions are packed with Gaucher cells.
- **Osteosclerotic lesions:** These reflect increased bone formation, usually in the medullary cavity of the long bones and pelvis. Reactive new bone formation following osteonecrosis may be involved.
- **Corticomedullary osteonecrosis:** This disabling complication of Gaucher disease is most common in patients between 8 and 35 years old. It mostly involves the femoral head or proximal humerus. Extensive marrow infiltration by Gaucher cells restricts adequate blood flow to the bone.
- **Pathologic fractures:** Vertebrae, long bones and even the pelvis may show spontaneous fractures, owing to bone necrosis or osteopenia.
- **Osteomyelitis and septic arthritis:** Commonly caused by coliform or anaerobic organisms, spread via bloodstream to the bones and joints of Gaucher patients is common, especially after surgery.

FIBROUS DYSPLASIA

Fibrous dysplasia is viewed as a developmental abnormality characterized by a disorganized mixture of fibrous and osseous elements in the medullary region of affected bones. It occurs in children and young adults and may affect one (monostotic) or multiple bones (polyostotic) or other systems (McCune-Albright syndrome).

MOLECULAR PATHOGENESIS: Activating mutations in the *GNAS1* gene encoding the α subunit of the stimulatory $G_S\alpha$ protein, which is linked to adenyl cyclase, have been described in bone cells from patients with fibrous dysplasia and McCune-Albright syndrome. The result is constitutive activation of adenyl cyclase and increased levels of cyclic adenosine 3′,5′-monophosphate (cAMP), and so enhancing certain functions of the affected cells (e.g., c-*fos* and c-*jun* proto-oncogenes, IL-6 and IL-11).

PATHOLOGY AND CLINICAL FEATURES:

MONOSTOTIC FIBROUS DYSPLASIA: Monostotic fibrous dysplasia is the most common form of the disease and is most often seen in the second and third decades, with no predilection for either sex. The bones commonly involved are the proximal femur, tibia, ribs and facial bones, although any bone may be affected. The disease may be asymptomatic or it may lead to a pathologic fracture.

POLYOSTOTIC FIBROUS DYSPLASIA: One fourth of patients with polyostotic fibrous dysplasia exhibit disease in more than half of the skeleton, including the facial bones. Symptoms usually are seen in childhood, and almost all patients have pathologic fractures, limb deformities or limb-length discrepancies. Polyostotic fibrous dysplasia is more common in females. Sometimes the disease becomes quiescent at puberty, but pregnancy tends to stimulate the growth of lesions.

MCCUNE-ALBRIGHT SYNDROME: This condition is characterized by endocrine dysfunction, including acromegaly, Cushing syndrome, hyperthyroidism and vitamin D–resistant rickets. The most common endocrine abnormality is precocious puberty in girls (boys rarely have McCune-Albright syndrome). As a result, premature closure of the growth plates leads to abnormally short stature. The most common extraskeletal manifestations of McCune-Albright syndrome are characteristic skin lesions: pigmented macules

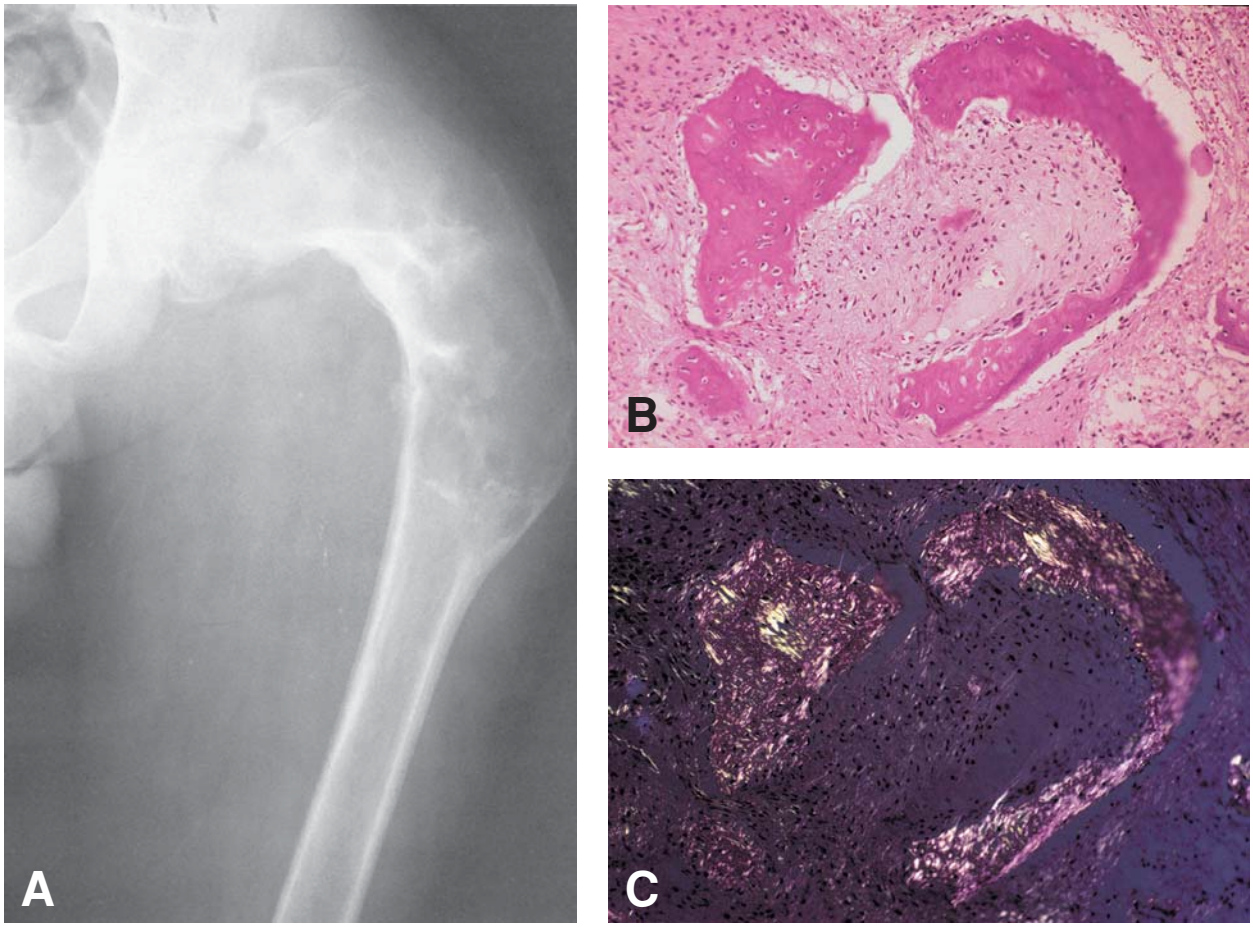

FIGURE 30-35. Fibrous dysplasia. A. A radiograph of the proximal femur shows the "shepherd's crook" deformity caused by fractures sustained over the years. Irregular, marginated, ground-glass lucencies are surrounded by reactive bone. The shaft has an appearance that has been likened to a soap bubble. **B.** Histologically, fibrous dysplasia consists of moderately cellular fibrous tissue in which irregular, curved spicules of woven bone develop without discernible appositional osteoblast activity. **C.** The same section in polarized light demonstrates not only that the spicules are woven but also that their fiber pattern extends imperceptibly into the fiber pattern of the surrounding stroma.

("café-au-lait" spots) with irregular ("coast of Maine") borders that do not cross the midline of the body and are usually located over the buttocks, back and sacrum. These often overlie the skeletal lesions.

Polyostotic fibrous dysplasia may also be associated with soft tissue myxomas **(Mazabraud syndrome)**. The radiographic features of fibrous dysplasia are distinctive. The bone lesion has a lucent ground-glass appearance with well-marginated borders and a thin cortex. The bone may be ballooned, deformed or enlarged, and involvement may be focal or may encompass the entire bone (Fig. 30-35A).

All forms of fibrous dysplasia have an identical histologic pattern (Fig. 30-35B,C). Benign fibroblastic tissue is arranged in a loose, whorled pattern. Irregularly arranged, purposeless spicules of woven bone that lack osteoblastic rimming are embedded in the fibrous tissue. In 10% of cases, irregular islands of hyaline cartilage are also present. Occasionally, cystic degeneration occurs, with hemosiderin-laden macrophages, hemorrhage and osteoclasts congregated about the cyst. Rarely (<1% of cases), malignant transformation (osteosarcoma, chondrosarcoma, fibrosarcoma) has been reported, but many of these cases involved prior radiation therapy. Treatment of fibrous dysplasia consists of curettage, repair of fractures and prevention of deformities.

BENIGN TUMORS OF BONE

Bone tumors of all kinds are uncommon but are nevertheless important neoplasms because many occur in children and young adults and are potentially lethal. A primary bone tumor may arise from any of the cellular elements of bone. Most neoplasms of bone occur near the metaphyseal area, and more than 80% of primary tumors are found in the distal femur or proximal tibia (Fig. 30-36). In a growing child, these areas show conspicuous growth activity.

Nonossifying Fibroma Is a Solitary Lesion of Childhood

Nonossifying fibroma, also called **fibrous cortical defect,** is a benign tumor that occurs in the metaphysis of a long bone, most commonly the tibia or femur. It is very common and may be present in as many as 25% of all children between the ages of 4 and 10 years, after which it characteristically regresses. Nonossifying fibroma is a developmental lesion and not a neoplasm. Most cases are asymptomatic, although pain or fracture through the thin cortex overlying the lesion occasionally calls attention to the condition. Multiple

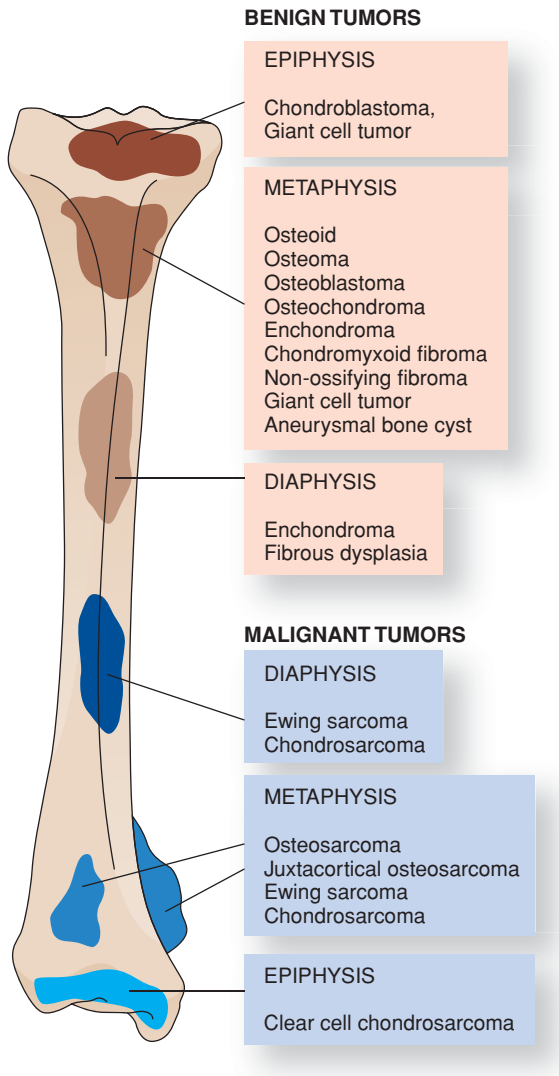

FIGURE 30-36. Location of primary bone tumors in long tubular bones.

ossifying fibromas may be seen with neurofibromatosis type 1 and in the **Jaffe-Campanacci syndrome (associated with café au lait spots)**.

PATHOLOGY: Radiologically, nonossifying fibromas are characterized by a cortical, eccentric position and by well-demarcated, central lucent zones surrounded by scalloped, sclerotic margins (Fig. 30-37A). On gross examination, the lesion is granular and dark red to brown. Microscopically, bland spindle cells are arranged in an interlacing, whorled pattern, with scattered multinucleated giant cells and foamy macrophages (Fig. 30-37B). Spontaneous regression is common. Radiologic follow-up is sufficient management in most cases. The rare, symptomatic or expanded lesions that are prone to fracture are treated with curettage and bone grafting.

Solitary Bone Cyst Occurs in Children and Adolescents

Solitary, unicameral or simple bone cyst is a benign, fluid-filled, unilocular lesion. There is a male predilection (3:1), and 80% occur in the first two decades of life. More than two thirds of all solitary bone cysts are located in the proximal humerus, proximal femur or proximal tibia, usually in the metaphysis adjacent to the growth plate.

ETIOLOGIC FACTORS: Solitary bone cysts are not neoplasms but rather disturbances of bone growth with superimposed trauma. Secondary organization of a hematoma or some abnormality of the metaphyseal vessels causes accumulation of fluid. The "tumor" then grows by expansion of the fluid cavity. The resulting pressure causes bone resorption, mediated by neighboring osteoclasts. The process is slow, so that as the endosteal surface of the cortex is resorbed, a thin periosteal shell of new bone is laid down. This sequence results in a thin, well-marginated, radiolucent bone lesion (Fig. 30-38), which is never greater in diameter than the growth plate and is particularly susceptible to pathologic fracture.

PATHOLOGY: Solitary bone cyst is not a true cyst since there is no distinct cell lining. It is rather lined by fibrous tissue, a few osteoclastic giant cells, hemosiderin-laden macrophages, chronic inflammatory cells and reactive bone. Osteoclasts are present in the advancing front of the cyst and allow expansion of the lesion. The cyst wall may contain characteristic masses of amorphous, calcified, fibrinous material resembling cementum.

CLINICAL FEATURES: Most solitary bone cysts are entirely asymptomatic until a pathologic fracture calls attention to it. Once the diagnosis is confirmed by imaging studies and by finding clear fluid by needle aspiration, intralesional corticosteroids may be given. Currently, curettage and bone grafting are the preferred treatment of choice.

Aneurysmal Bone Cyst May Be Primary or Secondary

Aneurysmal bone cyst (ABC) is an uncommon, benign, expansive and often destructive lesion arising within a bone or on its surface. It occurs in children and young adults, with a peak incidence in the second decade. Although the lesion has been observed at every skeletal site, it is most frequent in the metaphysis of long bones and the vertebral column.

MOLECULAR PATHOGENESIS: The pathogenesis of ABC is controversial. Some cases represent cystic and hemorrhagic transformation of an underlying lesion, most commonly chondroblastoma, osteoblastoma, fibrous dysplasia, giant cell tumor and osteosarcoma ("secondary ABC"). Other cases of ABC have no detectable associated lesion ("primary ABC"). Primary ABC may be a true neoplasm, since it is associated with a recurring chromosomal translocation t(16;17)(q22;p13). This anomaly fuses the promoter region of the osteoblast cadherin 11 gene (*CDH11*) on chromosome 16q22 to the coding sequence of the ubiquitin protease (*USP6*) gene on chromosome 17p13. USP6 is thought to have a role in regulating actin remodeling. However, the possible mechanism of neoplastic transformation by upregulation of USP6 has not been elucidated.

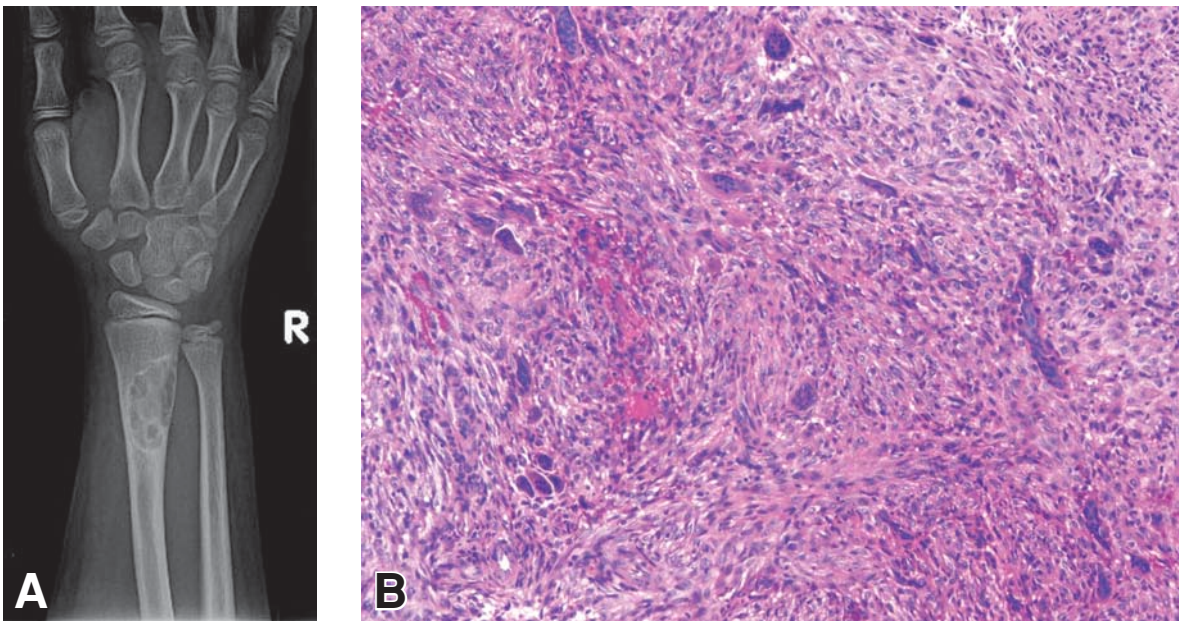

FIGURE 30-37. Nonossifying fibroma. A. A radiograph of the distal radius of a child with an eccentric, metaphyseal lytic lesion with scalloped and sclerotic margins. **B.** Microscopically, the lesion is composed of bland spindle cells arranged in interlacing fascicles, with scattered, multinucleated, osteoclast-type giant cells.

PATHOLOGY: The periosteum around an aneurysmal bone cyst is ballooned but intact. In the spine, the lesion may actually extend across more than one bone. By MRI, fluid-fluid levels may be seen as blood cells separate from plasma (Fig. 30-39A). The cut surface of the cyst resembles a sponge permeated with blood and blood clots (Fig. 30-39B). The walls and septa are composed of moderately cellular fibrous tissue with multinucleated giant cells and reactive bone (Fig. 30-39C).

FIGURE 30-38. Solitary bone cyst. A radiograph of the proximal humerus of a child (note the epiphyseal plate) shows a large, well-demarcated, lytic epiphyseal and diaphyseal lesion. The cortex is thinned, but there is no cortical distortion or malformation of the shape of the bone.

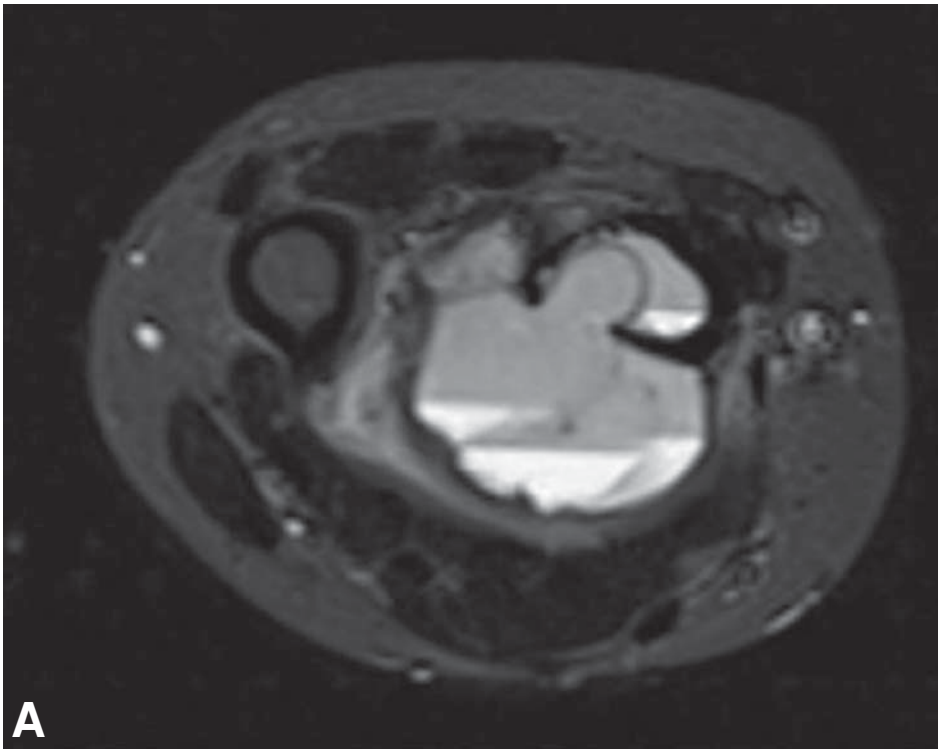
CLINICAL FEATURES: Although some aneurysmal bone cysts tend to grow slowly, most expand rapidly, and some are enormous. They usually manifest with pain and swelling, sometimes in relation to trauma, and often develop in a short period of time. A bone cyst may "blow out," that is, rupture and produce local hemorrhage. Treatment is usually excision and curettage with bone grafting. Recurrence rate is variable (20%–70%). At surgery, incising the cyst decreases its internal pressure, causing brisk bleeding that may be difficult to control. In sites such as the vertebral column or the pelvis, selective arterial embolization has been successful.

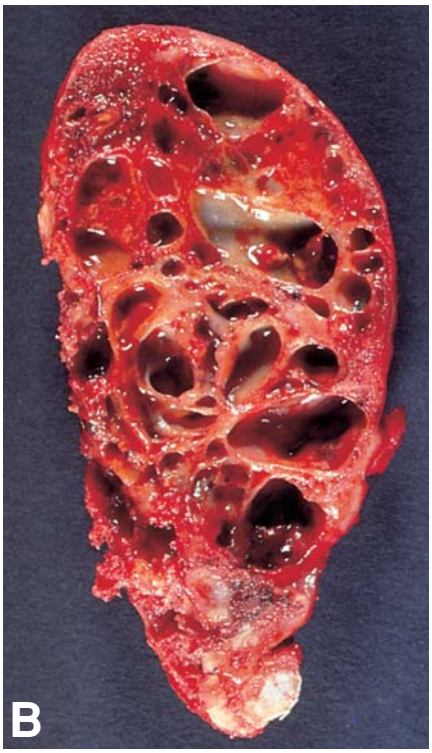
Osteoma Is a Benign Tumor Composed of Compact Cortical Bone

Osteoma is a benign, slow-growing tumor composed of cortical-type dense bone. These lesions can be divided into four major clinicopathologic subtypes: (1) calvarial and mandibular osteomas, (2) osteomas of the sinonasal and orbital bones, (3) bone islands occurring in medullary bone and (4) surface osteomas of long bones. Some osteomas are likely developmental or hamartomatous in nature. However, sinonasal osteomas may be benign osteoblastic neoplasms. Interestingly, multiple osteomas are associated with familial adenomatous polyposis in Gardner syndrome (see Chapter 19).

Osteoid Osteoma Is a Benign, Painful Lesion

Osteoid osteoma is composed of immature osseous tissue (the nidus) surrounded by a halo of dense reactive bone. The typical patient is between 5 and 25 years old. Boys are





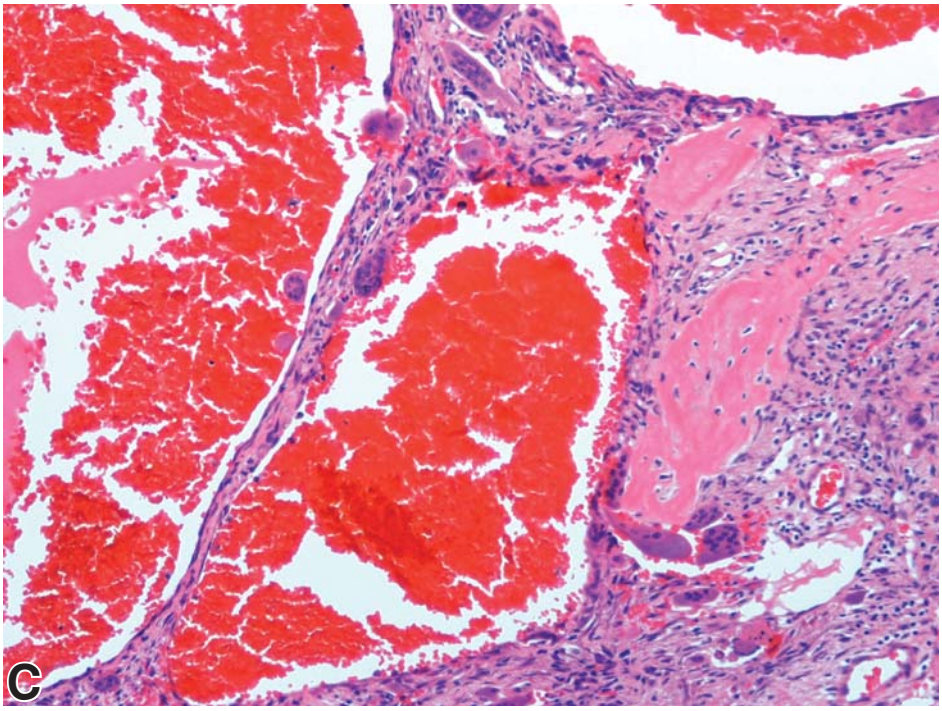


FIGURE 30-39. Aneurysmal bone cyst. A. A magnetic resonance image showing fluid-fluid levels. **B.** In cross-section, the lesion consists of a spongy mass containing multiple blood-filled cysts. Some of the septa between the cysts contain bony tissue. **C.** Microscopically, the blood-filled spaces are separated by cellular fibrous septa with scattered osteoclast-type giant cells and reactive bone.

affected more often than girls (3:1). The lesion frequently arises in the diaphyseal cortex of the tubular bones of the leg but may occur elsewhere. Osteoid osteomas have limited growth potential and do not metastasize.

MOLECULAR PATHOGENESIS: Chromosomal analysis of a few osteoid osteomas has disclosed structural abnormalities of chromosome 22q13 and loss of part of 17q, which suggests that the lesions are neoplasms.

PATHOLOGY: Osteoid osteoma is a spherical, hyperemic tumor, about 1 cm in diameter, which is considerably softer than the surrounding bone (Fig. 30-40A) and easily enucleated at surgery. Microscopically, the center of the tumor (nidus) is composed of thin, irregular trabeculae of woven bone within a cellular and vascular fibrous stroma containing many osteoblasts and osteoclasts (Fig. 30-40B). The trabeculae are more mature in the center, which is often partially calcified. Reactive sclerotic bone surrounds the nidus.

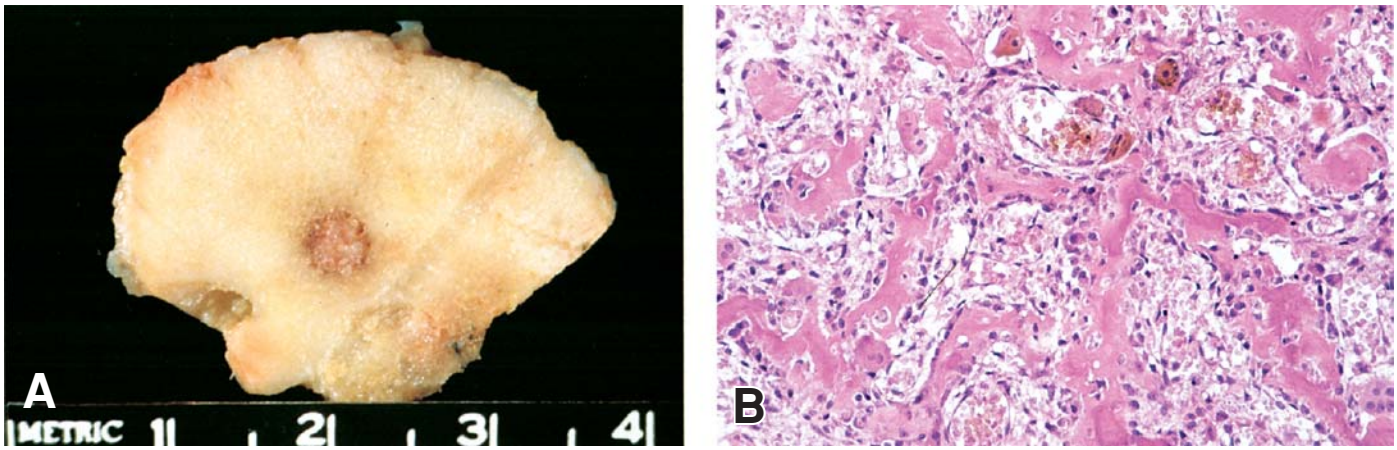

FIGURE 30-40. Osteoid osteoma. A. A gross specimen of an osteoid osteoma shows the central nidus, which is embedded in dense bone. **B.** A photomicrograph of the nidus reveals irregular trabeculae of woven bone surrounded by osteoblasts, osteoclasts and fibrovascular marrow.

CLINICAL FEATURES: Pain is typically nocturnal and out of proportion to the size of the lesion. Interestingly, the pain is often exacerbated by drinking alcohol and promptly relieved by aspirin or other anti-inflammatory drugs, possibly because of the high prostaglandin content and abundant nerve fibers within the tumor. Surgical excision or radioablation (electric probe inserted into the tumor) is curative.

Osteoblastoma Is Usually Not Painful

Osteoblastoma is an uncommon, benign neoplasm that is histologically similar to osteoid osteoma but larger (usually >2 cm) and with a tendency to progressive growth. It is not accompanied by the characteristic nocturnal pain of osteoid osteoma, although dull pain sometimes occurs. It stimulates less bone reaction and appears mostly as a purely radiolucent lesion, with only a thin shell of surrounding bone. Osteoblastoma occurs in people between the ages of 10 and 35 years, is more common in males and mainly affects the spine and long bones. The histologic features of osteoblastoma are similar to those of osteoid osteoma. Secondary aneurysmal bone cysts may be seen. Curettage cures small osteoblastomas, but larger lesions require wide resection. Recurrences are uncommon and prognosis is excellent.

MOLECULAR PATHOGENESIS: Although several chromosomal and molecular abnormalities have been described in osteoblastoma, no consistent abnormality has emerged. Aneuploid to hyperdiploid karyotypes have been demonstrated. *MDM2* gene amplification and *TP53* gene deletion implicate cell cycle abnormalities in the pathogenesis of osteoblastoma.

Osteochondroma

Osteochondroma is a benign cartilaginous neoplasm consisting of a bony projection with a cartilaginous cap that arises on the surface of the bone. It occurs in bones formed by endochondral ossification and was viewed for many years as a developmental defect of the growth plate. Most are solitary but 15% are multiple and hereditary. Recently described gene mutations in solitary and multiple osteochondromas favor a neoplastic nature. Solitary osteochondroma is one of the most common benign bone tumors and is more frequent in young males. Most osteochondromas are asymptomatic, and some may need surgical excision if cosmetically displeasing or if they press upon an artery or nerve. Recurrence is very rare.

MOLECULAR PATHOGENESIS: Cytogenetic aberrations have been characterized in sporadic and hereditary osteochondromas, including chromosomes 8q24.1, 11p11–12 and 19p, where the tumor suppressor genes *EXT1, EXT2* and *EXT3 (recently described)* are located, respectively. The *EXT* genes may be involved in chondrocyte proliferation and differentiation by affecting the Indian hedgehog–PTH-related protein (Ihh–PTHrP) pathway, which is vital for the proper development of endochondral bones. *EXT* mutations induce increased chondrocyte proliferation in the cartilage cap and disrupt the differentiation process, which may alter the direction of chondrocyte growth and lead to the development of osteochondromas.

PATHOLOGY: Osteochondromas tend to grow away from the nearest joint. In radiographs, the cartilaginous mass is in direct continuity with the parent bone and lacks an underlying cortex (Fig. 30-41A). The marrow cavity of the lesion is in continuity with that of the bone where it arose. The cartilage-capped, bony mass is surrounded by a surface fibrous membrane, which is the perichondrium. Histologically, the cap is composed of benign hyaline cartilage with active endochondral ossification, which is morphologically similar to that seen in the epiphyseal growth plate (Fig. 30-41B). The bony stalk is composed of cortical lamellar bone, and the medullary cavity contains lamellar bone trabeculae and fatty marrow.

HEREDITARY MULTIPLE OSTEOCHONDROMATOSIS: This inherited autosomal dominant disorder is characterized by multiple osteochondromas and associated skeletal deformities. Hereditary multiple osteochondromatosis (HMO) is one of the most common inherited musculoskeletal disorders and is caused by loss of *EXT1* or *EXT2* gene function (see Molecular Pathogenesis above). Although not as common as solitary osteochondroma, the heritable variety is not rare, with an incidence of about 1 in 50,000. It

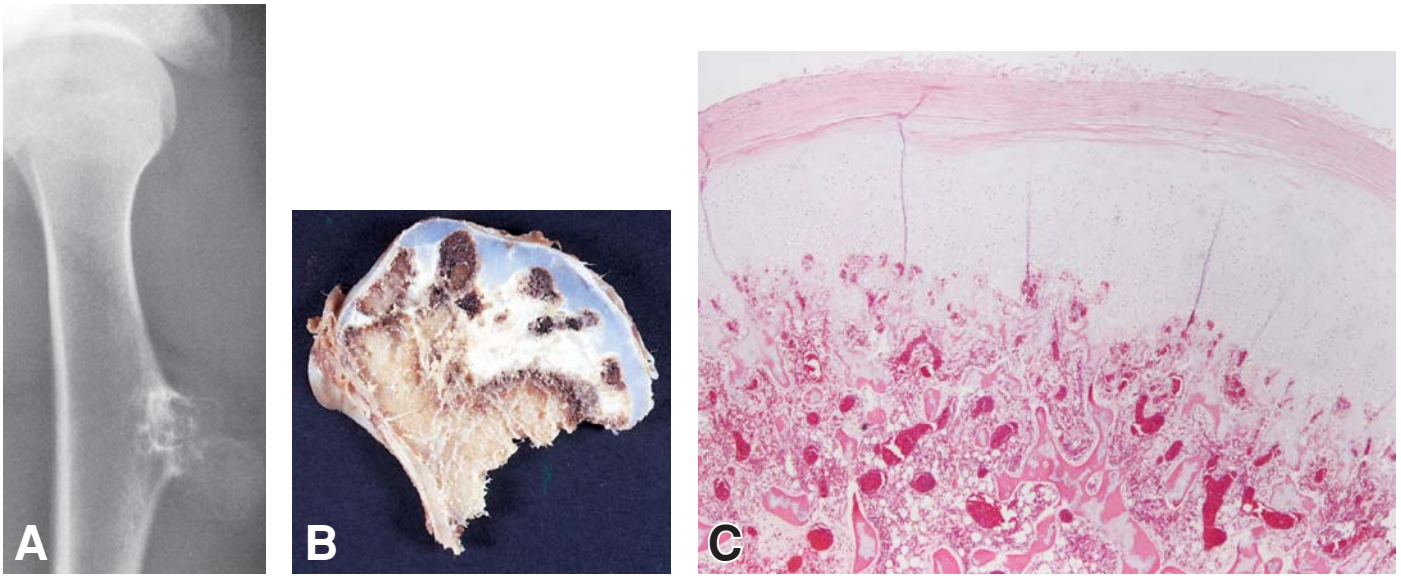

FIGURE 30-41. Osteochondroma. A. A radiograph of an osteochondroma of the humerus shows a lesion that is directly contiguous with the marrow space. **B.** The cross-section of an osteochondroma shows the cap of calcified cartilage overlying poorly organized cancellous bone. **C.** Microscopically, the cartilaginous cap is covered by a fibrous membrane (perichondrium) and undergoes endochondral ossification.

occurs predominantly in males, but because of its variable expression, a seemingly unaffected female from an afflicted family may transmit the disorder to her offspring.

PATHOLOGY: Each individual lesion in multiple osteochondromatosis is identical to a solitary osteochondroma. In severe cases of hereditary osteochondromatosis, dwarfism may result because of lateral displacement of the longitudinal growth plate by the osteochondroma. Metacarpals may be shortened, and fixed pronation or supination may develop if the lesions occur in the forearm and interfere with wrist function. Further difficulties may be caused by unequal leg length and disturbed joint function because of encroaching osteochondromas. Chondrosarcoma is a rare complication.

Solitary Chondroma Is a Benign Intraosseus Tumor of Mature Hyaline Cartilage

Although their neoplastic nature has been questioned, these benign tumors, also called **enchondromas (because most are intramedullary),** may occasionally show chromosomal abnormalities suggesting that they are in fact neoplasms. They occur at any age, and many cases are entirely asymptomatic. Rarely, they arise on the bone surface under the periosteum, in which case they are regarded as periosteal or juxtacortical chondromas.

PATHOLOGY: Most solitary enchondromas occur in the metacarpals and phalanges of the hands, the remainder being in almost any other tubular bone. The tumor is usually small and grows slowly. Radiologically, it appears as an intramedullary, well-delimited, radiolucent area, sometimes containing stippled calcifications (Fig. 30-42A). On gross examination, solitary enchondromas have the semitranslucent appearance of hyaline cartilage, often with a few calcified areas. Microscopically, the cartilaginous tissue is well differentiated with sparse chondrocytes, extensive cartilaginous matrix and a lobular configuration (Fig. 30-42B). Asymptomatic enchondromas are best left untreated and followed radiographically. When pain or pathologic fracture occurs, curettage and bone grafting are the treatment of choice. Recurrences are uncommon.

Enchondromatosis Is Marked by Multiple Cartilaginous Tumors

Enchondromatosis, *or* Ollier disease, *is characterized by development of multiple cartilaginous masses that lead to bony deformities.* The condition is not strictly a disease of delayed maturation of bone; residual hyaline cartilage, anlage cartilage or cartilage from the growth plate does not undergo endochondral ossification and remains in the bones. As a consequence, bones show multiple, tumor-like masses of abnormally arranged hyaline cartilage (enchondromas), with zones of proliferative and hypertrophied cartilage (Fig. 30-43). These tumors tend to be located in the metaphyses. As growth continues, the enchondromas settle in the diaphysis of adolescents and adults.

Enchondromatosis is asymmetric and may cause bone deformities. There is a strong tendency for malignant transformation, mostly into chondrosarcoma. Therefore, a patient with enchondromatosis who has increasing pain or a lesion that is actively growing should be evaluated to rule out an underlying sarcoma.

Solitary enchondroma and enchondromas of Ollier disease are histologically similar, but the latter tend to be more cellular and atypical.

Maffucci syndrome is characterized by multiple enchondromas and cavernous or spindle cell hemangiomas of soft tissue. It usually manifests in early childhood and may lead to significant skeletal deformities. Chondrosarcoma develops in as many as half of all patients with Maffucci syndrome. The incidence of extraskeletal malignant tumors of different types (i.e., carcinomas, gliomas, etc.) is also greatly increased in patients with Maffucci syndrome.

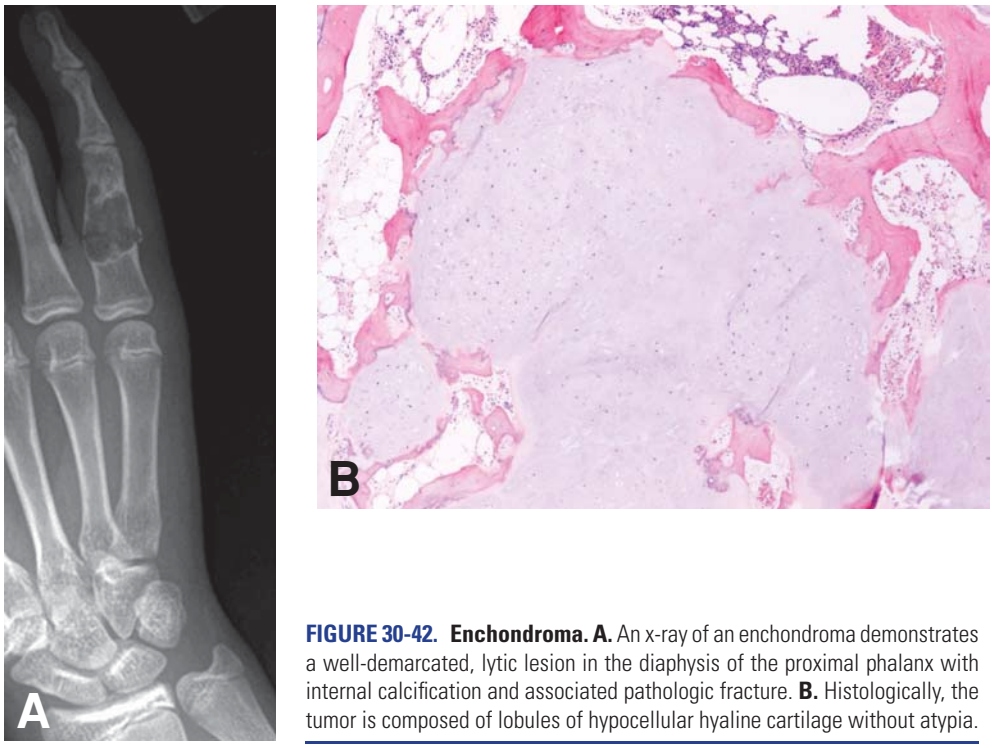

FIGURE 30-42. Enchondroma. A. An x-ray of an enchondroma demonstrates a well-demarcated, lytic lesion in the diaphysis of the proximal phalanx with internal calcification and associated pathologic fracture. **B.** Histologically, the tumor is composed of lobules of hypocellular hyaline cartilage without atypia.

MOLECULAR PATHOGENESIS: Most cases of enchondromatosis are sporadic, but a familial form, possibly with autosomal dominant inheritance, has been reported. Recent studies have disclosed mutations in the *PTHR1* gene, encoding a receptor for PTH and PTHrP, in some cases of enchondromatosis. The mutation results in a substitution in the receptor's extracellular domain, increasing cAMP signaling. The mutant receptor may delay chondrocyte differentiation by activating Hedgehog signaling, which results in the formation of the multiple cartilaginous masses characteristic of the disease.

FIGURE 30-43. Multiple enchondromatosis (Ollier disease). A radiograph of the hand shows bulbous swellings that represent nodular masses composed of hyaline cartilage, which is sometimes admixed with more primitive myxoid cartilage.

Chondroblastoma Is a Benign Tumor of the Epiphyses of Long Bones

Chondroblastoma is an uncommon, chondrogenic tumor with predilection for epiphyses of the proximal femur, tibia and humerus. It is more common in males than in females (2:1), and 90% of cases occur in young people between the ages of 5 and 25.

MOLECULAR PATHOGENESIS: Genetic abnormalities suggest a neoplastic origin of chondroblastoma, including aneuploidy, abnormalities involving chromosomes 5 and 8 and mutations in the *p53* gene.

PATHOLOGY: Chondroblastoma grows slowly and on radiologic examination displays an eccentric, radiolucent appearance with sharply defined borders (Fig. 30-44A). On gross examination, the tumor is soft and compact with scattered gray or hemorrhagic areas. Microscopically, primitive chondroblasts are arranged as sheets of round to polyhedral cells that have well-defined cytoplasmic borders and large, ovoid nuclei, often with prominent nuclear grooves (Fig. 30-44B). Osteoclastic-type giant cells are frequently present. The usually scanty cartilage matrix is variably calcified and appears primitive. This accounts for the mottled pattern often seen in CT scans. Well-developed hyaline cartilage as seen in enchondroma is not found in chondroblastoma. The tumor causes bone

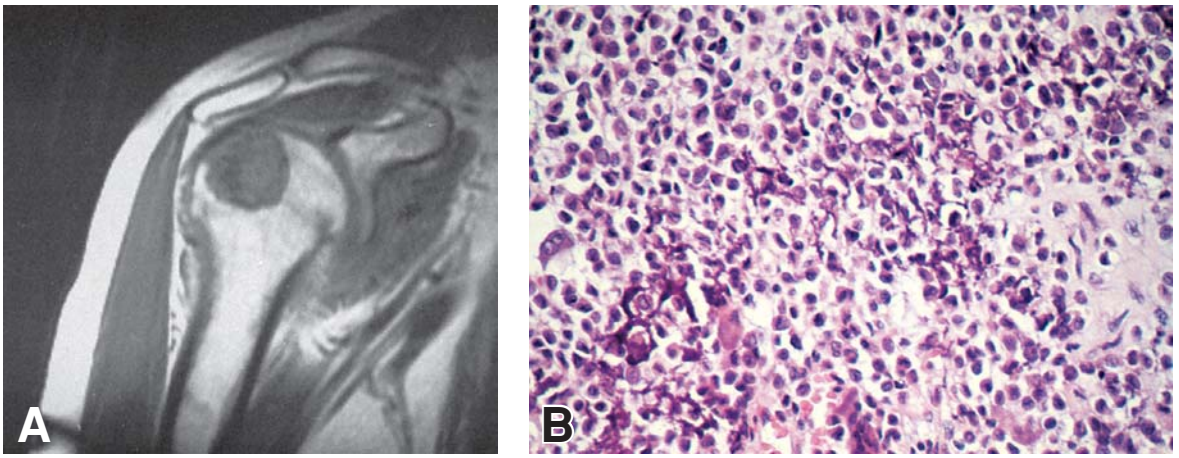

FIGURE 30-44. Chondroblastoma. A. A magnetic resonance image of the shoulder of a child shows a prominent lytic lesion of the head of the humerus that involves the epiphysis and extends across the epiphyseal plate. **B.** The histologic appearance of a chondroblastoma is defined by plump, round cells (chondroblasts) surrounded by a mineralized primitive chondroid matrix.

destruction by stimulating osteoclastic resorption. In fact, these neoplasms may perforate the cortex, although they remain confined by the periosteum.

CLINICAL FEATURES: Because of its paraarticular location, chondroblastoma tends to cause joint pain, with mild swelling and functional limitation of joint movement. If neglected, it may (rarely) attain a large size, destroy the epiphyseal area and invade the joint. Curettage is the treatment of choice, although in over 10% of cases, the tumor recurs.

Giant Cell Tumors of Bone Rarely Metastasize

Giant cell tumor (GCT) of bone is a benign, locally aggressive neoplasm characterized by the presence of osteoclastic, multinucleated giant cells, randomly and uniformly distributed in a background of proliferating mononuclear cells. It usually occurs in the third and fourth decades, has a slight predilection for women and seems to be more common in Asia than in Western countries. Paget disease may produce a giant cell reactive lesion that closely resembles a true GCT.

MOLECULAR PATHOGENESIS: GCT is composed of numerous, large osteoclastic giant cells and two lineages of mononuclear cells. One population of mononuclear cells is believed to be of macrophage-monocyte origin and is likely nonneoplastic. The other has a preosteoblastic phenotype and is the neoplastic cell of GCT. These tumor cells produce RANKL and induce osteoclast formation (hence the large number of giant cells).

PATHOLOGY: In most cases (90%), GCT of bone originates at the junction between the epiphysis and the metaphysis of a long bone, with more than half being situated in the knee area (distal femur and proximal tibia). The lower end of the radius, humerus and fibula are also occasionally involved. Radiologically, the tumor presents as an eccentric, expansile, lytic lesion with no matrix formation, which tends to be surrounded by a thin bony shell (Fig. 30-45A). Often, it has a multiloculated or "soap bubble" appearance, representing endosteal resorption of the bone.

On gross examination, GCT is clearly circumscribed and its cut surface is soft and light brown, without bone or calcification. Numerous hemorrhagic areas result in the

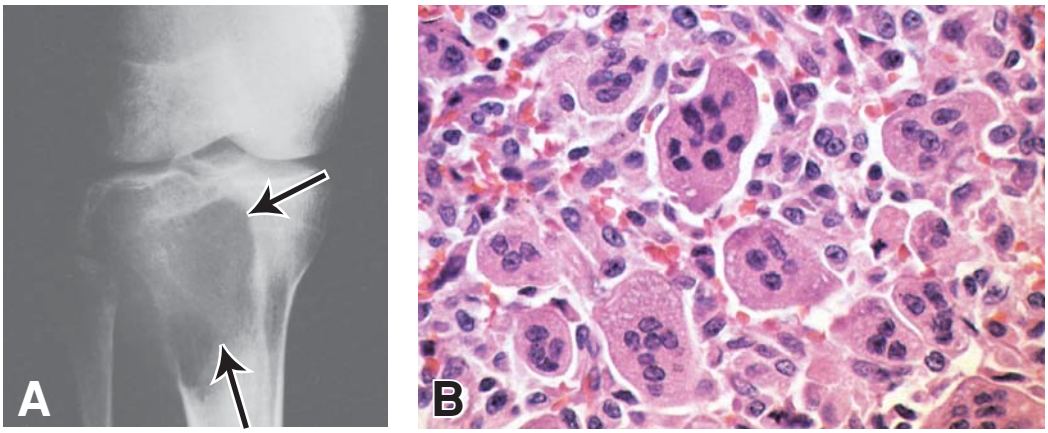

FIGURE 30-45. Giant cell tumor of bone. A. Radiograph of the proximal tibia shows an eccentric lytic lesion with virtually no new bone formation (*arrows*). The tumor extends to the subchondral bone plate and breaks through cortex into the soft tissue. **B.** Photomicrograph shows osteoclast-type giant cells and plump, oval, mononuclear cells. The nuclei of both types of cells are identical.

appearance of a sponge full of blood. In some cases, cystic cavities and necrotic areas are present. GCT is often limited by the periosteum, although aggressive forms penetrate the cortex and the periosteum, even reaching the joint capsule and the synovial membrane.

Microscopically, GCT exhibits two types of cells (Fig. 30-45B). The mononuclear ("stromal") cells are plump and oval, with large nuclei and scanty cytoplasm. Large osteoclastic giant cells, some with more than 100 nuclei, are scattered throughout the richly vascularized stroma. Diffuse interstitial hemorrhage is common. Secondary aneurysmal bone cyst may also be seen. On low-power examination, the tumor often appears as a syncytium of nuclei with poor demarcation of cytoplasmic borders and random distribution of the giant cells. It is evident that the mononuclear cells are the neoplastic and proliferative components of GCT (mitotic activity is common in the mononuclear cells but is not observed in the giant cells). Indeed, the diagnosis of malignancy in a GCT depends on the morphology of the mononuclear cells rather than that of the multinucleated cells.

CLINICAL FEATURES: The vast majority of GCTs are considered benign, but locally aggressive tumors have the potential to recur locally after simple curettage and (rarely) metastasize to distant sites, particularly the lungs. Virtually all metastases have occurred after an initial surgical intervention and have the benign histology in appearance of the primary tumor. In contrast to patients with lung metastases from other malignant bone tumors, most of these patients enjoy an essentially normal life span, especially if the metastatic deposits are few and can be surgically removed. Thus, historical belief has been that local recurrence of the tumor reflects inadequate resection rather than biological aggressiveness and that distant metastases result from dislodgment of tumor fragments during surgery.

True malignancy in GCT is observed in 1% of cases as either a sarcomatous lesion arising in a typical GCT or as a pure sarcoma after a GCT has been curetted. Recurrence as pure sarcoma may occur spontaneously or after local radiation therapy.

GCTs manifest with pain, usually in the joint adjacent to the tumor. Microfractures and pathologic fractures are frequent, owing to thinning of the cortex. The tumor is treated with thorough curettage and bone grafting, although more aggressive management, including en bloc resection or even amputation, may be necessary. Local recurrence after simple curettage has been reported in one third to one half of cases, and 2%–5% metastasize to the lungs.

MALIGNANT TUMORS OF BONE

Osteosarcoma Is the Most Common Primary Malignant Bone Tumor

Osteosarcoma, or* osteogenic sarcoma, *is a highly malignant bone tumor characterized by formation of bone tissue by tumor cells. It represents one fifth of all bone cancers and is most frequent in adolescents between 10 and 20 years old, affecting boys more often than girls (2:1).

MOLECULAR PATHOGENESIS: Conventional osteosarcoma has complex karyotypes, with multiple numerical and structural chromosomal aberrations. Osteosarcomas are associated with mutations in tumor suppressor genes; almost two thirds show mutations in the retinoblastoma (*Rb*) gene (see Chapter 5) and many have mutations in the *p53* gene. There are also many other chromosomal and molecular abnormalities pertaining to apoptosis, replicative potential, insensitivity to growth inhibitory signals and cell cycle regulation that contribute in some part to the development of the tumor. For example, amplification of *MDM2*, *CDK4* and *PRIM1*, as well as overexpression of *MET* and *FOS*, have been detected in a significant proportion of cases.

ETIOLOGIC FACTORS: These tumors are more common in tall people. Interestingly, they occur more frequently in tall breeds of dogs. In older people, they usually occur in the context of Paget disease or radiation exposure. For example, radium watch dial painters, who wetted their brushes by licking them, developed osteosarcoma many years later, owing to radium depositing in their bones. Today, osteosarcoma can develop in adults and children previously subjected to external therapeutic radiation for some other tumor such as lymphoma. Several preexisting benign bone lesions are associated with an increased risk of developing osteosarcoma, including fibrous dysplasia, osteomyelitis and bone infarcts. Although trauma may call attention to an existing osteosarcoma, there is no evidence that it ever causes the tumor.

PATHOLOGY: Osteosarcomas often arise near the knee, in the distal femur (Fig. 30-46A), proximal tibia or fibula, although any metaphyseal area of a long bone may be affected. The proximal humerus is the second most common site; 75% of tumors arise adjacent to the knee or shoulder.

Radiologic evidence of bone destruction and bone formation by osteosarcoma is characteristic, the latter representing neoplastic bone. Often, the periosteum produces an incomplete rim of reactive bone adjacent to the site where it is lifted from the cortical surface by the tumor. When this appears on a radiograph as a shell of bone intersecting the cortex at one end and open at the other end, it is referred to as **Codman triangle**. A "sunburst" periosteal reaction is also often superimposed (Fig. 30-15).

The gross appearance of osteosarcoma is highly variable, depending on the proportions of bone, cartilage, stroma and blood vessels. The cut surface may show any combination of hemorrhagic, cystic, soft and bony areas. The neoplastic tissue may invade and break through the cortex, spread into the marrow cavity, elevate or perforate the periosteum or grow into the epiphysis and even reach the joint space.

Histologic examination reveals malignant polygonal to spindled cells with osteoblastic differentiation, producing woven bone (Fig. 30-46B). The malignant cells have large hyperchromatic and pleomorphic nuclei, with a high nucleocytoplasmic ratio. Numerous mitoses, including atypical forms, are commonly seen. The tumor cells stain prominently for alkaline phosphatase, osteocalcin and osteonectin. The tumorous bone is laid down haphazardly and not aligned along stress lines. Often, foci of malignant cartilage or pleomorphic giant cells are intermixed. In areas of osteolysis, nonneoplastic osteoclasts are found at the advancing front of the tumor.

Osteosarcoma spreads through the bloodstream to the lungs. In fact, almost all patients (98%) who die of this

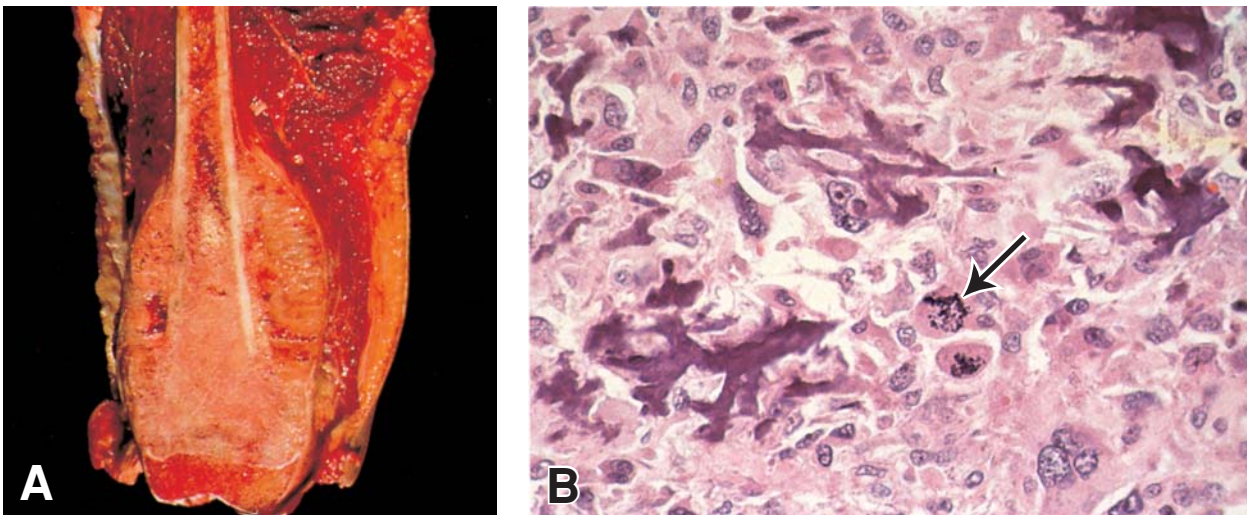

FIGURE 30-46. Osteosarcoma. A. The distal femur contains a dense osteoblastic malignant tumor that extends through the cortex into the soft tissue and the epiphysis. **B.** A photomicrograph reveals pleomorphic malignant cells, tumor giant cells and mitoses (*arrows*). The tumor cells produce woven bone that is focally calcified.

disease have lung metastases. Less commonly, the tumor metastasizes to other bones (35%), the pleura (33%) and the heart (20%).

CLINICAL FEATURES: Osteosarcoma presents with mild or intermittent pain around the involved area. As pain intensifies, the area becomes swollen and tender. The adjacent joint becomes functionally limited. Serum alkaline phosphatase is increased in half of patients and may decrease after amputation, only to increase again with recurrence or metastasis. Metastatic disease heralds rapid clinical deterioration and death.

Historically, osteosarcoma was treated exclusively by amputation or disarticulation of the involved limb, but the prognosis for 5-year survival did not exceed 20%. Today, standard therapy with preoperative chemotherapy and limb-sparing surgery gives 5-year disease-free rates from 60% to 80%. Resection of isolated pulmonary metastases may prolong survival.

Juxtacortical osteosarcoma is a rare variant of osteosarcoma that occurs on the surface of the bone, especially the lower posterior metaphysis of the femur (70% of cases). Unlike classic osteosarcoma, most patients are older than 25 years, and the tumor is more common in women. Juxtacortical osteosarcoma spares the deep cortex and medulla of the bone and grows external to the shaft. Usually, Codman triangle is not evident radiologically, because the periosteum is not elevated. Most juxtacortical osteosarcomas are low-grade lesions and do not require adjunctive chemotherapy. Surgical excision is the treatment of choice. The prognosis is good, with a 5-year survival of more than 80%.

Other rare variants of osteosarcoma include telangiectatic and small cell osteosarcoma, which are high-grade tumors, and low-grade intramedullary osteosarcoma.

Chondrosarcoma Is a Cartilaginous Malignancy Whose Grade Determines Prognosis

Chondrosarcoma is a malignant tumor of cartilage that arises from a preexisting cartilage rest or a preexisting lesion like an enchondroma. Some patients have a history of multiple enchondromas, solitary osteochondroma or hereditary multiple osteochondromas. Most have no known preexisting lesion. ***Chondrosarcoma is the second most common primary malignant bone tumor and is more common in men than in women (2:1).*** It is most frequently seen in the fourth to sixth decades (average age, 45 years).

MOLECULAR PATHOGENESIS: Numerous nonrandom chromosomal abnormalities have been discovered in chondrosarcoma. There probably is a different molecular mechanism resulting in tumor development between central chondrosarcoma and secondary peripheral chondrosarcoma (tumors arising in the cartilaginous cap of an osteochondroma; see below). The latter may develop by upregulation of PTHrP and Bcl-2 expression in an osteochondroma, along with mutations in other genes such as *p53* and nonspecific chromosomal abnormalities. Development of central chondrosarcoma is related, at least in part, to abnormalities of chromosome 9p12-22, which may involve the *CDKN2A* tumor suppressor gene. The transcription factor *SOX9,* which plays a critical role in normal chondrocyte development, is expressed in chondrosarcomas.

PATHOLOGY: Chondrosarcoma occurs in three anatomic variants:

CENTRAL CHONDROSARCOMA: This form arises in the medullary cavity of pelvic bones, ribs and long bones, although any site may be affected. Radiologically, poorly defined borders, a thickened shaft and perforation of the cortex characterize these tumors. There are usually stippled or ring-like radiopacities representing calcification or endochondral ossification in the tumor (Fig. 30-47A). Although central chondrosarcoma may penetrate the cortex, extension beyond the periosteum is uncommon. On gross examination, the neoplastic cartilaginous tissue is compressed inside the bone and exhibits areas of necrosis, cystic change and hemorrhage (Fig. 30-47B). The cortex of the bone and the intertrabecular spaces of the marrow are infiltrated by the tumor.

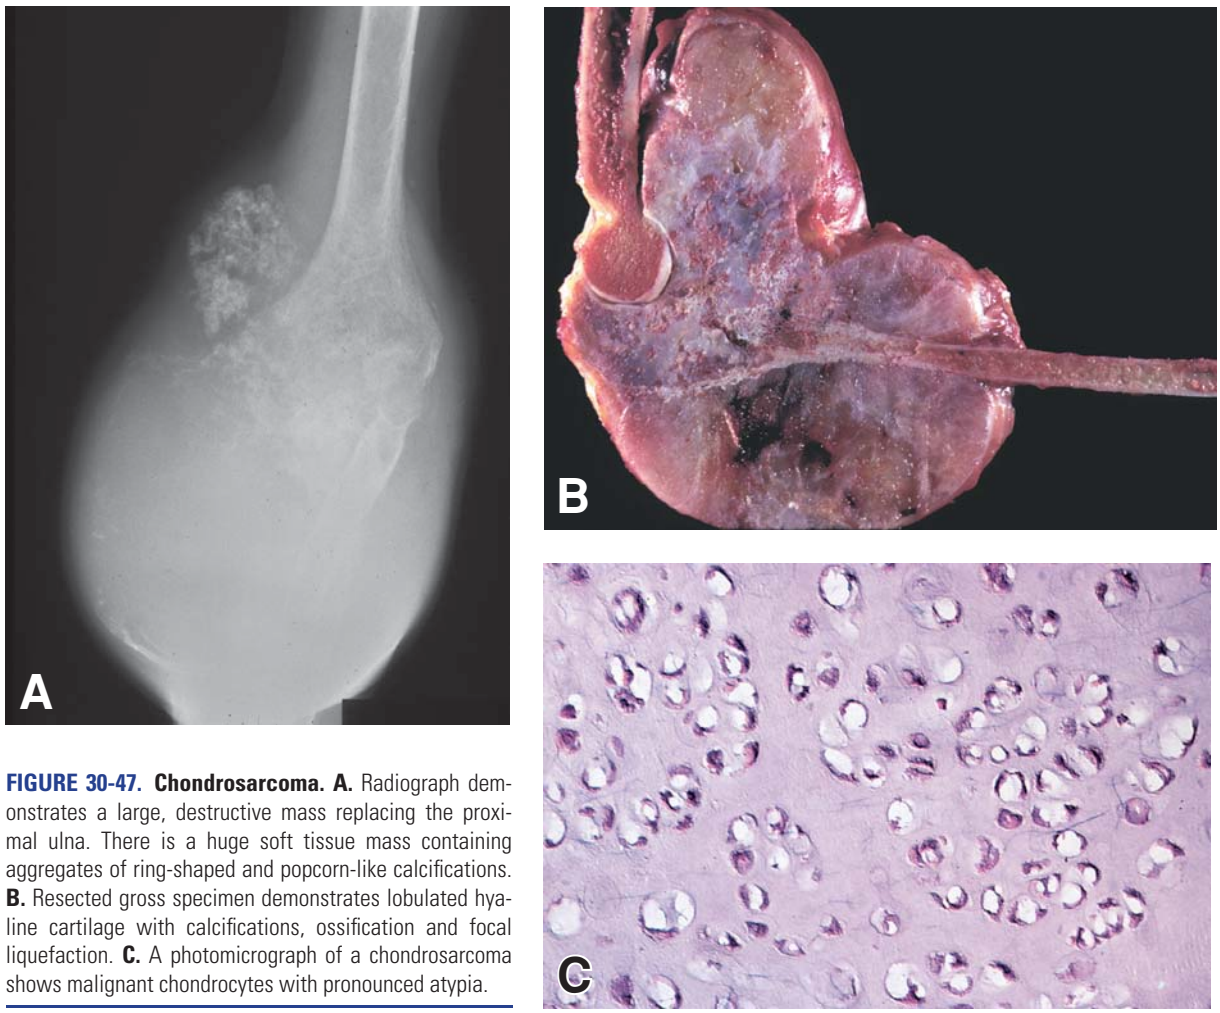

FIGURE 30-47. Chondrosarcoma. A. Radiograph demonstrates a large, destructive mass replacing the proximal ulna. There is a huge soft tissue mass containing aggregates of ring-shaped and popcorn-like calcifications. **B.** Resected gross specimen demonstrates lobulated hyaline cartilage with calcifications, ossification and focal liquefaction. **C.** A photomicrograph of a chondrosarcoma shows malignant chondrocytes with pronounced atypia.

Central chondrosarcoma begins with deep pain, which becomes more intense with time. The tumor is only rarely palpable, but in untreated cases, large masses may eventually form.

PERIPHERAL CHONDROSARCOMA: This variant is less common than the central variety of chondrosarcoma and arises outside the bone, almost always in the cartilaginous cap of an osteochondroma. It occurs after the age of 20 years and never before puberty. The most frequent location of peripheral chondrosarcoma is the pelvis, followed by the femur, vertebrae, sacrum, humerus and other long bones. It arises only rarely distal to the knee or elbow. Radiologically, characteristic radiopacities, representing calcification or ossification of the neoplastic cartilage, are virtually pathognomonic for the lesion. Macroscopically, peripheral chondrosarcoma tends to be a large bosselated mass that surrounds the base of an osteochondroma and invades and destroys the bone.

Peripheral chondrosarcoma is usually seen as a slowly growing mass. Expansion of the mass causes pain and local symptoms. In the pelvis, the lumbosacral plexus may be compressed, and tumors in the vertebrae may cause paraplegia.

JUXTACORTICAL CHONDROSARCOMA: This is the least common variety of chondrosarcoma and is similar to central chondrosarcoma in its predilection for middle-aged men. It tends to be situated in the metaphysis of long bones, lying on the outer surface of the cortex. Thus, it is probably periosteal or parosteal in origin. Radiologically, it may be entirely translucent or focally calcified. The symptoms of juxtacortical chondrosarcoma are dominated by swelling, with little accompanying pain.

Histologically, chondrosarcomas are composed of malignant cartilage cells in various stages of maturity (Fig. 30-47C). Occasionally, a well-differentiated chondrosarcoma is difficult to distinguish from a benign enchondroma on cytologic grounds alone. Zones of calcification are often conspicuous and are seen radiographically as splotches or bulky masses. Chondrosarcoma expands by stimulating osteoclastic resorption of bone and often breaks through the cortex. Most chondrosarcomas grow slowly, but hematogenous metastases to the lungs are common in poorly differentiated variants.

There is a positive correlation between histologic grade, morphologic features and the degree of karyotypic complexity. Trisomy 7 is associated with chondrosarcoma. Rearrangement of the short arm of chromosome 17 is associated with high-grade chondrosarcoma. Alterations of 12q13 are found in tumors that exhibit myxoid features.

OTHER VARIANTS OF CHONDROSARCOMA: The above forms of chondrosarcoma are all characterized by a hyaline cartilage matrix. Uncommon histopathologic variants of chondrosarcoma include **clear cell chondrosarcoma,** which occurs almost exclusively in the proximal epiphysis of the femur or humerus and is composed of chondrocytes with abundant clear cytoplasm, areas of woven trabecular

bone and focal regions with a hyaline cartilage matrix. The prognosis for this tumor following complete excision is close to that of a conventional low-grade chondrosarcoma. **Dedifferentiated chondrosarcoma** is defined as a high-grade nonchondrogenic pleomorphic sarcoma (e.g., osteosarcoma or fibrosarcoma) arising in association with a low-grade conventional chondrosarcoma or enchondroma. This tumor usually arises in flat bones of the pelvis or long bones of the extremities and has a dismal prognosis, with less than 10% of patients surviving 5 years. Another variant is known as **mesenchymal chondrosarcoma** and is histologically characterized by two distinct components. The first is a high-grade malignant, small, round, blue-cell tumor that resembles Ewing sarcoma. Sheets of these cells are interrupted by discrete islands of malignant hyaline cartilage histologically similar to conventional chondrosarcoma. The bones of the jaw and the chest wall are the most commonly affected sites. The prognosis for these tumors is poor.

CLINICAL FEATURES: Patients generally present with pain at the affected site. Chondrosarcoma is one of the few tumors in which microscopic grading has a significant prognostic value. The 5-year survival rate for low-grade conventional chondrosarcomas is

TABLE 30-2
SELECTED CHROMOSOMAL ABNORMALITIES IN SOFT TISSUE TUMORS

80%, for moderate-grade tumors 50% and for high-grade tumors only 20%. Wide excision is the usual treatment, since response to radiation and chemotherapy is poor.

Ewing Sarcoma Is a Primitive Neuroectodermal Tumor of Childhood

Ewing sarcoma (EWS) is an uncommon malignant bone tumor composed of small, uniform, round cells (blue cells). It represents only 5% of all bone tumors and is found in children and adolescents, with two thirds of cases occurring in patients younger than 20 years. Boys are affected more often than girls (2:1). EWS is very rare in blacks. About 10%–20% of Ewing sarcomas are extraskeletal.

MOLECULAR PATHOGENESIS: EWS is thought to arise from primitive marrow elements or immature mesenchymal cells. Most (90%) of these tumors have a reciprocal translocation between chromosomes 11 and 22 [t(11;22)(q24;q12)], resulting in the fusion of the amino terminus of the *EWS1* gene to the carboxy terminus of the *FLI-1* gene, which encodes a transcription factor. The resulting fusion protein, EWS/FLI-1, is an aberrant transcription factor whose target genes are not yet fully identified. A less common translocation, t(21;22)(q22;q12), generates *EWS/ERG* gene fusion. Other alternate chromosomal rearrangements seen in EWS are listed in Table 30-2.

PATHOLOGY: EWS is primarily a tumor of the long bones in childhood, especially the humerus, tibia and femur, where it occurs as a midshaft or metaphyseal lesion. It tends to parallel the distribution of red marrow, so when it arises in the third decade or later, it affects the pelvis and spine. However, no bone is immune from involvement.

The radiographic findings are variable and depend on the interaction of the tumor with the host bone. There is often a destructive process in which the border between normal bone and the lesion is indistinct. Periosteal reaction and a soft tissue mass are also commonly seen (Fig. 30-48A). The onion-skin pattern of periosteal bone that is sometimes present on radiologic examination represents circumferential discontinuous layers of periosteal new bone associated with a lytic lesion in the medulla and endosteal surface of the cortex. Some patients present with fever and weakness as well as bone pain, so it is not surprising that their condition may be mistaken for osteomyelitis.

On gross examination, EWS is typically soft and grayish white, often studded by hemorrhagic foci and necrotic areas. The tumor may infiltrate the medullary spaces without destroying the bony trabeculae. It may also diffusely infiltrate the cortical bone or form nodules in which the bone is completely resorbed. In many cases, the tumor mass penetrates the periosteum and extends into the soft tissues.

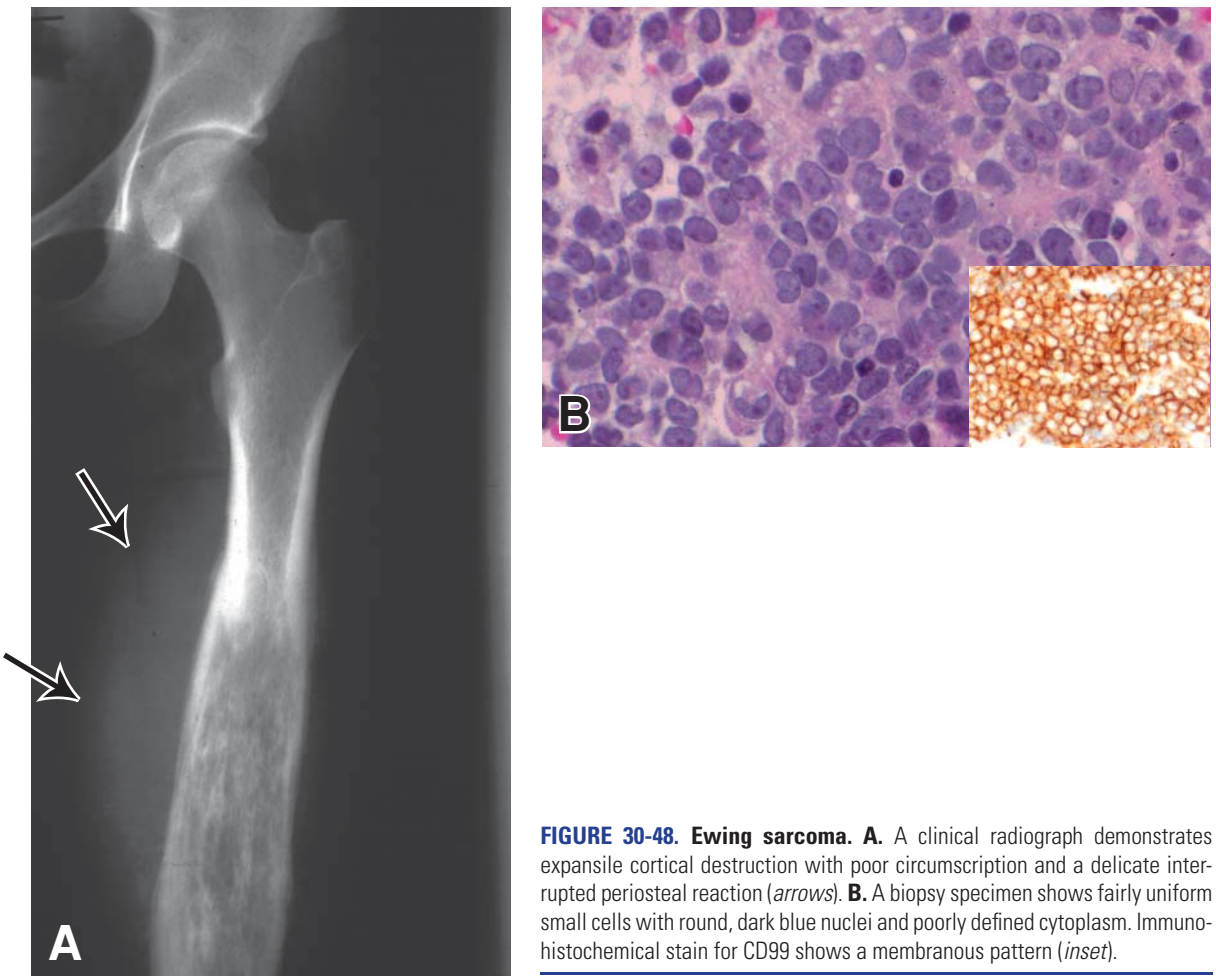

FIGURE 30-48. Ewing sarcoma. A. A clinical radiograph demonstrates expansile cortical destruction with poor circumscription and a delicate interrupted periosteal reaction (*arrows*). **B.** A biopsy specimen shows fairly uniform small cells with round, dark blue nuclei and poorly defined cytoplasm. Immunohistochemical stain for CD99 shows a membranous pattern (*inset*).

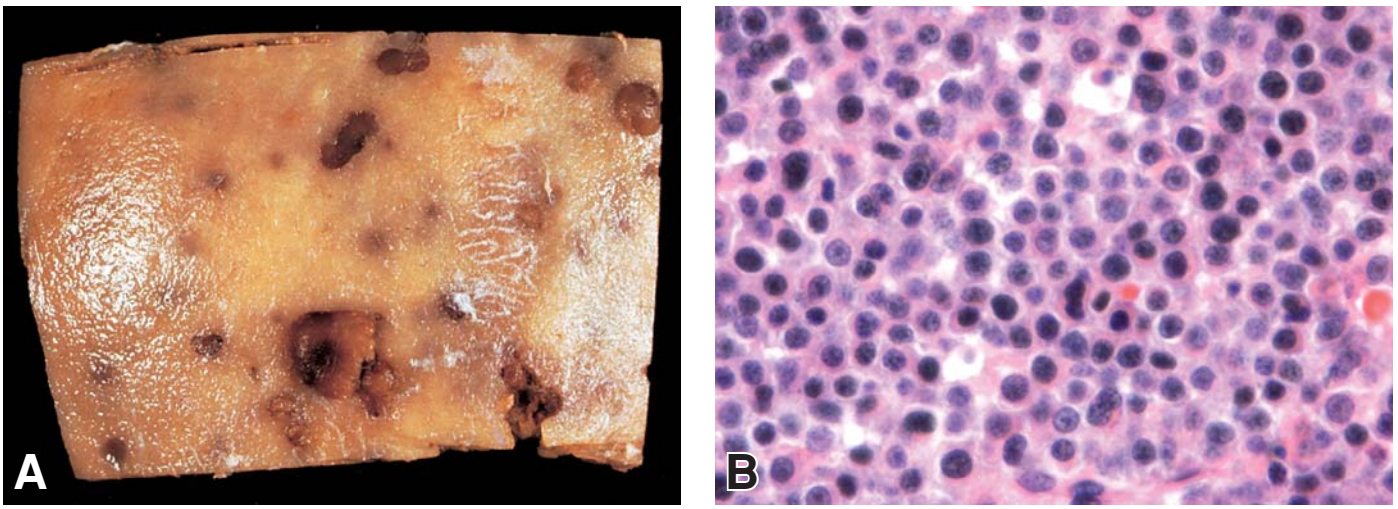

FIGURE 30-49. Multiple myeloma. A. A segment of the skull from a patient with multiple myeloma reveals numerous punched-out, lytic lesions. **B.** Microscopically, the lesions are composed of sheets of plasma cells with atypia, binucleation and discernible nucleoli.

Microscopically, EWS cells appear as sheets of closely packed, small, round cells with little cytoplasm, which are up to twice the size of a lymphocyte (Fig. 30-48B). Fibrous strands separate the sheets of cells into irregular nests. There is little or no interstitial stroma, and mitoses are frequent. In some areas, the neoplastic cells tend to form rosettes. An important diagnostic feature is the presence of substantial amounts of glycogen in the cytoplasm of the tumor cells, which is well visualized with the periodic acid–Schiff (PAS) stain. EWS cells also express characteristic antigens that can be detected by immunohistochemistry (Fig. 30-48B, *inset*), some of which are part of the translocation product (e.g., CD99 and FLI-1).

EWS metastasizes to many organs, including the lungs and brain. Other bones, especially the skull, are common sites for metastases (50%–75% of cases).

CLINICAL FEATURES: EWS initially presents with mild pain, which becomes more intense and is followed by swelling of the affected area. Nonspecific symptoms, including fever and leukocytosis, commonly follow. In some cases, a soft tissue mass is encountered.

Although EWS prognosis used to be dismal, with current use of chemotherapy plus radiation and limb-sparing surgery, the 5-year disease-free survival is 60%–75% in the absence of metastases.

Multiple Myeloma Produces Lytic Lesions in Bone

Malignant plasma cell tumors may be either localized (plasmacytoma) or diffuse (see Chapter 26). Multiple myeloma occurs mostly in older people (average age, 65) and affects men twice as often as women. Because myeloma cells secrete cytokines that recruit osteoclasts, the lesions are unique in that they are almost exclusively lytic. The bones most frequently involved are the skull (Fig. 30-49A), spine, ribs, pelvis and femur. Pathologic fractures are common. On microscopic examination, sheets of plasma cells show varying degrees of maturity (Fig. 30-49B). Amyloid deposits, in both skeletal and extraskeletal sites, are seen in 10% of patients.

With newer therapeutic agents, the median survival of patients with multiple myeloma now is about 5 years. Death is usually due to infection or renal failure. Solitary plasmacytoma has a better prognosis, with a 60% 5-year survival.

Metastatic Tumors Are the Most Common Malignant Tumors in Bone

In adults, most metastatic lesions to bone are carcinomas, particularly of the prostate, breast, lung, thyroid and kidney. In children, the most common bone metastases are from rhabdomyosarcoma, neuroblastoma, Wilms tumor and clear cell sarcoma of the kidney. It is estimated that skeletal metastases are found in at least 85% of cancer cases that have run their full clinical course. The vertebral column is the most common location in adults (Fig. 30-50A), and the appendicular skeleton is the most common site in children. Tumor cells usually arrive in the bone via the bloodstream; in the case of spinal metastases, the vertebral veins often transport them.

Some tumors (e.g., thyroid, gastrointestinal tract, kidney and neuroblastoma) produce mostly lytic lesions by stimulating osteoclasts (Fig. 30-50B). A few neoplasms (e.g., prostate, breast, lung, stomach) stimulate osteoblastic components to make bone, creating dense foci on radiographs (blastic or sclerotic lesions). However, most deposits of metastatic cancer in the bones have mixtures of both lytic and blastic elements.

Joints

A joint (or articulation) is a union between two or more bones, whose construction varies with the function of that joint. There are two types of joints: (1) a **synovial** or **diarthrodial joint,** which is a movable joint, such as the knee or elbow, that is lined by a synovial membrane; and (2) a **synarthrosis,** which is a joint that has little movement.

Synarthroses are further divided into four subclassifications:

- A **symphysis** is an articulation joined by fibrocartilaginous tissue and firm ligaments that allows little movement. Examples are the symphysis pubis and the ends of vertebral joints.

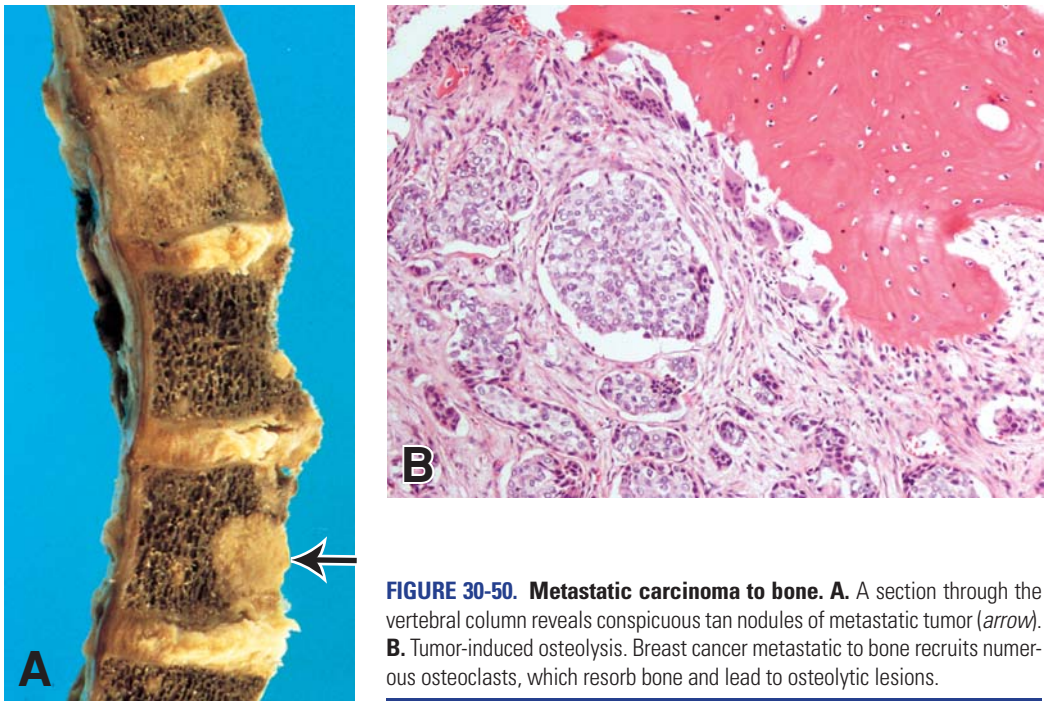

FIGURE 30-50. Metastatic carcinoma to bone. A. A section through the vertebral column reveals conspicuous tan nodules of metastatic tumor (*arrow*). **B.** Tumor-induced osteolysis. Breast cancer metastatic to bone recruits numerous osteoclasts, which resorb bone and lead to osteolytic lesions.

- A **synchondrosis** is found at the ends of bones and has articular cartilage but is not associated with synovium or a significant joint cavity (e.g., the sternal manubrial joint).
- A **syndesmosis** connects bones by fibrous tissue without any cartilaginous elements. The distal tibiofibular articulation and the cranial sutures are syndesmoses.
- A **synostosis** is a pathologic bony bridge between bones as, for example, in ankylosis of the spine.

Diseases of diarthrodial joints are among the oldest pathologic conditions known, having been found in the fossil bones of dinosaurs. One third of the population of the United States older than 50 years develop some form of clinically significant joint disease.

CLASSIFICATION OF SYNOVIAL JOINTS

The synovial, or diarthrodial, joints are classified according to the type of movement they permit.

- A **uniaxial joint** allows movement around only one axis. Examples include a hinge joint such as the elbow and a pivot (rotational) joint such as the radioulnar joint.
- A **biaxial joint** allows movement around two axes, as the condyloid joint of the wrist axis is oriented in the long diameter and the other along the short diameter of the articular surfaces. This allows four-way movement: flexion, extension, abduction and adduction. In a saddle joint, such as the carpometacarpal joint of the thumb, joint surfaces allow movement as in a condyloid joint.
- **Polyaxial joints** permit movement in virtually any axis. In a ball-and-socket joint, such as is found in the shoulder and hip, all movements, including rotation, are possible.
- A **plane joint,** represented by the patella, allows articular surfaces to glide over one another.

UNIT LOAD: **The concept of unit load is the most important principle in understanding joint function.** The unit load is the compressive force, expressed as kilograms per cubic centimeter of articular cartilage. It is fairly constant over the hip, knee and ankle (20–26 kg/cm^3 along the articular surfaces). Because the articular cartilage is injured if a load exceeds these values, several mechanisms protect a joint from exceeding the unit load.

Adjacent muscles are the major shock-absorbing structures that protect the joint. Deformation, even to the extent of microscopic fractures of the coarse cancellous bone, also helps protect the joint. Joint deformation allows the contact area to increase with increasing load. Diarthrodial joints may have intra-articular structures, such as ligaments and menisci. Menisci hold distributed force along the articular surface and allow two planes of motion, such as flexion and rotation. However, 90% or more of energy absorption across the knee joint is by active muscle contraction, and only 10% or less is by secondary mechanisms, such as by the coarse cancellous bone of the knee joint. A properly functioning joint also requires support from ligaments and tendons, periarticular connective tissues such as the joint capsule and nerves that provide proprioception. Thus, to protect the articular cartilage from forces that exceed the critical unit load, virtually any structure is sacrificed, even to the point of a bone fracture.

Once there is an insult to one component of the joint, the resulting dysfunction can lead to degeneration of other components of the joint. For example, knee ligament injuries sustained by athletes, such as a torn anterior cruciate ligament, can result in joint instability. Over time, this situation contributes to degeneration of articular cartilage, owing to changes in movement and load on the joint (secondary osteoarthritis).

ARTHRITIS: Arthritis refers to joint inflammation, usually accompanied by pain, swelling and sometimes change in structure. Arthritis is divided into two major forms: (1) **inflammatory arthritis** usually involves the synovium and is mediated by inflammatory cells (e.g., rheumatoid arthritis), and (2) **noninflammatory arthritis,** as featured in primary

osteoarthritis, may involve cytokines in its pathogenesis (see below).

STRUCTURES OF THE SYNOVIAL JOINT

Movement plays a major role in joint formation. Lack of movement retards joint development and may cause **arthrogryposis,** a rare but crippling disease characterized by joint fusion.

Synovium

Synovial joints are partially lined on their internal aspects by the synovium. Synovial linings are not true membranes since they lack basement membranes to separate synovial lining cells from subsynovial tissue. The synovium is composed of one to three layers of lining cells and is made up of two cell types distinguishable only by electron microscopy. **Type A cells** are macrophages with lysosomal enzymes and dense bodies. **Type B cells** secrete hyaluronic acid. Synovial cell membranes are disposed in villi and microvilli, an arrangement that creates an enormous surface area. It is estimated that the knee alone has 100 m^2 of synovial lining.

The synovium controls (1) diffusion in and out of the joint; (2) ingestion of debris; (3) secretion of hyaluronate, immunoglobulins and lysosomal enzymes; and (4) lubrication of the joints by secreting glycoproteins. Synovial fluid is clear, sticky and viscous. It is present only in small amounts, not exceeding 1–4 mL, and is the main source of nourishment for chondrocytes of the articular cartilage, which lacks a blood supply. Synovial fluid is an ultrafiltrate that acts as a molecular sieve. It does not contain tissue thromboplastin and so cannot clot. Hyaluronate is a very large molecule and, because it is highly charged, has a high affinity for water.

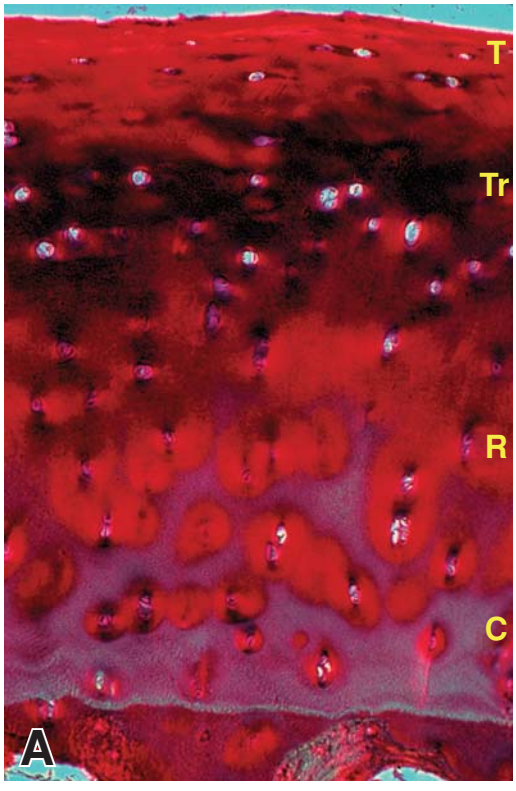
Articular Cartilage

The hyaline cartilage that covers the articular ends of bones does not participate in endochondral ossification and is well suited for its dual role of absorbing shocks and lubricating the surfaces of movable joints. On gross examination, the articular cartilage is glistening, smooth, white and semirigid, and is generally not thicker than 6 mm.

Joint Histology

The articular surface appears smooth to the eye, but scanning electron microscopy reveals gentle waves and pits that correspond to the underlying lacunae of the surface chondrocytes. There are four zones in articular cartilage (Fig. 30-51).

- **Tangential** or **gliding zone:** This is the region closest to the articular surface, where chondrocytes are elongated, flattened and parallel to the long axis of the surface. Within this zone, a condensation of type II collagen fibers forms the so-called skin of the articular cartilage.
- **Transitional zone:** Chondrocytes in this slightly deeper zone are larger, ovoid and more randomly distributed than those in the tangential zone. The standard hyaline cartilage matrix is present, and by electron microscopy, the collagen fibers are arranged transverse to the articular surface.
- **Radial zone:** The next deeper zone is the radial zone, where chondrocytes are small and are arranged in short columns like those seen in the epiphyseal plate. In this area, collagen fibers are large and oriented perpendicular to the long axis of the articular surface.



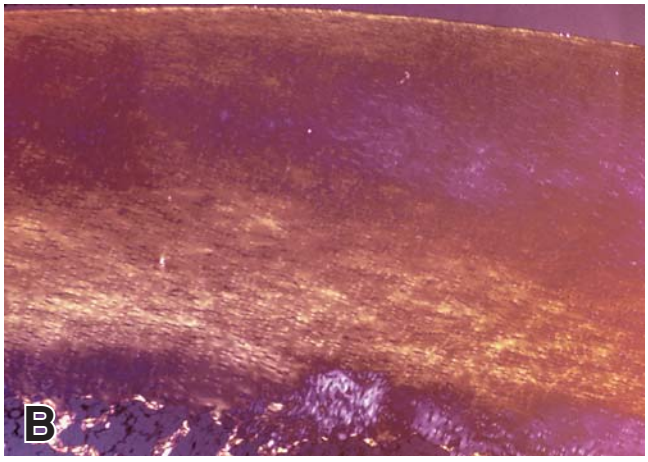


FIGURE 30-51. Articular hyaline cartilage. A. Demonstrating tangential zone (T), transitional zone (Tr), radial zone (R) and calcified zone (C). The chondrocyte lacunae change shape in conformation with the direction of the collagen arcades in the cartilage. **B.** Articular cartilage, polarized light. The tangential and radial zones have the highest concentration of collagen fibers and appear bright yellow.

- **Calcified zone:** Small chondrocytes and a heavily calcified matrix characterize the deepest region.

The calcified zone is separated from the radial zone by a transverse, undulating, heavily calcified "blue line" (evident on hematoxylin–eosin staining), called the **tidemark**. The tidemark is the interface between mineralized and unmineralized cartilage. Above the tidemark on the joint side, all of the cartilage is nourished by diffusion from the synovial fluid. Deep to the tidemark, the calcified cartilage is supplied by epiphyseal blood vessels.

The tidemark is the area where the cartilage cells are renewed. As a result of cell division, true articular chondrocytes migrate upward toward the joint surface. Cell division below the tidemark occurs in the calcified cartilage, if there is appropriate stimulation. For example, in acromegaly, when the epiphyseal plates have already closed, the bones may grow in minute increments, because growth hormone stimulates the calcified cartilage remnant of the epiphyseal cartilage anlage. Because the joints in acromegaly do not keep pace, joint incongruity leads to severe osteoarthritis. Deep to the calcified cartilage, the transverse bony plate, called the **subchondral bone plate,** supports the articular cartilage. It is directly contiguous with the coarse cancellous bone of the epiphysis.

OSTEOARTHRITIS

Osteoarthritis (OA), also known as degenerative joint disease (DJD), is a slowly progressive destruction of articular cartilage that affects weight-bearing joints and fingers of older individuals or the joints of younger people subjected to trauma. OA is the single most common form of joint disease and the major form of noninflammatory arthritis. It is a group of conditions that have in common the mechanical destruction of a joint.

In **primary OA,** destruction of joints results from intrinsic defects in the articular cartilage. The prevalence and severity of primary OA increase with age. About 4% of people aged 18–24 are affected, versus 85% of those 75–79 years. Before age 45, the disease mainly affects men. After age 55, OA is more common in women. Many cases of primary OA exhibit a familial clustering, suggesting a hereditary predisposition.

In primary OA, progressive degradation of articular cartilage leads to joint narrowing, subchondral bone thickening and eventually a nonfunctioning painful joint. Although OA is not primarily an inflammatory process, a mild inflammatory reaction may occur within the synovium.

Secondary OA has a known underlying cause, including congenital or acquired incongruity of joints, trauma, crystal deposits, infection, metabolic diseases, endocrinopathies, chronic inflammatory diseases, osteonecrosis and hemarthrosis.

Chondromalacia is a term applied to a subcategory of OA that affects the patellar surface of the femoral condyles of young people and produces pain and stiffness of the knee.

ETIOLOGIC FACTORS:

INCREASED UNIT LOAD: Abnormal force on the cartilage may have many causes but is often attributable to incongruities of the joint. Thus, in congenital hip dysplasia, a fairly common abnormality, the socket of the acetabulum is shallow, covering only 35% of the femoral head (normal, 50%). Less surface area is covered by articular cartilage, which thus bears an increased load. When the critical unit load is exceeded, chondrocyte death causes degradation of articular cartilage.

RESILIENCE OF THE ARTICULAR CARTILAGE: Because articular cartilage binds extensive amounts of water, it normally has a swelling pressure of at least 3 atmospheres. Disruption in water bonding leads to decreased resilience.

STIFFNESS OF SUBCHONDRAL COARSE CANCELLOUS BONE: The structure of bone adjacent to a joint is important in maintaining articular cartilage. Mechanical forces are not transferred to articular cartilage by normal stress, but rather are dissipated by microfractures of coarse cancellous bone. Damage to this structure results in an increased unit load on the cartilage because of an increase in the stiffness of subchondral bone (e.g., in Paget disease).

MOLECULAR PATHOGENESIS:

BIOCHEMICAL ABNORMALITIES: The biochemical changes of OA mainly involve proteoglycans. Proteoglycan content and aggregation decrease, and glycosaminoglycan chain length is reduced. Collagen fibers are thicker than normal and the water content of osteoarthritic cartilage increases. The reduction in proteoglycans allows more water to be bound to the collagen. Thus, osteoarthritic cartilage, or any cartilage that is fibrillated, swells more than normal cartilage.

Although matrix synthesis by chondrocytes is increased early in OA, protein synthesis eventually declines, suggesting that the cells reach a point at which they fail to respond to reparative stimuli. Similarly, chondrocytes in early osteoarthritic cartilage replicate, but cell replication diminishes with advanced disease. Acid cathepsin, which attacks the protein cores of the matrix macromolecules, increases in osteoarthritic cartilage. Collagenase is absent in normal cartilage but is found in osteoarthritic cartilage.

Chondrocyte apoptosis, decreased type II collagen synthesis and breakdown of extracellular matrix also occur and have been correlated with local increases in IL-1β and TNF-α. In turn, these cytokines induce increased production of matrix metalloproteinases (MMPs), nitric oxide and PGE_2. Mechanical stress appears to be the triggering factor for these signaling cascades.

Studies of identical twins have demonstrated genetic contributions to the prevalence of OA. Genetic analysis of patients with a type of familial, early-onset OA revealed a variety of mutations in the gene for type II collagen (*COL2A1*), the major collagen species of articular cartilage.

PATHOLOGY: Joints commonly affected by OA are the proximal and distal interphalangeal joints, as well as the joints of the arms, knees, hips and cervical and lumbar spine. Radiologically, OA is characterized by (1) narrowing of the joint space, which represents the loss of articular cartilage; (2) increased thickness of the subchondral bone; (3) subchondral bone cysts; and (4) large peripheral growths of bone and cartilage, called **osteophytes** (Fig. 30-52). Histologic changes follow a well-described sequence.

1. First, loss of proteoglycans from the surface of the articular cartilage is seen histologically as decreased metachromatic staining. At the same time, empty lacunae in articular cartilage indicate that chondrocytes have died

FIGURE 30-52. A radiograph of a patient with osteoarthritis of the right knee demonstrating marked narrowing of the joint space, increased density of subchondral bone and osteophyte formation laterally.

(Fig. 30-53A). Viable chondrocytes enlarge, aggregate into groups or clones (Fig. 30-53C) and become surrounded by basophilic staining matrix called the **territorial matrix**.

2. OA may arrest at this stage for many years before progressing to the next stage, which is characterized by fibrillation (i.e., development of surface cracks parallel to the long axis of the articular surface). These fibrillations may persist for many years before further progression occurs (Fig. 30-53B).
3. As fibrillations propagate, synovial fluid begins to flow into the defects. The cracks are progressively oriented more vertically, parallel to the long axis of the collagen fibrils. Synovial fluid penetrates deeper into the articular cartilage along these cracks. Eventually, pieces of articular cartilage break off and lodge in the synovium, inducing inflammation and a foreign body giant cell reaction. The result is a hyperemic and hypertrophied synovium.
4. As the crack extends down toward the tidemark and eventually crosses it, neovascularization from the epiphysis and subchondral bone extends into the area of the crack, inducing subchondral osteoclastic bone resorption (Fig. 30-53C). Adjacent osteoblastic activity also occurs and results in a thickening of the subchondral bone plate in the area of the crack. As neovascularization progressively extends into the area of the crack, mesenchymal cells invade and fibrocartilage forms as a poor substitute for the articular hyaline cartilage (Figs. 30-53D and 30-54A). These fibrocartilaginous plugs may persist, or they may be swept into the joint. The subchondral bone becomes exposed and burnished as it grinds against the opposite joint surface, which is undergoing the same process. These thick, shiny, smooth areas of subchondral bone are referred to as **eburnated** (ivory-like) bone.
5. In some areas, the eburnated bone cracks, allowing synovial fluid to extend from the joint surface into the subchondral bone marrow, where it eventually produces a **subchondral bone cyst** (Figs. 30-53E and 30-54B). These cysts increase in size as synovial fluid is forced into the space but cannot exit. Eventually, osteoclasts resorb bone and osteoblasts attempt to wall off the area. The result is a subchondral bone cyst filled with synovial fluid, with a well-marginated, reactive bone wall.
6. An osteophyte develops, usually in the lateral portions of the joint, when the mesenchymal tissue of the synovium differentiates into osteoblasts and chondroblasts to form a mass of cartilage and bone. Osteophytes are pearly grayish bone nodules on the periphery of the joint surface. These osteophytes, or bony spurs, also occur at lateral edges of intervertebral disks, extending from the adjacent vertebral bodies. They produce the "lipping" pattern seen on radiologic studies as OA of the spine. In the fingers, osteophytes at the distal interphalangeal joints are called **Heberden nodes**.

CLINICAL FEATURES: The signs and symptoms of OA are functions of the location of the involved joints and the severity and duration of the joint deterioration. Physical findings vary. The involved joints may be enlarged, tender and boggy and may demonstrate crepitus. Deep, achy joint pain that follows activity and is relieved by rest is the clinical hallmark of OA. Pain is usually a sign of significant joint destruction and arises in the periarticular structures, since articular cartilage lacks a nerve supply. Discomfort also is caused by short periods of stiffness, which is frequently experienced in the morning or after periods of minimal activity. Restricted joint motion indicates severe disease and may result from joint or muscle contractures, intra-articular loose bodies, large osteophytes and loss of congruity of the joint surfaces.

At present, OA cannot be prevented or arrested. Therapy is directed at specific orthopedic conditions and includes exercise, weight loss and other supportive measures. In disabling osteoarthritis, joint replacement may be necessary.

NEUROPATHIC JOINT DISEASE (CHARCOT JOINT)

Neuropathic joint disease is a form of noninflammatory arthritis characterized by progressive joint destruction due to a primary neurologic disorder, such as peripheral neuropathy or central motor abnormality. In the mid-19th century, Jean-Martin Charcot described destruction of knee joints in patients with syphilitic tabes dorsalis (Charcot joint). ***Today, the most common form of neuropathic joint disease is destruction of foot joints in people with diabetic peripheral neuropathy.*** Destruction of shoulder or other upper extremity joints can occur in patients with syringomyelia, an abnormality affecting the cervical spinal cord.

Neuropathic joint disease can be viewed as a rapid and severe form of secondary OA in which a joint essentially fragments. Microscopically, there is marked destruction of articular cartilage and subchondral bone, inciting subchondral sclerosis, cyst formation and large amounts of cartilage and bone detritus within hyperplastic synovium. Although the pathogenesis remains uncertain, it is most likely that loss of innervation to the joint structures brings on a lack of proprioception and pain, abnormal joint mechanics and ultimately joint destruction.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a systemic, chronic inflammatory disease in which chronic polyarthritis involves

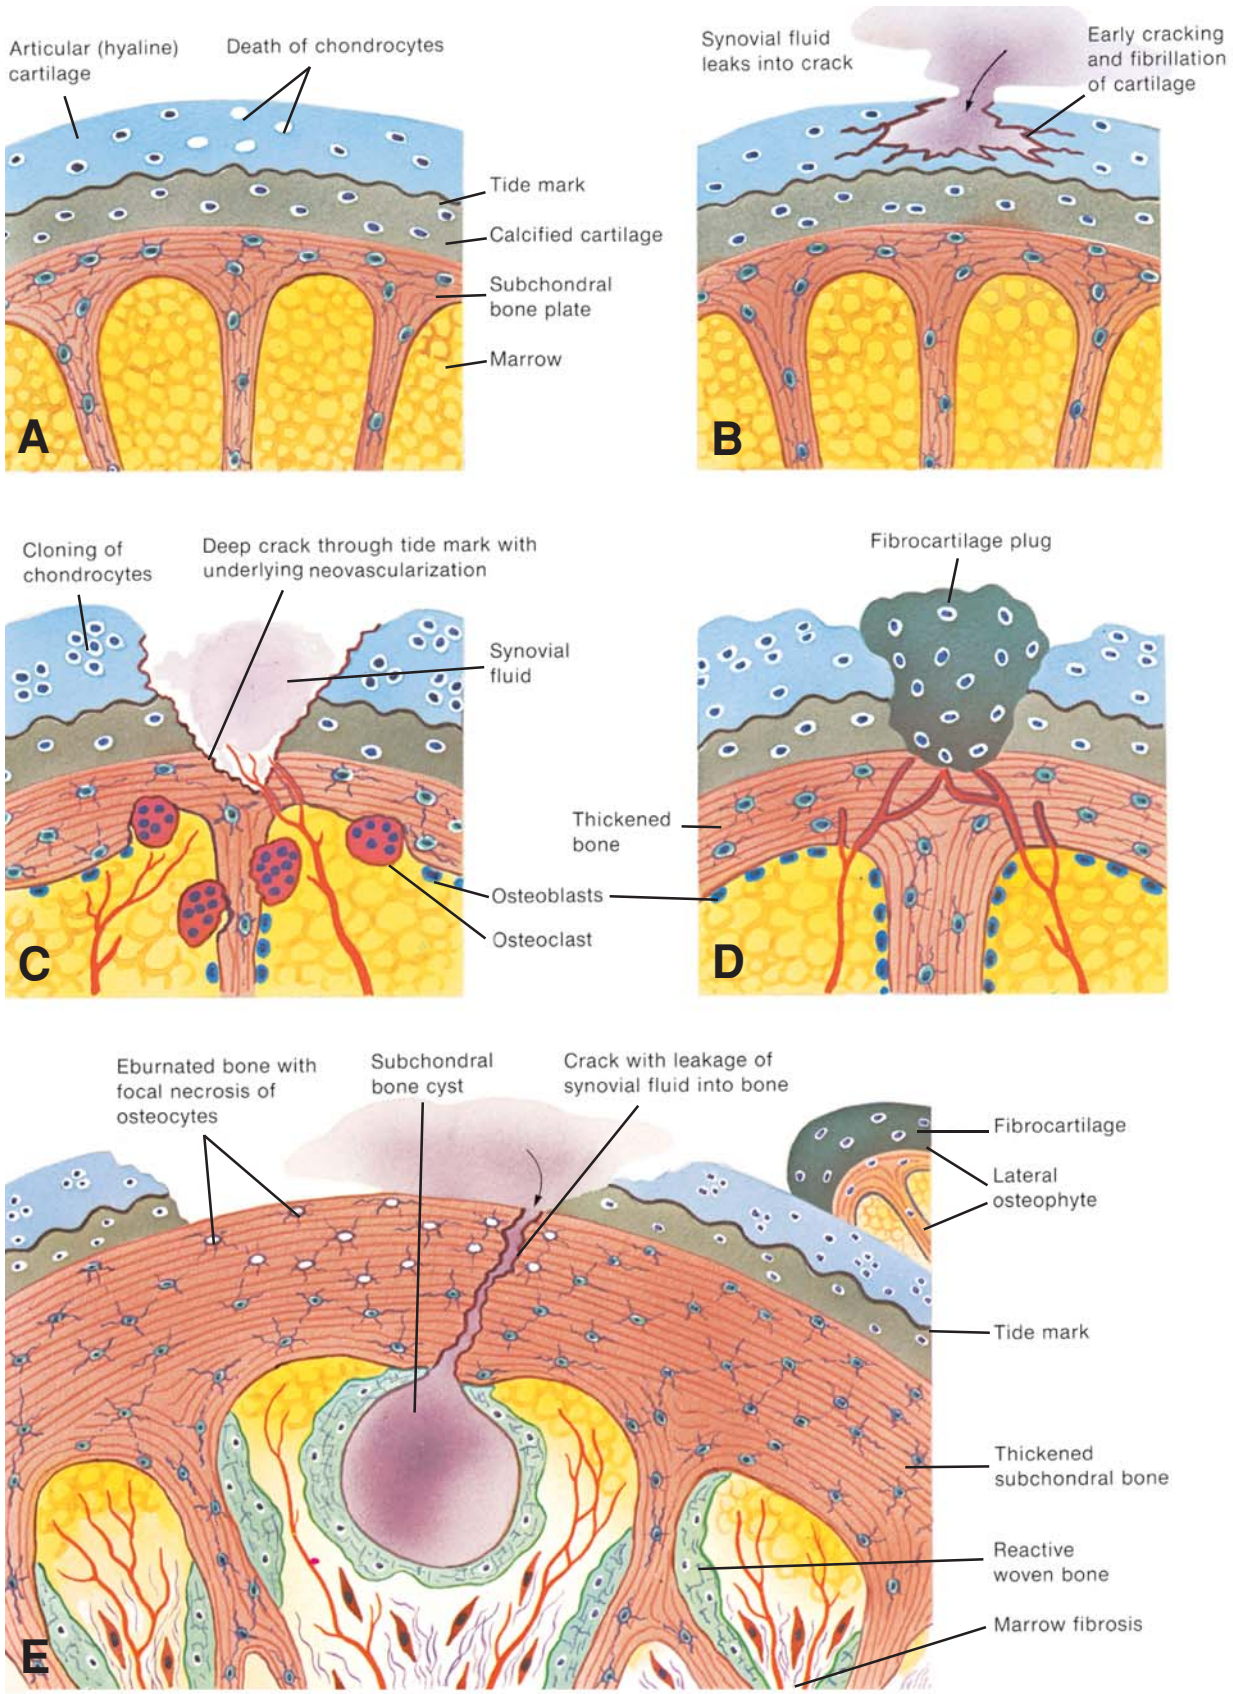

FIGURE 30-53. Histogenesis of osteoarthritis. A, B. The death of chondrocytes leads to a crack in the articular cartilage that is followed by an influx of synovial fluid and further loss and degeneration of cartilage. **C.** As a result of this process, cartilage is gradually worn away. Below the tidemark, new vessels grow in from the epiphysis, and fibrocartilage **(D)** is deposited. **E.** The fibrocartilage plug is not mechanically sufficient and may be worn away, thus exposing the subchondral bone plate, which becomes thickened and eburnated. If there is a crack in this region, synovial fluid leaks into the marrow space and produces a subchondral bone cyst. Focal regrowth of the articular surface leads to the formation of osteophytes.

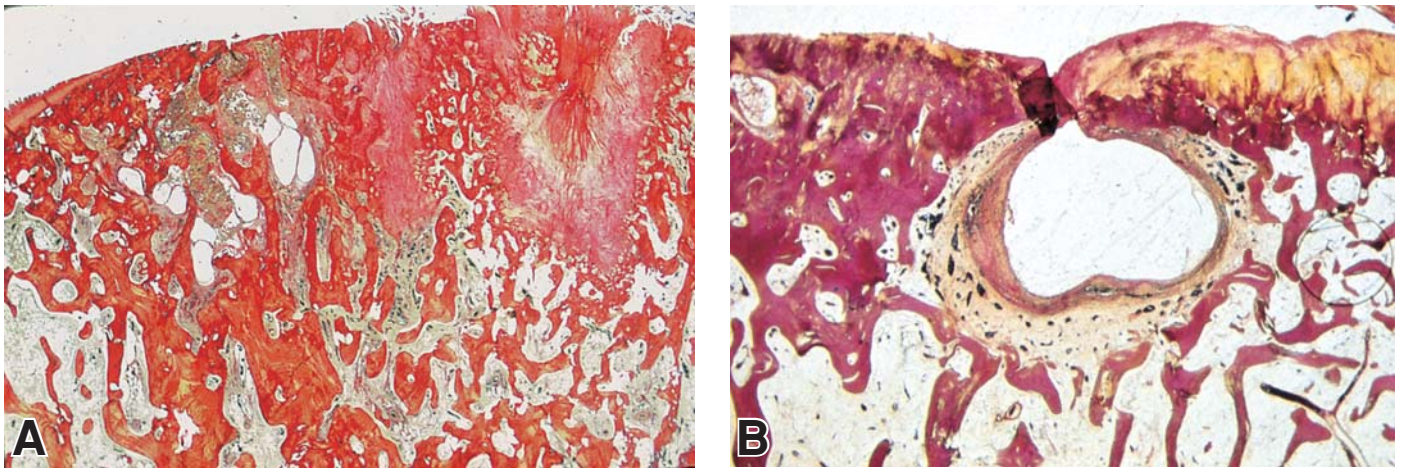

FIGURE 30-54. Osteoarthritis. A. A femoral head with osteoarthritis shows a fibrocartilaginous plug (*far right*) extending from the marrow onto the joint surface. Eburnated bone is present over the remaining surface. **B.** A section through the articular surface of an osteoarthritic joint demonstrates focal absence of the articular cartilage, thickening of subchondral bone (*left*) and a subchondral bone cyst.

diarthrodial joints, symmetrically and bilaterally (see Chapter 11). The proximal interphalangeal and metacarpophalangeal joints, elbows, knees, ankles and spine are most commonly affected. RA may occur at any age but usually begins in the third or fourth decade, and prevalence increases until age 70. The disease afflicts 1%–2% of the adult population, and its incidence is greater in women than in men (3:1). The excess incidence of RA in women is firmly established before menopause, after which the frequency for men and women increases uniformly. Commonly, joints of the extremities are simultaneously affected, often in a symmetric fashion. The course of the disease varies and is often punctuated by remissions and exacerbations. The broad spectrum of clinical manifestations ranges from barely discernible to severe, destructive, mutilating disease.

It is now thought that classic RA comprises a heterogeneous group of disorders. Patients who are persistently seronegative for rheumatoid factor probably have disease of a different etiology than those who are seropositive. There are also rheumatoid-like diseases associated with underlying conditions, such as inflammatory bowel disease and cirrhosis. The pathogenesis of RA is presented in Chapter 11.

PATHOLOGY: The early synovial changes of RA are edema and accumulation of plasma cells, lymphocytes and macrophages (Fig. 30-55-2). Vascularity increases, with exudation of fibrin into the joint space, which may result in small fibrin nodules that float in the joint **(rice bodies)**.

PANNUS FORMATION: Synovial lining cells, normally only one to three layers thick, undergo hyperplasia and form layers 8–10 cells deep. Multinucleated giant cells are often found among the synovial cells. The synovial lining is thus thrown into numerous villi and frond-like folds that fill the peripheral recesses of the joint (Figs. 30-55-3 and 30-56A,B). This inflammatory synovium, which now contains mast cells, creeps over the surface of the articular cartilage and adjacent structures and is a **pannus** (cloak). Pannus covers the articular cartilage and isolates it from the synovial fluid (Fig. 30-55-4). Lymphocytes aggregate and eventually develop follicular centers (Figs. 30-55-3 and 30-56B). The pannus erodes the articular cartilage and adjacent bone, probably through the action of collagenase produced by the pannus. Since PGE_2 and IL-1 are produced in the rheumatoid synovium, they may mediate bone erosion by stimulating osteoclasts.

The characteristic bone loss of RA is juxta-articular; that is, it is immediately adjacent to both sides of the joint. The pannus penetrates the subchondral bone; it may involve tendons and ligaments, leading to deformities and instabilities. Eventually, the joint is destroyed and undergoes fibrous fusion, or **ankylosis** (Fig. 30-55-5 and 30-57). Long-standing cases feature bony bridging of the joint **(bony ankylosis)**. The pannus may destroy cartilage by depriving it of nourishment; alternately, it may stimulate T lymphocytes to secrete a factor that causes release of lysosomal enzymes. In turn, this process may lead to secondary OA.

Changes in synovial fluid include a massive increase in volume, increased turbidity and decreased viscosity. The protein content and the number of inflammatory cells in the fluid increase, correlating with the activity of the rheumatoid process. In some cases, the leukocyte count exceeds 50,000/μL, with 95% polymorphonuclear leukocytes.

RHEUMATOID NODULES: RA is a systemic disease that also involves tissues other than joints and tendons. A characteristic lesion, the "rheumatoid nodule," is found in extra-articular locations. It has a central core of fibrinoid necrosis, which is a mixture of fibrin and other proteins, such as degraded collagen (Fig. 30-58). A surrounding rim of macrophages is arranged in a radial or palisading fashion. Beyond the macrophages is a circle of lymphocytes, plasma cells and other mononuclear cells. The overall appearance resembles a peculiar granuloma surrounding a core of fibrinoid necrosis. Rheumatoid nodules, which are usually found in areas of pressure (e.g., the skin of elbows and legs), are movable, firm, rubbery and occasionally tender. A large nodule may ulcerate. They often recur after surgical removal.

Rheumatoid nodules may also be seen in lupus erythematous and rheumatic fever. They are sometimes found in visceral organs, such as the heart, lungs, intestinal tract and even the dura. Nodules in the bundle of His may cause cardiac arrhythmias; in the lungs, they produce fibrosis and even respiratory failure (see Chapter 18). RA also may be accompanied by **acute necrotizing vasculitis,** which can affect any organ.

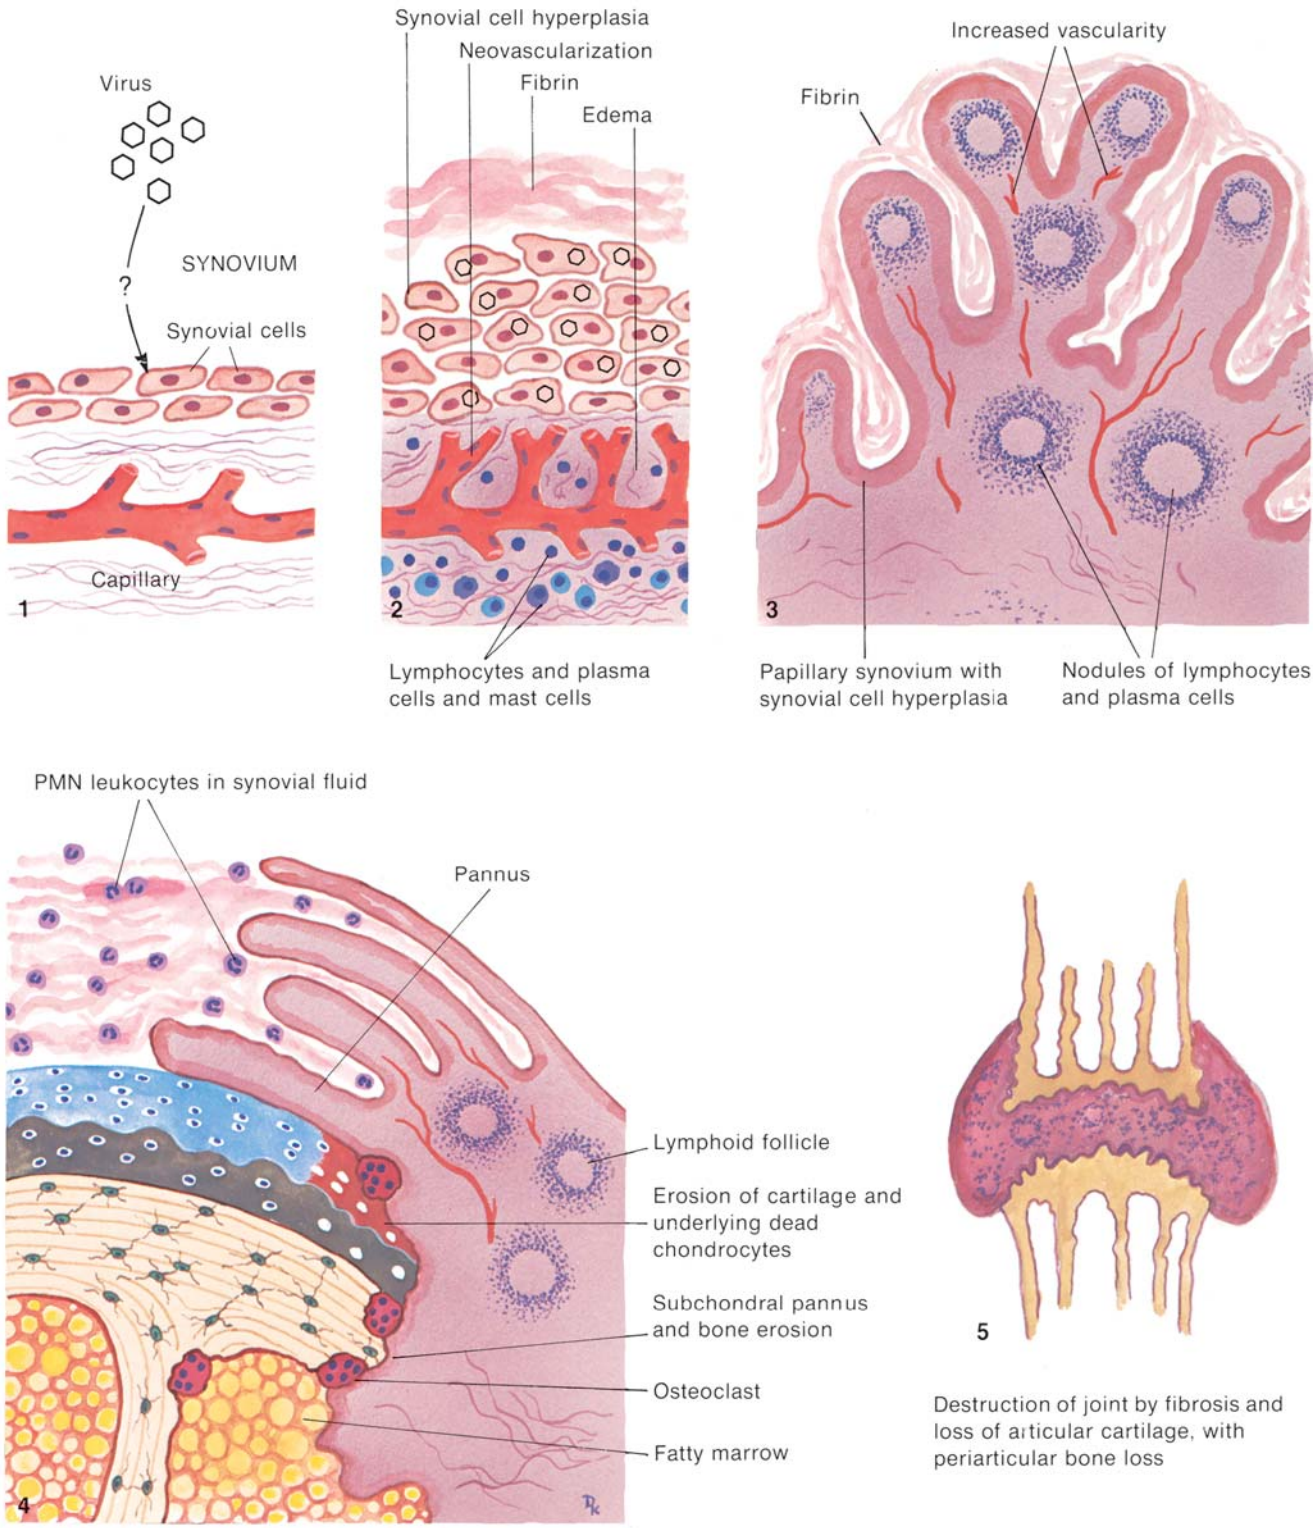

FIGURE 30-55. Histogenesis of rheumatoid arthritis. 1. A virus or an unknown stress may stimulate the synovial cells to proliferate. **2.** The influx of lymphocytes, plasma cells and mast cells, together with neovascularization and edema, leads to hypertrophy and hyperplasia of the synovium. **3.** Lymphoid nodules are prominent. **4.** Proliferating synovium extends into the joint space, burrows into the bone beneath the articular cartilage and covers the cartilage as a pannus. The articular cartilage is eventually destroyed by direct resorption or deprivation of its nutrient synovial fluid. The synovial tissue continues to proliferate in the subchondral region, as well as in the joint. **5.** Eventually, the joint is destroyed and becomes fused, a condition termed **ankylosis.**

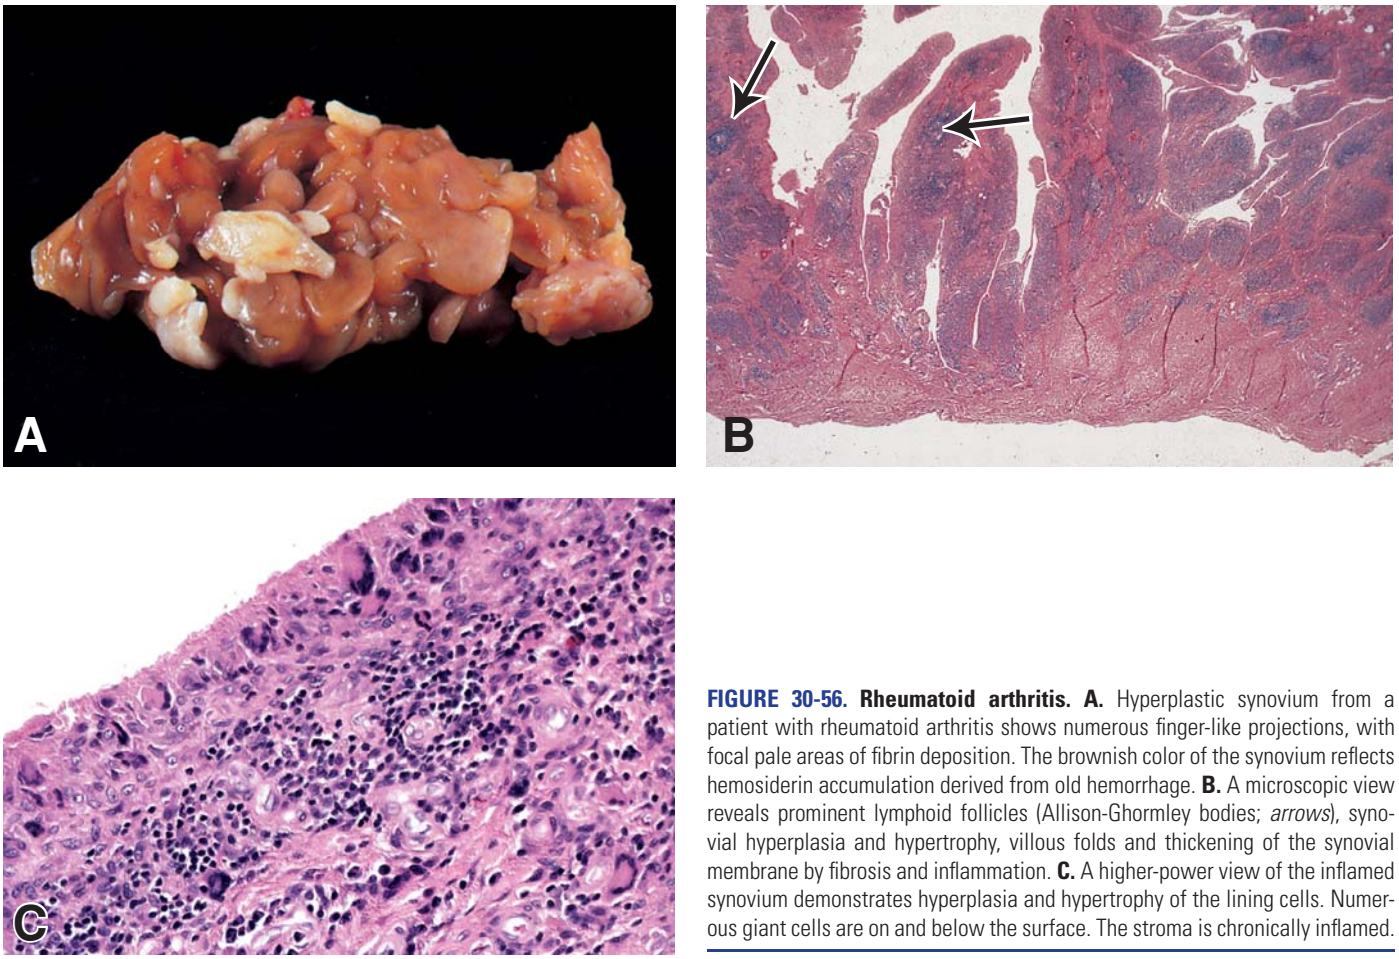

FIGURE 30-56. Rheumatoid arthritis. A. Hyperplastic synovium from a patient with rheumatoid arthritis shows numerous finger-like projections, with focal pale areas of fibrin deposition. The brownish color of the synovium reflects hemosiderin accumulation derived from old hemorrhage. **B.** A microscopic view reveals prominent lymphoid follicles (Allison-Ghormley bodies; *arrows*), synovial hyperplasia and hypertrophy, villous folds and thickening of the synovial membrane by fibrosis and inflammation. **C.** A higher-power view of the inflamed synovium demonstrates hyperplasia and hypertrophy of the lining cells. Numerous giant cells are on and below the surface. The stroma is chronically inflamed.

CLINICAL FEATURES: The clinical diagnosis of RA is imprecise and is based on a number of criteria, such as the number and types of joints involved, the presence of rheumatoid nodules and RF and radiographic features characteristic of the disease.

The onset of RA may be acute, slowly progressing or insidious. Most patients describe slowly developing fatigue, weight loss, weakness and vague musculoskeletal discomfort, which eventually localizes to the involved joints. Diseased joints tend to be warm, swollen and painful. The pain is heightened by motion and is most severe after periods of disuse. Unabated disease causes progressive destruction of the joint surfaces and periarticular structures. Eventually, patients manifest severe flexion and extension deformities, associated with joint subluxation, which may terminate in joint ankylosis.

FIGURE 30-57. Rheumatoid arthritis. The hands of a patient with advanced arthritis show swelling of the metacarpophalangeal joints and the classic ulnar deviation of the fingers.

The natural history of RA is variable. In most patients, disease activity waxes and wanes. One fourth of patients seem to recover completely. Another quarter have only slight functional impairment for many years. However, half develop serious progressive and disabling joint disease. There is increased mortality from infection, gastrointestinal hemorrhage and perforation, vasculitis, heart and lung involvement, amyloidosis and subluxation of the cervical spine. In fact, survival of patients with active RA is comparable to that in Hodgkin disease and diabetes.

Three types of drugs are used to suppress synovial inflammation and to induce a remission:

- **Nonsteroidal anti-inflammatory drugs (NSAIDs).**
- **Corticosteroids,** which have both anti-inflammatory and immunoregulatory activity.
- **Disease-modifying antirheumatic drugs (DMARDs),** which have been shown to alter the course of the disease and improve outcome. These include drugs such as methotrexate, leflunomide, cyclosporin, cyclophosphamide, azathioprine, sulfasalazine, gold salts, penicillamine,

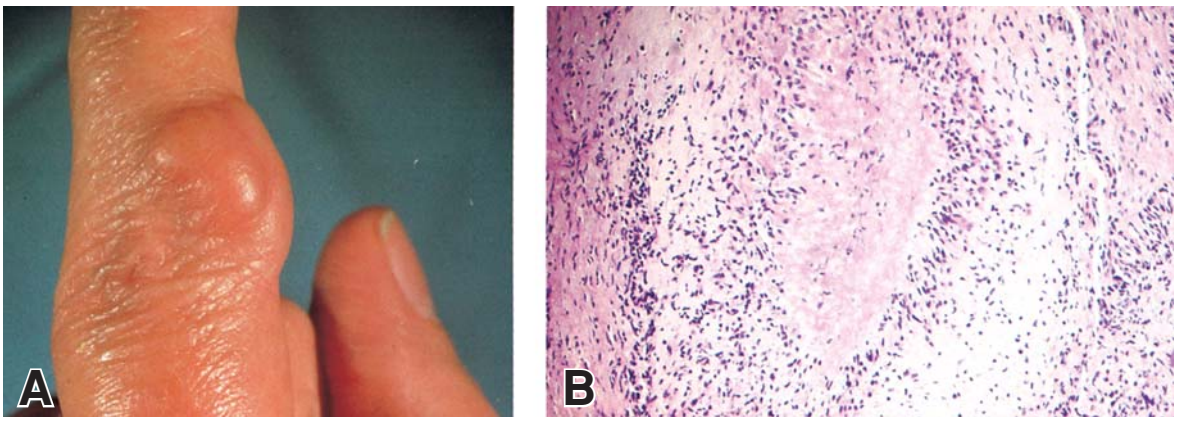

FIGURE 30-58. Rheumatoid nodule. A. A patient with rheumatoid arthritis has a subcutaneous mass on a digit. **B.** Microscopic view of a rheumatoid nodule shows a central area of necrosis surrounded by palisaded macrophages and a chronic inflammatory infiltrate.

antimalarial drugs (hydroxychloroquine), TNF inhibitors, T-cell costimulatory blockers, B-cell–depleting agents and IL-1 receptor antagonists. They are now recommended early in the course of the disease to prevent progression, induce remission and prevent joint deformities and functional disabilities.

Spondyloarthropathy Is a Seronegative Arthritis Mostly Linked to HLA-B27

A number of clinical entities were formerly classified as variants of RA but are now recognized to be distinct disorders. These forms of arthritis are now known as **spondyloarthropathies** and include ankylosing spondylitis, Reiter syndrome, psoriatic arthritis and arthritis associated with inflammatory bowel disease. They share several features:

- Seronegativity for RF and other serologic markers of RA
- Association with class I histocompatibility antigens, particularly human leukocyte antigen (HLA)-B27
- Sacroiliac and vertebral involvement
- Asymmetric involvement of only a few peripheral joints
- A tendency to inflammation of periarticular tendons and fascia
- Systemic involvement of other organs, especially uveitis, carditis and aortitis
- Preferential onset in young men

Ankylosing Spondylitis

Ankylosing spondylitis is an inflammatory arthropathy of the vertebral column and sacroiliac joints. It may be accompanied by asymmetric, peripheral arthritis (30% of patients) and systemic manifestations. It is most common in young men, with peak incidence at about age 20. Over 90% of patients have HLA-B27 (normal, 4%–8%), although the disorder affects only 1% of people with this haplotype.

PATHOLOGY: Ankylosing spondylitis begins at the sacroiliac joints bilaterally, then ascends the spinal column by involving the small joints of the posterior elements of the spine. The result is destruction of these joints, after which the spine becomes fused posteriorly. The unburdened vertebral bodies become square and osteoporotic, because the main force of gravity is borne by the fused posterior elements. In such cases, the intervertebral disk undergoes ossification and may disappear. Eventually, bony fusion of the vertebral bodies ensues (Fig. 30-59).

Although a few patients with ankylosing spondylitis rapidly develop crippling spinal disease, most are able to maintain their employment and live a normal life span. However, up to 5% of patients develop AA amyloidosis and uremia and a few manifest severe cardiac involvement.

Reactive Arthritis

Reactive arthritis (previously, Reiter syndrome) is a triad that includes (1) seronegative polyarthritis, (2) conjunctivitis/uveitis

FIGURE 30-59. Ankylosing spondylitis. The vertebrae have been cut longitudinally. The vertebral bodies are square and have lost most of their trabecular bone, owing to osteoporosis from disuse. Bone bridges fuse one vertebral body to the next across the intervertebral disks. Portions of the intervertebral disk are replaced by bone marrow. Bony bridges also fuse the posterior elements **(ankylosis)**.

and (3) nonspecific urethritis. It occurs almost exclusively in men and usually follows venereal exposure or an episode of bacillary dysentery. As in ankylosing spondylitis, this syndrome is associated with HLA-B27 in 90% of patients. In fact, after an attack of dysentery, 20% of HLA-B27–positive men develop reactive arthritis.

The pathologic features of this syndrome are comparable to those of RA. More than half of patients develop mucocutaneous lesions similar to those of pustular psoriasis **(keratoderma blennorrhagica)** over the palms, soles and trunk. In most patients, the disease remits within a year, but in 20%, progressive arthritis develops, including ankylosing spondylitis.

Psoriatic Arthritis

Of all patients with psoriasis, particularly in those with severe disease, 7% develop an inflammatory seronegative arthritis. HLA-B27 has been linked to psoriatic spondylitis and inflammation of distal interphalangeal joints, and HLA-DR4 has been associated with a rheumatoid pattern of involvement. Joint disease is usually mild and slowly progressive, although a mutilating form is occasionally encountered.

Enteropathic Arthritis

Ulcerative colitis and Crohn disease are accompanied by seronegative peripheral arthritis in 20% of cases and spondylitis in 10%. This form of arthritis also is seen in patients with Whipple disease and after certain bacterial infections of the gut. No particular tissue type is associated with peripheral arthritis, but most patients with ankylosing spondylitis are HLA-B27 positive. It has been proposed that HLA-B27 and proteins from enteric bacteria are structurally related in a manner that affects antigen presentation to the T-cell receptor. Resection of the affected bowel in ulcerative colitis relieves the arthritis, but in Crohn disease, this complication often does not resolve.

Juvenile Arthritis Includes Any Inflammatory Arthritis in Children

Several different chronic arthritic conditions in children are included in this designation, also called **Still disease**. In addition to RA, many children with juvenile arthritis eventually develop ankylosing spondylitis, psoriatic arthritis and other connective tissue diseases.

- **Seropositive arthritis:** Fewer than 10% of children with arthritis are positive for RF and have a polyarticular presentation. Females predominate (80%) among children with seropositive Still disease, and in most cases (75%), antinuclear antibodies are present. HLA-D4 is often present, and more than half of the children eventually develop severe arthritis.
- **Polyarticular disease without systemic symptoms:** One fourth of juvenile arthritis patients (90% girls) have disease of several joints, are seronegative and do not manifest systemic symptoms. Fewer than 15% of these patients eventually develop severe arthritis.
- **Polyarticular disease with systemic symptoms:** Twenty percent of children with polyarticular arthritis have prominent systemic symptoms, which include high fever, rash, hepatosplenomegaly, lymphadenopathy, pleuritis, pericarditis, anemia and leukocytosis. Most (60%) are boys who are negative for RF, and one fourth of all of these children are left with severe arthritis.
- **Pauciarticular arthritis:** Children with involvement of only a few large joints, such as the knee, ankle, elbow or hip girdle, account for half of all cases of juvenile arthritis and fall into two general groups. The larger group (80%) mainly comprises girls who are negative for RF but exhibit antinuclear antibodies and are positive for HLA-DR5, HLA-DRw6 or HLA-DRw8. Of these patients, one third have ocular disease, characterized by chronic iridocyclitis (inflammation of the iris and ciliary body). Only a small minority of these children have residual polyarthritis or ocular damage. The smaller group of children with a pauciarticular presentation is composed almost exclusively of boys, is negative for both RF and antinuclear bodies and is positive for HLA-B27 (75%). A few have acute iridocyclitis, which resolves spontaneously. Some of these boys subsequently develop ankylosing spondylitis.

LYME DISEASE

Lyme disease usually involves the knee or other large joints and is caused by the spirochete **Borrelia burgdorferi** ***transmitted by the Ixodes tick*** (see Chapter 9). Patients generally present with joint effusion and other manifestations of Lyme disease. Although there may be a transient arthritis with acute infection, some patients can develop chronic Lyme arthritis, which is microscopically identical to rheumatoid arthritis.

GOUT

Primary Gout Is a Disorder of Uric Acid Metabolism

Gout is a heterogeneous group of diseases collectively characterized by increased serum uric acid and urate crystal deposition in joints and kidneys. All such patients have hyperuricemia, but fewer than 15% of people with hyperuricemia have gout. It is characterized by acute and chronic arthritis. Gout is classified as primary or secondary, depending on the etiology of the hyperuricemia. In **primary gout,** hyperuricemia occurs without any other disease; **secondary gout** occurs in association with another illness that results in hyperuricemia. Of all cases of hyperuricemia, one third are primary and the remainder secondary.

MOLECULAR PATHOGENESIS: Uric acid results from purine catabolism, due to either a high-purine diet or increased de novo synthesis. In humans, there is a tight balance between uric acid production and tissue deposition of urates. Uric acid is only eliminated in the urine. Thus, the blood uric acid level (normal, <7.0 mg/dL in men, <6.0 mg/dL in women) reflects the difference between the amount of purines ingested and synthesized and renal excretion. Gout can result from (1) overproduction of purines, (2) increased catabolism of nucleic acids due to greater cell turnover, (3) decreased salvage of free purine bases or (4) decreased urinary uric acid excretion (Fig. 30-60). A high dietary intake of purine-rich foods (e.g., meat) by an otherwise normal person does not lead to hyperuricemia and gout.

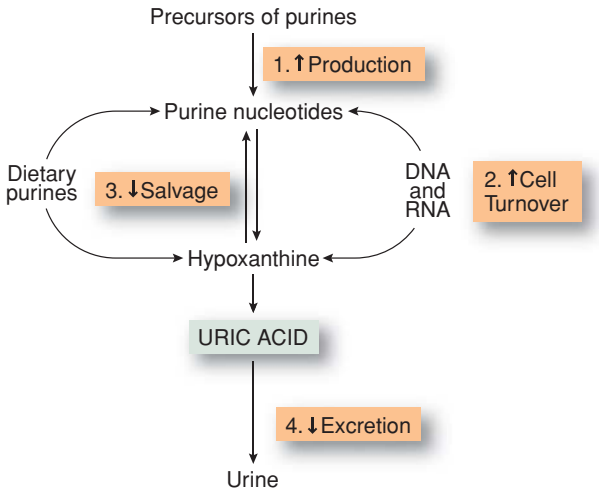

FIGURE 30-60. Pathogenesis of hyperuricemia and gout. Purine nucleotides are synthesized de novo from nonpurine precursors or derived from preformed purines in the diet. Purine nucleotides are catabolized to hypoxanthine or incorporated into nucleic acids. The degradation of nucleic acids and dietary purines also produces hypoxanthine. Hypoxanthine is converted to uric acid, which in turn is excreted into the urine. Hyperuricemia and gout result from (1) increased de novo purine synthesis, (2) increased cell turnover, (3) decreased salvage of dietary purines and hypoxanthine and (4) decreased uric acid excretion by the kidneys.

Most cases (85%) of idiopathic gout result from an as-yet-unexplained impairment of renal uric acid excretion. In the remainder, there is a primary overproduction of uric acid, but the underlying abnormality has been identified only in a minority of cases.

A ***familial tendency*** to gout has been recognized since the time of Galen. Hyperuricemia is common among relatives of patients with gout. It has been proposed that primary hyperuricemia in some people is inherited as an autosomal dominant trait with variable expression, in some as an X-linked abnormality and in others as instances of multifactorial inheritance. Precocious gout exhibits a strong familial tendency. The consensus today is that multiple genes control the level of serum uric acid.

Gout Can Be Due to Inborn Errors of Metabolism

The rate-limiting step in purine synthesis is condensation of glutamine with phosphoribosyl pyrophosphate (PP-ribose-P) to form phosphoribosylamine. Increased intracellular PP-ribose-P accelerates purine biosynthesis. PP-ribose-P, through the activity of hypoxanthine phosphoribosyl transferase (HPRT), also condenses with, and so salvages, purine bases (hypoxanthine and guanine) derived from the catabolism of nucleic acids. Although the specific cause of an abnormally high rate of urate production is not known, in most cases of primary gout, two inborn errors of metabolism are known to lead to elevated PP-ribose-P.

Lesch-Nyhan syndrome is an inherited, X-linked (Xq26-q27) deficiency of HPRT, a defect that leads to accumulation of PP-ribose-P, and in turn to enhanced purine synthesis. Children with this syndrome are clinically normal at birth but exhibit delays in development and neurologic dysfunction within the first year. Most are mentally retarded and exhibit self-mutilation. They are hyperuricemic and eventually develop gouty arthritis. In addition, obstructive nephropathy and hematologic abnormalities are often present.

Secondary Gout Often Results from DNA Turnover

A number of conditions result in hyperuricemia and secondary gout. As in primary gout, secondary hyperuricemia may reflect overproduction or decreased urinary excretion of uric acid. Increased production is most often associated with increased nucleic acid turnover, as seen in leukemias and lymphomas and after chemotherapy. Accelerated adenosine triphosphate (ATP) degradation may also lead to overproduction of uric acid and occurs in glycogen storage diseases and tissue hypoxia. Ethanol intake evokes secondary hyperuricemia, in part owing to accelerated ATP catabolism and (to a lesser degree) decreased renal excretion of uric acid. Reduced urate excretion may also result from primary renal disease. Dehydration and diuretics increase tubular reabsorption of uric acid and induce hyperuricemia. In fact, various drugs are implicated in 20% of patients with hyperuricemia.

Saturnine gout was described in 18th-century England, where this disease was prevalent among the upper classes with lead plumbing in their houses (Saturn is the symbol for lead). It is now recognized that these patients were afflicted with lead nephropathy. The Romans had a similar problem, because they drank from vessels containing lead.

EPIDEMIOLOGY: Primary gout usually afflicts adult men; only 5% of cases occur in women. It is rare in children before puberty and in women during the reproductive years. Peak incidence is in the fifth decade. This sex distribution can be traced to the fact that at all ages, mean serum urate concentrations in women are lower than in men, although they increase after menopause. Many patients have a family history of gout, but environmental factors are also important. Positive correlations exist between the prevalence of hyperuricemia in a population and mean weight, protein intake, alcohol consumption, social class and intelligence. Thus, gout is a disease that exemplifies the interplay between genetic predisposition and environmental influences.

PATHOLOGY: When sodium urate crystals precipitate from supersaturated body fluids, they absorb fibronectin, complement and a number of other proteins on their surfaces. Neutrophils that have ingested urate crystals release activated oxygen species and lysosomal enzymes, which mediate tissue injury and promote an inflammatory response.

The presence of long, needle-shaped crystals that are negatively birefringent under polarized light is diagnostic of gout (Fig. 30-61). Monosodium urate monohydrate crystals may be found intracellularly in leukocytes of the synovial fluid. A **tophus** is an extracellular soft tissue deposit of urate crystals surrounded by foreign body giant cells and an associated inflammatory response of mononuclear cells. These granuloma-like areas are found in cartilage, in any of the soft tissues around joints and even in the subchondral bone marrow adjacent to joints.

Macroscopically, any chalky white deposit on intraarticular surfaces, including articular cartilage, suggests gout. Radiologically, gouty arthritis exhibits characteristic, punched-out, juxta-articular, lytic ("rat bite") lesions that are

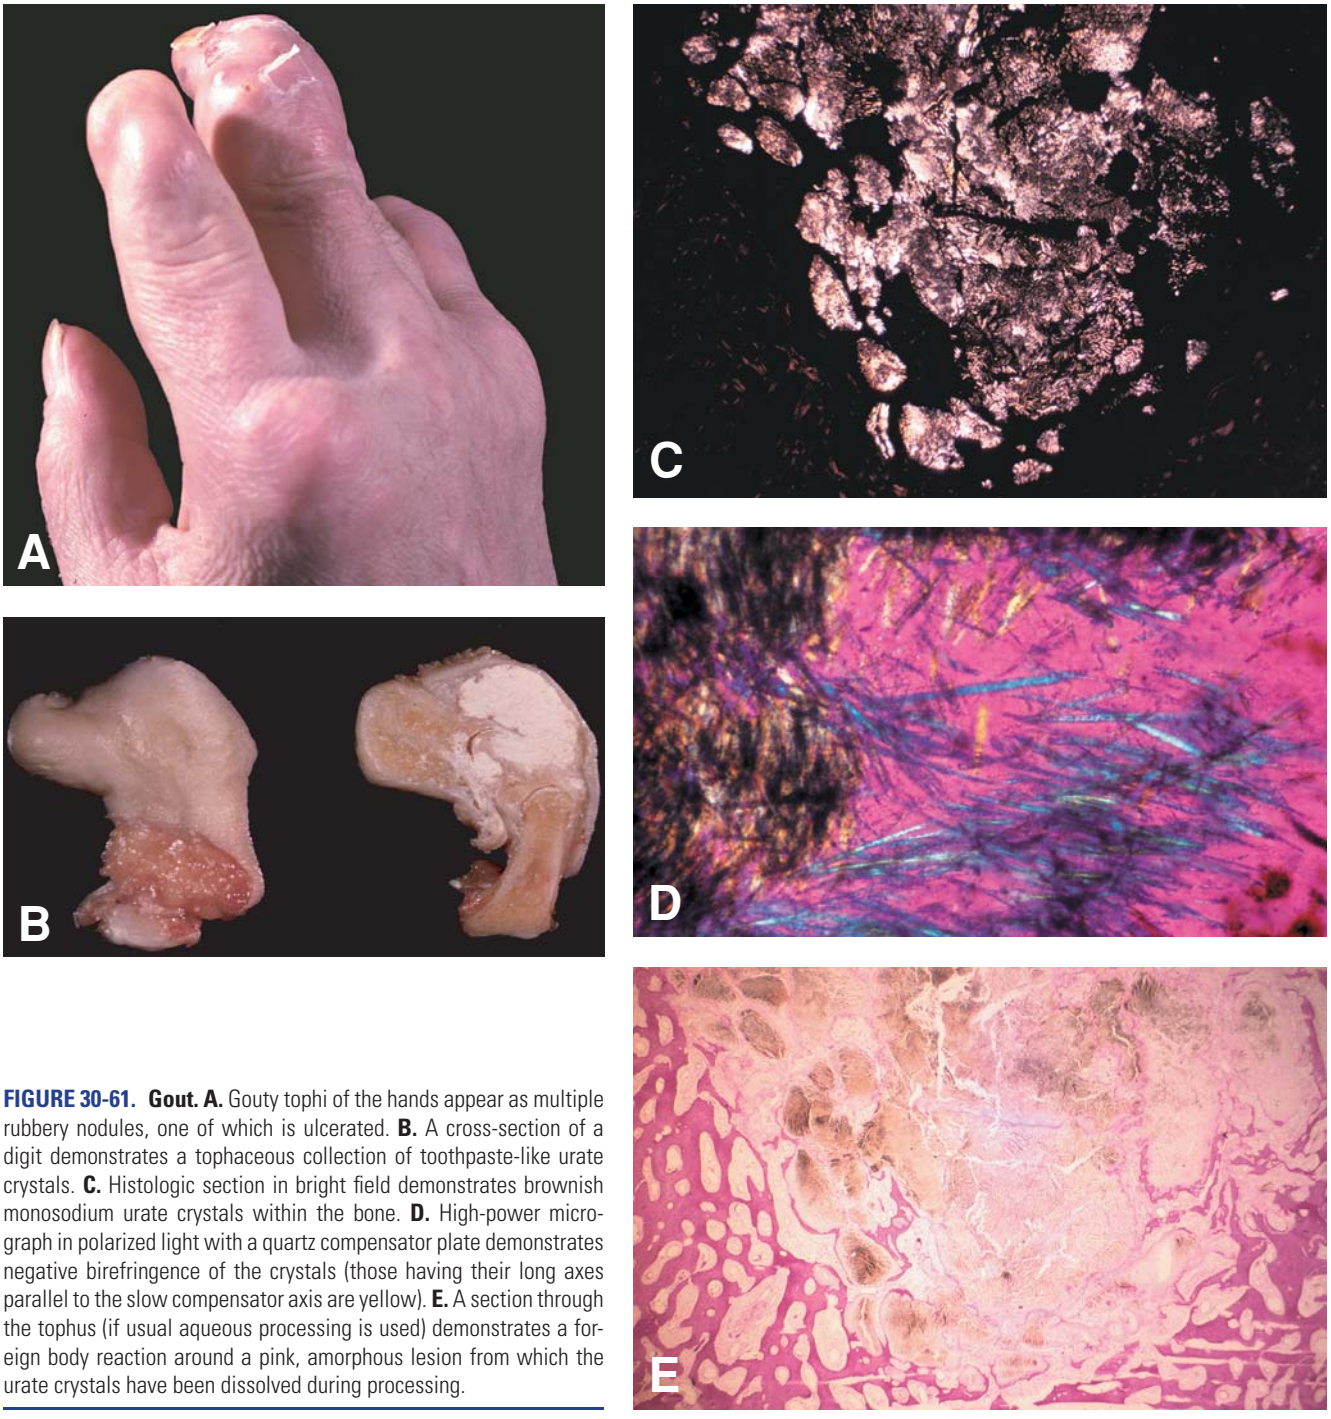

FIGURE 30-61. Gout. A. Gouty tophi of the hands appear as multiple rubbery nodules, one of which is ulcerated. **B.** A cross-section of a digit demonstrates a tophaceous collection of toothpaste-like urate crystals. **C.** Histologic section in bright field demonstrates brownish monosodium urate crystals within the bone. **D.** High-power micrograph in polarized light with a quartz compensator plate demonstrates negative birefringence of the crystals (those having their long axes parallel to the slow compensator axis are yellow). **E.** A section through the tophus (if usual aqueous processing is used) demonstrates a foreign body reaction around a pink, amorphous lesion from which the urate crystals have been dissolved during processing.

associated with only minimal reactive new bone (Fig. 30-62). In contrast to RA, there is no juxta-articular osteopenia in gout.

Renal urate deposits are between the tubules, especially at the apices of the medulla. These areas are grossly visible as small, shiny, golden-yellow, linear streaks in the medulla.

CLINICAL FEATURES: The clinical course of gout is divided into four stages: (1) asymptomatic hyperuricemia, (2) acute gouty arthritis, (3) intercritical gout and (4) chronic tophaceous gout. Renal stones may occur in any stage except the first. In most cases, symptomatic gout appears before renal stones, which usually require 20–30 years of sustained hyperuricemia.

- **Asymptomatic hyperuricemia** often precedes clinically evident gout by many years.
- **Acute gouty arthritis** was well characterized by Thomas Sydenham, who described his own disease in the 1600s. It is a painful condition that usually involves one joint, without constitutional symptoms. Later in the course of the disease, polyarticular involvement with fever is common. At least half of patients are first seen with a painful and red first metatarsophalangeal joint (great toe), designated **"podagra."** Eventually, 90% of all patients have

FIGURE 30-62. Gout. A radiograph of the first metatarsophalangeal joint shows a lytic lesion that destroys the joint space. There is an adjacent soft tissue tophus, as well as surrounding edema.

such an attack. Commonly, a gouty attack begins at night and is exquisitely painful, simulating an acute bacterial infection of the affected joint. A large meal or drinking alcoholic beverages may trigger an attack, but other specific events such as trauma, certain drugs and surgery may also be responsible. Even when untreated, acute attacks of gout are self-limited.

- The **intercritical period** is the asymptomatic interval between the initial acute attack and subsequent episodes. These periods may last up to 10 years, but later attacks tend to be increasingly severe, prolonged and polyarticular.
- **Tophaceous gout** eventually appears in the untreated patient in the form of tophi in the cartilage, synovial membranes, tendons and soft tissues.

Renal failure is responsible for 10% of deaths in patients with gout. One third of patients have mild albuminuria, reduced glomerular filtration and decreased renal concentrating ability. However, the contribution of urate nephropathy to chronic renal dysfunction is unclear, and hypertension, preexisting kidney disease and the intake of analgesic drugs may be more important. In patients with severe gout caused by inherited enzyme deficiencies and in those with a precocious presentation, urate nephropathy is a prominent feature of the clinical course. **Urate stones** are 10% of all renal calculi in the United States and up to 40% in Israel and Australia. The prevalence of urate stones correlates with the serum concentration of uric acid and affects 25% of gout patients. Patients also have an increased frequency of calcium-containing stones, in which case the uric acid may serve as a nidus for a calcium stone.

Treatment of gout is designed to (1) decrease the severity of acute attacks, (2) reduce serum urate, (3) prevent future attacks, (4) promote dissolution of urate deposits and (5) alkalinize the urine to prevent stone formation. The main drugs used to interrupt the inflammatory process, thus preventing or controlling the acute attack, are nonsteroidal anti-inflammatory agents. Colchicine has been used for hundreds of years and has been administered prophylactically during the intervals between gouty attacks to prevent recurrent episodes. Uricosuric drugs that interfere with urate reabsorption by the renal tubules are often useful.

Allopurinol is a competitive inhibitor of xanthine oxidase, the enzyme that converts xanthine and hypoxanthine to uric acid. This drug causes a prompt decrease in uricosemia and uricosuria and is used in people with renal insufficiency and those who are resistant to other uricosuric drugs. It also may be administered to patients undergoing chemotherapy for hematopoietic proliferative disorders, which increases the rate of urate production.

CALCIUM PYROPHOSPHATE DIHYDRATE DEPOSITION DISEASE (CHONDROCALCINOSIS AND PSEUDOGOUT)

Calcium pyrophosphate dihydrate (CPPD) deposition disease refers to the accumulation of this compound in synovial membranes (pseudogout), joint cartilage (chondrocalcinosis), ligaments and tendons. The disease can be idiopathic, associated with trauma, linked to a number of metabolic disorders or, in rare cases, hereditary.

CPPD deposition disease is principally a condition of old age; half of those over age 85 are afflicted. Most cases in the elderly are asymptomatic. Because fully two thirds of these patients manifest preexisting joint damage, it is believed that trauma and the aging process in cartilage promote nucleation of CPPD crystals. In asymptomatic cases, punctate or linear calcifications may be present in any fibrocartilage or hyaline cartilage surface. For example, radiography of the knee may disclose linear streaks that outline the menisci.

MOLECULAR PATHOGENESIS: The major predisposing abnormality in patients with CPPD deposition disease is an excessive level of inorganic pyrophosphate in the synovial fluid. This material derives from hydrolysis of nucleoside triphosphates in joint chondrocytes. Increased pyrophosphate levels in synovial fluid can result from either increased production or decreased catabolism.

CPPD deposition is commonly found in the knees after trauma and after surgical removal of the meniscus. Nucleotides released after injury to articular cartilage may act as substrates for nucleotide triphosphate pyrophosphohydrolase (NTP), thus increasing production of pyrophosphate. A number of other disorders are associated with deposition of CPPD crystals, including hyperparathyroidism, hypothyroidism, hemochromatosis, Wilson disease and ochronosis. Iron and copper are presumed to inhibit pyrophosphatase, accounting for decreased degradation of pyrophosphate.

Mutations in the *ANKH* gene cause familial autosomal dominant CPPD chondrocalcinosis. The *ANKH* gene is thought to encode a membrane pyrophosphate transporter that inhibits mineralization of several tissues including joints, articular cartilage and tendons. Mutated ANKH elevates intracellular pyrophosphate and reduces extracellular pyrophosphate.

Hypophosphatasia is a heritable condition in which activity of alkaline phosphatase (the enzyme that hydrolyzes pyrophosphate) in serum and tissue is deficient. As a result, pyrophosphate is not adequately metabolized and accumulates in synovial fluid.

PATHOLOGY AND CLINICAL FEATURES: A minority of patients symptomatic with CPPD deposition disease are classified according to the nature of joint involvement.

- **Pseudogout** refers to self-limited attacks of acute arthritis lasting from 1 day to 4 weeks and involving one or two joints. Some 25% of patients with CPPD deposition disease have an acute onset of gout-like symptoms manifesting as inflammation and swelling of the knees, ankles, wrists, elbows, hips or shoulders. Metatarsophalangeal joints, which are frequently affected in gout, are usually spared. The synovial fluid exhibits abundant leukocytes containing CPPD crystals.
- **Pseudorheumatoid arthritis** is a variant of CPPD deposition disease in which multiple joints are chronically involved. The symptoms are mild and resemble those of RA.
- **Pseudo-osteoarthritis** has symptoms similar to those of osteoarthritis.
- **Pseudoneurotrophic disease** is characterized by joint destruction severe enough to resemble a neurotrophic joint.

On gross examination, CPPD deposits appear as chalky white areas on cartilaginous surfaces (Fig. 30-63A). Unlike needle-shaped urate crystals, they are stubby, short and rhomboid ("coffin shaped") and display weak birefringence under polarized light. In contrast to urate crystals, CPPD crystals do not dissolve in water and are easily found in tissue sections (Fig. 30-63B). Only a few mononuclear cells and macrophages surround foci of crystal deposition.

The treatment of CPPD is essentially symptomatic (pain control). Nonsteroidal anti-inflammatory drugs and steroids are commonly used.

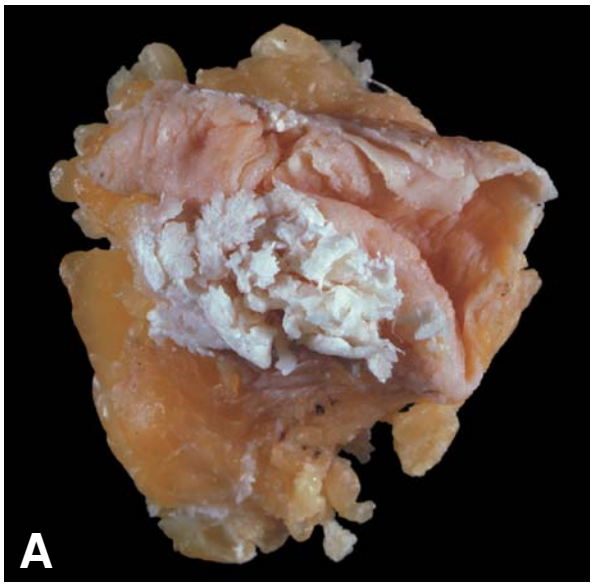
CALCIUM HYDROXYAPATITE DEPOSITION DISEASE

Calcium hydroxyapatite deposition disease is an acute or chronic arthritis characterized by hydroxyapatite crystals within leukocytes and mononuclear cells in joint tissue and synovial fluid. Calcium hydroxyapatite (HA) is the major mineral of bone and teeth and is the compound deposited in dystrophic and metastatic calcification. HA crystals are frequently encountered in the synovial fluid of joints involved by osteoarthritis, but there is reason to believe that severe HA deposition is a distinct entity. The joints most frequently involved are the knee, shoulder, hip and fingers. Attacks may last several days.

HEMOPHILIA, HEMOCHROMATOSIS AND OCHRONOSIS

Hemophilia, hemochromatosis and ochronosis (see Chapter 6) all produce joint disease with degradation of the matrix and destruction of the articular cartilage.

- **Hemophilia** gives rise to severe forms of arthritis because of extensive bleeding into joints (hemarthrosis), particularly the knees, elbows, ankles, shoulders and hips. In addition to the effects within the articular cartilage matrix, synovial proliferation also simulates RA.
- **Hemochromatosis** is complicated by arthritis in half of affected patients. The hands, hips and knees may be involved in recurrent attacks.
- **Ochronosis** is a rare, autosomal recessive disease caused by a defect in homogentisic acid oxidase. The deposition



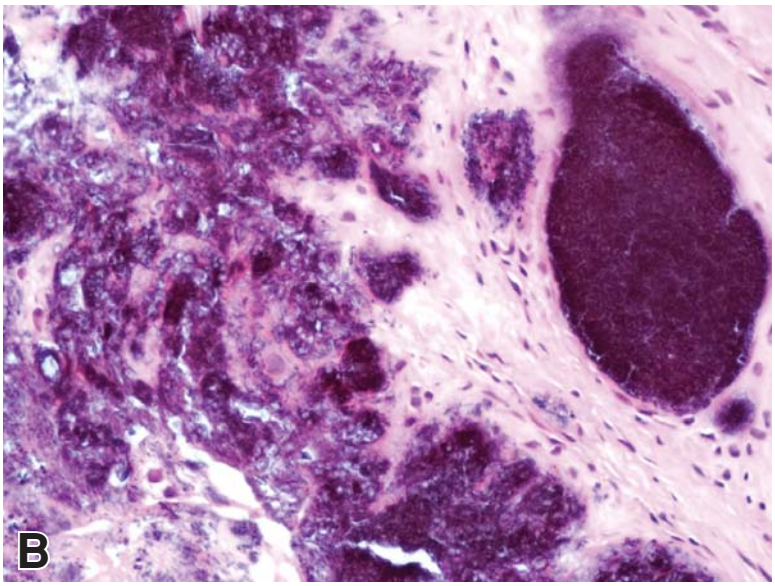


FIGURE 30-63. Calcium pyrophosphate dihydrate (CPPD) deposition disease. A. Gross specimen demonstrates chalky-white calcific material. **B.** Microscopically, the deposits are deep purple with discernible rhomboid-shaped crystals.

of ochronotic pigment in the cartilage of the joints, including the intervertebral disks, eventually causes them to become brittle and degenerate.

TUMORS AND TUMOR-LIKE LESIONS OF JOINTS

True neoplasms of the joints are rare. The most common malignant lesions of the synovium are metastatic carcinomas, particularly adenocarcinoma of the colon, breast and lung. Lymphoproliferative diseases (e.g., leukemia) may also involve the synovium, mimicking other conditions, such as RA. It is unusual for primary malignant bone tumors to extend into the joint, although they may invade the joint capsule from the soft tissues.

A Ganglion Is a Small Fluid-Filled Cyst

A ganglion is a thin-walled, simple cyst containing clear mucinous fluid, which occurs most commonly on the extensor surfaces of the hands and feet, especially the wrist. It is more common in women between the ages of 25 and 45 years. The cyst arises either from the synovium or from areas of myxoid change in the connective tissue, possibly after trauma. The wall is composed of fibrous tissue, and there is no cell lining. The lesion may be painful and can be readily removed surgically, although a blow with the family Bible was the traditional treatment for a ganglion on the dorsum of the wrist.

A **Baker cyst** is a herniation of the synovium of the knee joint into the popliteal space. It is most often seen in association with various forms of arthritis, in which the intra-articular pressure is increased. The cyst contains synovial fluid and microscopically demonstrates a synovial cell lining.

Synovial Chondromatosis Features Cartilage Nodules in a Joint

Synovial chondromatosis is a benign, self-limited disease in which hyaline cartilage nodules form in the synovium, detach from that structure and float in the synovial fluid, like grains of sand between gears. The chronic irritation produced by these "loose" bodies stimulates the synovium to secrete large amounts of synovial fluid and also causes bleeding in the synovial membrane. Synovial chondromatosis involves the large diarthrodial joints of young and middle-aged men, affecting the knee in most cases, but also the hip, elbow, shoulder, ankle and temporomandibular joints. Patients have pain, stiffness and locking of the joint, with associated bloody effusions.

Unlike cartilage that detaches from articular surfaces in osteoarthritis, in synovial chondromatosis the fragments of hyaline cartilage are formed de novo in the synovium (Fig. 30-64). They do not have a tidemark and thus differ morphologically from true articular cartilage. Occasionally, the cartilage nodules, while still in the synovium, undergo endochondral ossification, in which case the disease is called **synovial osteochondromatosis**. If these nodules detach, the bony portions undergo necrosis, but the cartilage fragments remain viable and enlarge because they are nourished by synovial fluid. The condition is treated by evacuating the joint and performing a synovectomy. Recurrence is seen in 15%–20% of the cases, but malignant transformation is rare.

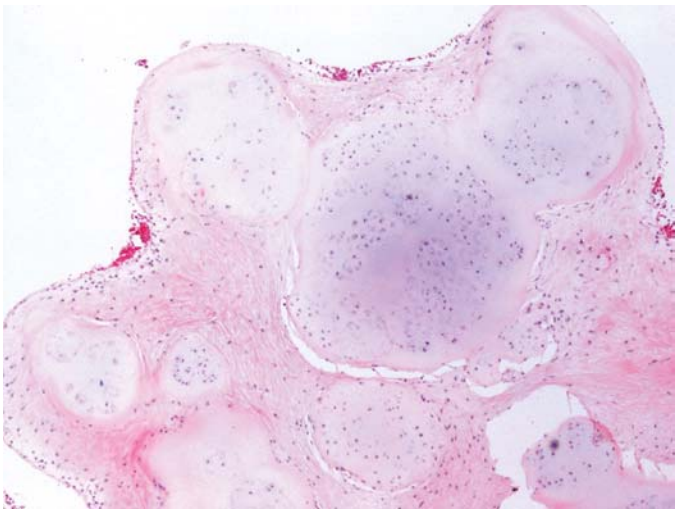

FIGURE 30-64. Synovial chondromatosis. Nodules of benign hyaline cartilage form in the synovium.

MOLECULAR PATHOGENESIS: Dysregulation of Hedgehog signaling is a factor in the development of synovial chondromatosis in animal models and suggests that this disorder is a neoplasm. Clonal karyotypic abnormalities have been detected in a few cases of synovial chondromatosis, with diploid or near-diploid complements, chromosome 6 anomalies, rearrangements of 1p22 and 1p13 and extra copies of chromosome 5.

Tenosynovial Giant Cell Tumor Is a Benign Neoplasm of Synovial Lining

This is the most common neoplasm of the synovium and tendon sheath and occurs in a localized and a diffuse form. The lesions may be intra- or extra-articular.

- **Localized tenosynovial giant cell tumor or giant cell tumor of the tendon sheath** involves the hands and feet. In fact, it is the most common soft tissue tumor of the hand. It occurs mostly in young and middle-aged women (30–50 years) and involves flexor surfaces of the middle or index fingers. The tumor is usually well circumscribed and grows slowly.
- **Diffuse tenosynovial giant cell tumor or pigmented villonodular synovitis (PVNS)** is characterized by an ill-defined, exuberant proliferation of synovial lining cells arising from periarticular soft tissues, with extension into the subsynovial tissue. It involves a single joint, usually in young adults, and is seen equally in men and women. The most common site is the knee (80%), but it also occurs in the hip, ankle, calcaneocuboid joint, elbow and, less frequently, tendon sheaths of the fingers and toes.

MOLECULAR PATHOGENESIS: In the past, these lesions were regarded as reactive/inflammatory, but recurrent chromosomal aberrations have been described in both forms, supporting a neoplastic nature. Translocations involving the short arm of chromosome 1 have been detected, most commonly t(1;2)(p11;q35-36) or (p13;q37), with evidence of a fusion of colony-stimulating

factor-1 (CSF-1) with COL6a3. Trisomies for chromosomes 5 and 7 have been found only in the diffuse form. The association of these anomalies with tumor pathogenesis is unclear.

PATHOLOGY: The localized tenosynovial giant cell tumor is characterized by a small (<4 cm), multinodular, smooth-contoured, partially encapsulated, exophytic mass attached to a tendon sheath. The diffuse form is usually larger than 5 cm and poorly circumscribed. It invades the joint and erodes the bone (Fig. 30-65A). It may insinuate through joint capsules into soft tissue and encompass nerves and arteries, sometimes necessitating radical surgical excision. The synovium develops enlarged folds and nodular excrescences, which are brown colored owing to their iron pigment content (Fig. 30-65B). Microscopically, both tumors have similar histology. They are composed of bland mononuclear cells resembling macrophages, admixed with scattered multinucleated giant cells, fibroblasts and foam cells. Hemosiderin-laden macrophages reflect previous hemorrhage (Fig. 30-65C,D). The diffuse form extensively infiltrates the surrounding tissue and frequently displays a villous configuration.

Treatment for these lesions is surgical excision. Radiation therapy has been used for unresectable cases. Amputation is occasionally necessary for local control. Tumors recur in 10%–20% of cases of localized tenosynovial giant cell tumor, in contrast to 40%–50% in the diffuse form. Metastases do not occur. A malignant counterpart has been described, but it is very rare.

Soft Tissue Tumors

Soft tissue tumors are mesenchymal neoplasms that may arise anywhere in the body but are most commonly found within skeletal muscle, fat, fibrous tissue or blood vessels. Tumors of peripheral nerves (see Chapter 32) and other tumors of neuroectodermal differentiation may be included in the category of soft tissue tumors. Malignant soft tissue tumors are rare, accounting for less than 1% of

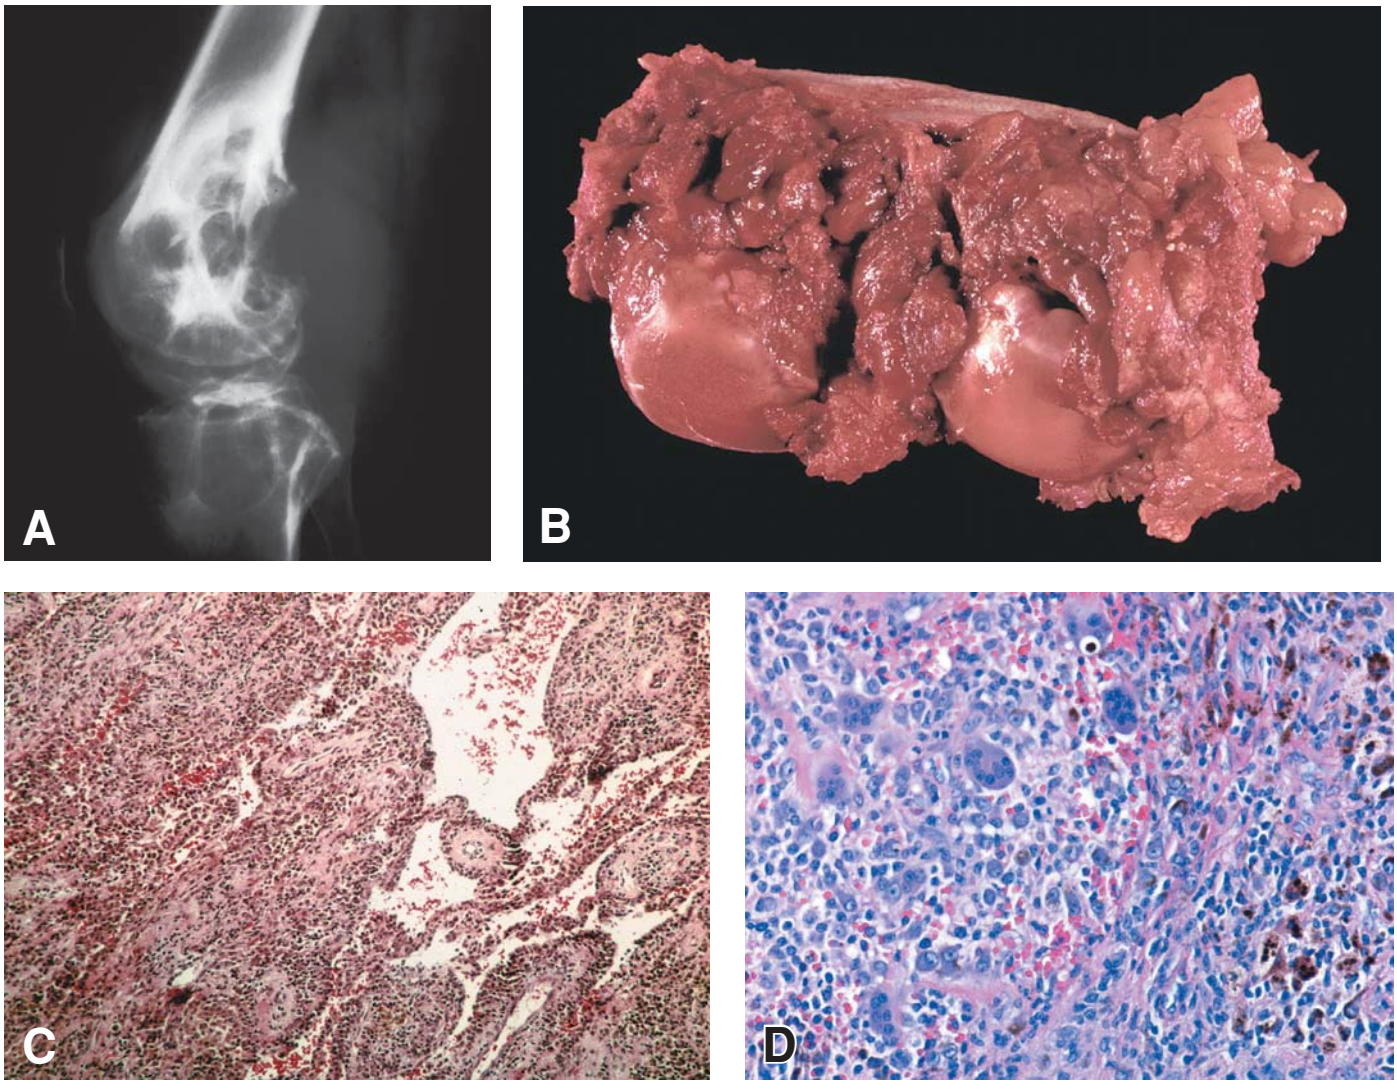

FIGURE 30-65. Pigmented villonodular synovitis. A. Radiograph of the knee demonstrates confluent erosions of the distal femur and proximal tibia and a soft tissue mass within the joint. **B.** Gross specimen shows massive destruction of the femoral condyles. Note brown color and nodular thickenings. **C.** Low-power microscopy demonstrates thickened villous synovium. **D.** At higher power, the cellular infiltrate mainly consists of mononuclear histiocytic synoviocytes, many of which contain brown hemosiderin pigment, and multinucleated giant cells.

all malignancies in the United States. Benign soft tissue neoplasms are 100 times more common than malignant ones.

Although soft tissue tumors may show evidence of differentiation toward a particular cell type (fibroblastic, adipocytic, vascular, myoid, etc.), they are thought to arise from pluripotent mesenchymal stem cells that reside in soft tissues and bone marrow. Not all soft tissue tumors can be readily classified by their line of differentiation. However, many do have characteristic and unique genomic abnormalities that are diagnostically useful (Table 30-2).

Soft tissue tumors may be benign, locally aggressive or malignant. Locally aggressive tumors invade and may recur locally (e.g., fibromatosis). Malignant soft tissue tumors (sarcomas) can metastasize via the bloodstream, usually to the lungs or bone. ***Patients generally die of metastatic disease rather than local invasion at the primary tumor site.***

The ability to distinguish sarcoma from benign mimics is key to prognostication; outcome is predicated upon both tumor grade and stage. A number of published grading schemes exist, among which the Fédération National des Centres de Lutte Contre le Cancer (FNCLCC) system is one of the most widely accepted. In the FNCLCC system, grading is based on cellular phenotype (histologic tumor type and degree of differentiation), mitotic activity and presence of tumor necrosis as indicators of aggressive behavior. In addition, tumor size and depth (superficial vs. deep soft tissue) are regarded by some as the most important prognostic criteria in primary tumors. These criteria are combined with grade and metastatic status for overall staging and risk prediction.

A group of genetic disorders associated with soft tissue tumors includes neurofibromatosis type 1, tuberous sclerosis, Osler-Weber-Rendu disease, Li-Fraumeni syndrome and Gardner syndrome. Burns in childhood produce scars, which in rare instances lead to soft tissue fibroblastic tumors many years later. Radiation injury can also contribute to the development of sarcomas, in particular angiosarcoma, osteosarcoma or undifferentiated sarcoma, years after exposure. There is no evidence to support the association of trauma with the development of soft tissue tumors, and injury merely draws attention to a preexisting tumor.

A few important general principles relate to soft tissue tumors:

- Superficial tumors tend to be benign.
- Deep lesions are often malignant.
- Large tumors are more often malignant than small ones.
- Rapidly growing tumors are more likely to be malignant than tumors that develop slowly.
- Calcification may exist in both benign and malignant tumors.
- Benign tumors are relatively avascular, while most malignant ones are hypervascular.
- Some soft tissue tumors are classified on the basis of genetic or molecular findings.

TUMORS AND TUMOR-LIKE CONDITIONS OF FIBROUS ORIGIN

Nodular Fasciitis Is a Benign Lesion That May Mimic a Sarcoma

Nodular fasciitis is a rapidly growing but self-limited tumor that commonly affects superficial tissues of the forearm, trunk and back and is characterized by a t(17;22)(p13;q13) translocation. Most cases occur in young adults who present to medical attention following the rapid growth of the lesion. Histologically, nodular fasciitis may be mistaken for a sarcoma, because it is hypercellular and has abundant mitoses and numerous immature, spindle-shaped fibroblasts and myofibroblasts in a myxoid stroma (Fig. 30-66). While nodular fasciitis was long thought to be a posttraumatic reactive condition, the discovery of a recurrent translocation and associated chimeric fusion gene has resulted in a reclassification of this tumor as a form of neoplasia. *MYH-USP6* gene fusion results in overexpression of USP6, an oncogenic protein with possible roles in inflammation and proliferation. In addition, cytogenetic abnormalities involving chromosome 15 have been reported in some cases. The affected region on chromosome 15 codes for several proteins involved in tissue repair (e.g., FGF7) and oncogenesis. Despite these underlying genetic alterations, nodular fasciitis is self-limited and is cured by surgical excision.

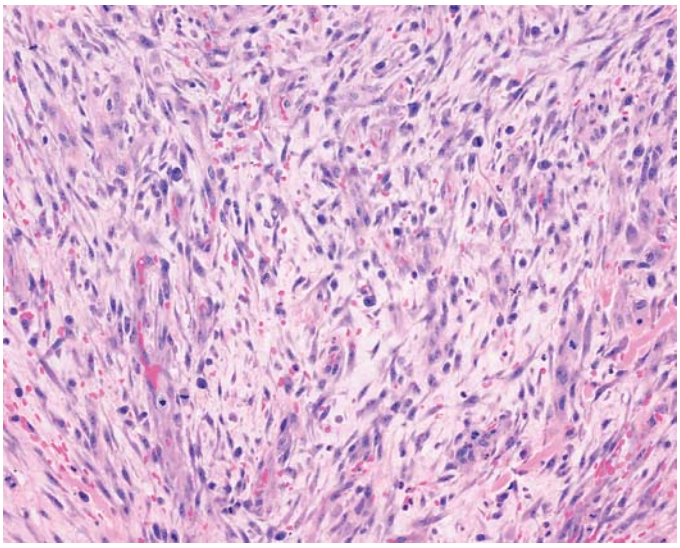

FIGURE 30-66. Nodular fasciitis. Elongated spindle and stellate cells are arranged haphazardly in a loose myxoid stroma, giving the lesion a "tissue culture–like" appearance. Extravasated erythrocytes and scattered lymphocytes are a common finding. Mitotic figures may be prominent.

Fibromatosis Is a Locally Aggressive Proliferation of Fibroblasts

Fibromatosis is a locally invasive, slowly growing mass that may occur virtually anywhere in the body. Although histologically similar, there are genetic distinctions between superficial and deep "aggressive" variants of fibromatosis. Fibromatosis does not metastasize, but surgical resection of deep tumors is often followed by local recurrence. Diabetics, alcoholics and epileptics have an increased incidence of fibromatosis, as do patients with familial adenomatous polyposis.

MOLECULAR PATHOGENESIS: Fibromatosis results from signaling alterations in the Wnt pathway. Mutations involving *APC* or *CTNNB1* are present in deep aggressive fibromatosis (desmoid tumor) but have not been identified in superficial variants. Inactivating

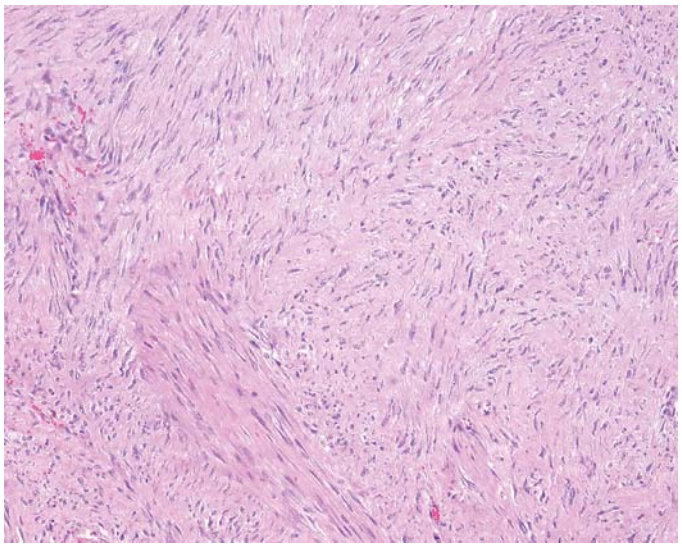

FIGURE 30-67. Fibromatosis. Microscopically, the lesion is composed of fascicles of bland spindle cells arrayed in long sweeping fascicles in a collagenous stroma.

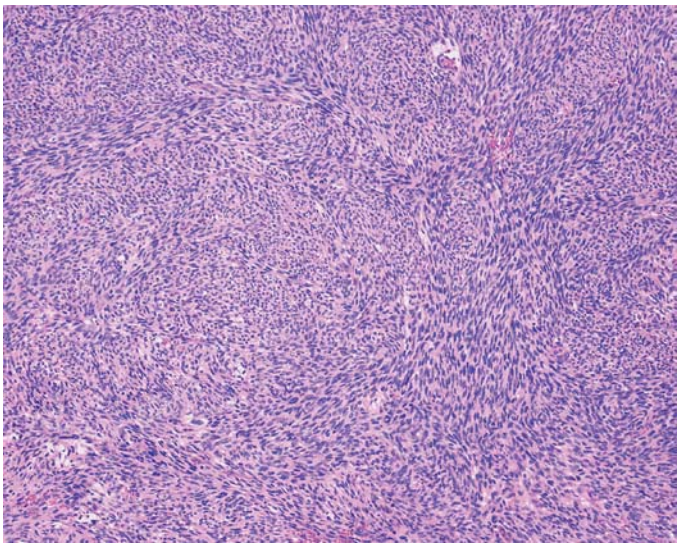

FIGURE 30-68. Fibrosarcoma. A photomicrograph demonstrates irregularly arranged malignant fibroblasts characterized by dark, irregular and elongated nuclei of varying sizes.

mutations in the *APC* gene are found mostly in cases of fibromatosis that are associated with familial adenomatous polyposis. The APC protein binds to β-catenin and enhances its degradation. Thus, loss of APC indirectly stabilizes β-catenin. β-Catenin in turn promotes Wnt pathway signaling, which modulates developmental genes and is thought to be important in the development of fibromatosis. Most sporadic cases of desmoid tumor have activating mutations in *CTNNB1,* the gene encoding β-catenin, which make it resistant to the inhibitory effect of APC. In short, mutations in both the *APC* and *CTNNB1* genes result in persistent stabilization of β-catenin.

PATHOLOGY: On gross examination, the lesions of fibromatosis tend to be large, firm and whitish, with poorly demarcated borders and a whorled cut surface. Microscopic examination reveals sheets and interdigitating fascicles of benign-appearing spindle cells (fibroblasts) with little mitotic activity (Fig. 30-67). Because microscopic tongues of tumor extend between preexisting structures, surgical "shelling out" of the lesion is followed by recurrences in half of cases. Complete surgical excision is curative.

Specific forms of fibromatosis are identified by their characteristic locations:

- **Palmar fibromatosis** (Dupuytren contracture) is the most common form of fibromatosis. It affects 1%–2% of the general population but as many as 20% of people older than 65. In half of cases, the lesion is bilateral, and in 10% of cases, it is associated with fibromatosis in other locations. Fibrous nodules and cord-like bands in the palmar fascia eventually lead to flexion contractures of the fingers, particularly the fourth and fifth digits.
- **Plantar fibromatosis** is similar to palmar fibromatosis, except that it is less frequent and involves the plantar aponeurosis.
- **Penile fibromatosis** (Peyronie disease) is the least common of the localized fibromatoses. It is characterized by induration of, or a mass in, the penile shaft, causing it to curve toward the affected side **(penile strabismus)**. The lesion leads to urethral obstruction and pain on erection.
- Deep aggressive fibromatosis (desmoid tumor) frequently involves fascia and muscular aponeuroses of the extremities or abdominal wall musculature. It may also arise in the mesentery. Lesions are highly infiltrative and difficult to resect completely, accounting for the high recurrence rates. Mesenteric fibromatosis is more commonly associated with APC mutations, whereas abdominal fibromatosis shows a predilection for women.

Fibrosarcoma Is a Malignant Tumor of Fibroblasts

Many subtypes of sarcoma show evidence of fibroblastic differentiation. Pure adult fibrosarcoma is a diagnosis of exclusion, which shows no characteristic cytogenetic abnormality and accounts for less than 3% of adult sarcomas. Congenital (infantile) fibrosarcoma is characterized by a chromosomal translocation, t(12;15)(p13;q26), that fuses the *ETV6* and *NTRK3* genes. Fibrosarcomas arise from deep connective tissue, such as fascia, scar tissue, periosteum and tendons. Macroscopically, the tumors are sharply demarcated and frequently exhibit necrosis and hemorrhage. They are characterized histologically by malignant-appearing fibroblasts (Fig. 30-68), which often form densely interlacing bundles and fascicles, producing a "herringbone" pattern. The prognosis for high-grade adult fibrosarcoma is guarded; the survival at 5 years is only 40% and at 10 years is 30%. Infantile fibrosarcoma rarely metastasizes, with a less than 5% mortality rate.

Other variants of fibroblastic sarcomas exist, including low-grade fibromyxoid sarcoma, myofibroblastic sarcoma and myxofibrosarcoma, among others, each with its own distinct pathologic features and clinical course.

Undifferentiated Pleomorphic Sarcoma (Malignant Fibrous Histiocytoma) Is a Diagnosis of Exclusion

Malignant fibrous histiocytoma (MFH) was historically considered to be a malignant soft tissue tumor with fibroblastic

and histiocytic (macrophage) differentiation. More recently, it has been determined that the microscopic appearance of "MFH" may be seen in a phenotypically heterogeneous group of sarcomas generically called "undifferentiated pleomorphic sarcomas" (UPSs). Immunohistochemical, ultrastructural and, more recently, genomic studies have shown that the large majority of UPS represents the pleomorphic variants of liposarcoma, leiomyosarcoma or rhabdomyosarcoma. A small proportion of cases remain unclassifiable and may truly represent the most primitive undifferentiated form of sarcoma. Efforts to classify such tumors are important, as pleomorphic rhabdomyosarcoma or leiomyosarcoma may have a slightly worse prognosis. Collectively, UPS is the most common sarcoma in patients over the age of 40, but cases have been recorded at all ages. In half of the cases, tumors arise in the deep fascia or within skeletal muscle of the lower limbs. UPS has been reported in association with surgical scars and foreign bodies or after radiation treatment. At the molecular level, it shows highly complex chromosomal rearrangements, a phenotype associated with genomic instability. Several oncogenes may play a role in the pathogenesis of UPS, including *SAS*, *TP53*, *RB1* and *CDKN2A*, among others.

PATHOLOGY: Adult UPSs are usually unencapsulated, gray-white or tan tumors that may have areas of hemorrhage and necrosis. Microscopically, the tumor displays a highly variable morphologic pattern, with areas of spindle-shaped cells arrayed in an irregularly whorled (storiform) pattern adjacent to fields with bizarre pleomorphic cells (Fig. 30-69). The spindle cells tend to be better differentiated and often show focal fibroblastic features. Mitoses are abundant. Often a nonneoplastic population of tumor-infiltrating inflammatory cells is seen, including xanthomatous cells, dendritic or histiocytic cells and a moderate chronic inflammatory reaction. Some tumors contain numerous tumor giant cells, which exhibit intense cytoplasmic eosinophilia. The extent of collagen deposition varies and sometimes dominates the microscopic pattern. Necrosis is often present and may be extensive. A few tumors reveal a conspicuous myxoid stroma. Immunohistochemical and ultrastructural studies are generally performed to establish a specific line of differentiation (smooth muscle, skeletal muscle, adipose tissue, etc.). If no such differentiation can be demonstrated, then the tumor can be considered to be an **undifferentiated pleomorphic sarcoma**.

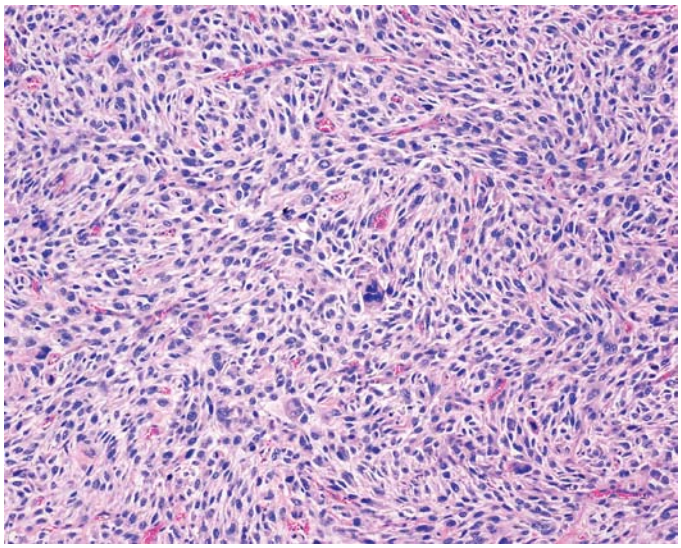

FIGURE 30-69. Undifferentiated pleomorphic sarcoma. An anaplastic tumor exhibits spindle cells, plump polygonal cells, bizarre tumor giant cells and scattered chronic inflammatory cells. This appearance can be seen in pleomorphic sarcomas with other lines of differentiation (e.g., pleomorphic liposarcoma).

The prognosis of adult undifferentiated pleomorphic sarcomas depends on the degree of cytologic atypia, the extent of mitotic activity and the degree of necrosis. Almost half of the patients develop a local recurrence after surgery, and a comparable proportion later manifest metastatic disease, particularly in the lungs. The overall 5-year survival range is about 50%.

Radiation-induced sarcomas are a form of adult undifferentiated pleomorphic sarcoma that arise in bone or soft tissue, usually 10–20 years after radiotherapy for a malignancy in that field. A typical story is development of UPS or osteosarcoma of a rib or vertebral body (uncommon sites for de novo osteosarcomas) after radiation to the thorax as treatment for mediastinal lymphoma or breast cancer. The incidence of postradiation sarcoma is low (<1% of irradiated patients).

TUMORS OF ADIPOSE TISSUE

Lipomas Are the Most Common Soft Tissue Mass and Closely Resemble Normal Fat

Composed of well-differentiated adipocytes, these benign, circumscribed tumors can originate at any site in the body that contains adipose tissue. Most occur in the subcutaneous tissues of the upper half of the body, especially the trunk and neck. Lipomas are seen mainly in adults, and patients with multiple tumors often have relatives with a similar history.

MOLECULAR PATHOGENESIS: Numerous cytogenetic abnormalities have been documented in lipomas. In general, the tumors can be subclassified into three major groups: (1) aberrations involving 12q13–15, (2) abnormalities involving 6p21–23 and (3) loss of portions of 13q. Some tumors have the translocation t(3;12)(q27–28;q13–15), which results in the generation of a fusion gene involving the *HMGIC* gene (a member of the high-mobility group of proteins) and the *LPP* gene (a member of the LIM protein family). Some lipomas have no cytogenetic abnormalities and may represent localized adipocyte hyperplasia.

PATHOLOGY: On gross examination, lipomas are encapsulated, soft, yellow lesions that vary in size and may become very large. Deeper tumors are often poorly circumscribed. Histologically, a lipoma is often indistinguishable from normal adipose tissue (Fig. 30-70). Lipomas are adequately treated by simple local excision.

An **angiolipoma** is a small, well-circumscribed, subcutaneous lipoma with extensive vascular proliferation that usually occurs in the upper extremities and trunk of young adults. They are often multiple and painful.

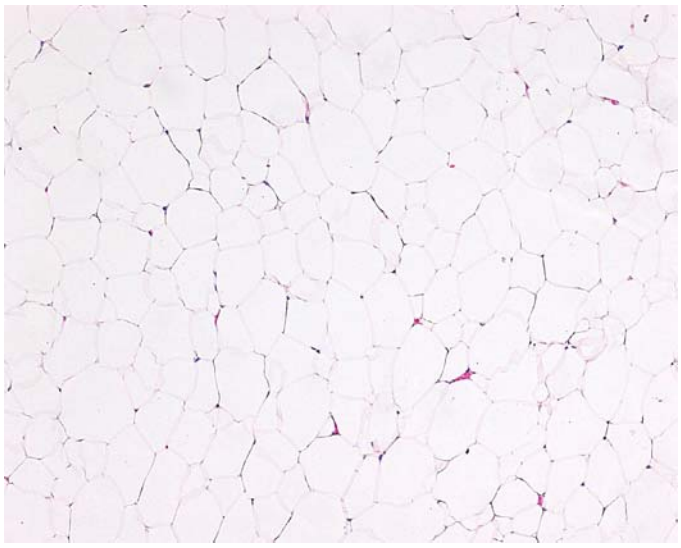

FIGURE 30-70. Lipoma. The tumor is composed of mature adipocytes with small eccentric nuclei.

Liposarcomas Are the Second Most Common Sarcoma in Adults

Liposarcomas account for 25% of all malignant soft tissue tumors. The neoplasm arises after age 50 years and is most common in the deep thigh and retroperitoneum. They tend to grow slowly but may become extremely large. There are several subtypes of liposarcoma, including myxoid/round cell liposarcoma, well-differentiated liposarcoma and pleomorphic liposarcoma.

MOLECULAR PATHOGENESIS: Myxoid/round cell liposarcomas exhibit a translocation between chromosomes 12 and 16, [t(12;16)(q13;p11)], in which the *TLS/FUS* gene on chromosome 16 is fused with the *DDIT3* gene on chromosome 12. The *TLS/FUS* gene product is a novel RNA-binding protein, with substantial homology to the EWS protein of Ewing sarcoma, while the DDIT3 protein is a transcriptional repressor. Atypical lipomatous tumors and well-differentiated liposarcomas are defined by a giant marker chromosome, or a supernumerary ring chromosome with amplification of the 12q14–15 region, which includes the *MDM2* and *CDK4* genes, among others. MDM2 is involved in regulating growth and signaling survival, in part by inhibition of p53 (see Chapter 5), while CDK4 is a regulatory factor promoting cell cycle progression. Pleomorphic liposarcomas have complex genomic rearrangements.

PATHOLOGY: Gross appearances of liposarcoma subtypes vary depending on the proportions of adipose, mucinous and fibrous tissue. Well-differentiated tumors may resemble normal fat or may show fibrotic or gelatinous cut surfaces. Dedifferentiated or pleomorphic liposarcomas grossly can appear soft and gelatinous, with necrosis, hemorrhage and cysts. Lipoblasts may be seen microscopically in all types of liposarcoma ***Lipoblasts are early adipocytes with univacuolated or multivacuolated cytoplasmic fat vesicles indenting the nucleus. While frequently seen in liposarcoma, lipoblasts may also be present in reactive or regenerative conditions and are neither necessary nor sufficient for the diagnosis of liposarcoma.***

WELL-DIFFERENTIATED/DEDIFFERENTIATED LIPOSARCOMA: Well-differentiated liposarcomas typically measure 5–10 cm in diameter, although retroperitoneal tumors may reach gigantic proportions (i.e., 40 cm in diameter and weighing in excess of 20 kg). Well-differentiated liposarcomas are often composed of large amounts of mature fat, and therefore can be confused with lipomas if inadequately sampled. Sclerosis, prominent lymphoid aggregates or inflammatory infiltrates may also be seen. The defining feature of well-differentiated liposarcoma is the presence of atypical neoplastic stromal cells with large, irregular nuclei and hyperchromatic chromatin (Fig. 30-71). Dedifferentiated liposarcoma arises in preexisting well-differentiated tumors and is usually composed of a monotonous population of mitotically active spindle cells, although some tumors may be pleomorphic and resemble UPS.

MYXOID/ROUND CELL LIPOSARCOMA: These tumors most frequently arise in the proximal extremities but are exceedingly rare in the retroperitoneum. Microscopically, myxoid liposarcoma consists of univacuolated "signet ring" lipoblasts and variable amounts of primitive ovoid to round cells embedded in a vascularized myxoid stroma. Round cell liposarcoma represents a poorly differentiated form of myxoid liposarcoma and contains a high proportion of primitive round cells and a scant amount of myxoid stroma.

PLEOMORPHIC LIPOSARCOMA: Pleomorphic liposarcomas have a UPS-like histologic appearance with numerous large, bizarre tumor cells. However, they also contain lipoblasts.

Well-differentiated liposarcoma is known as atypical lipomatous tumor in the extremities, where complete resection results in low recurrence rates. Retroperitoneal tumors cannot be completely resected and frequently recur. Well-differentiated liposarcoma almost never metastasizes. Myxoid liposarcoma and differentiated liposarcoma have an intermediate risk of local recurrence and metastasis, whereas round cell and pleomorphic liposarcomas have a high frequency of local recurrence and metastasis. Pleomorphic liposarcoma has the worst outcome, with less than 20% 5-year survival rates, compared to greater than 70% for well-differentiated or pure myxoid variants.

RHABDOMYOSARCOMA

Rhabdomyosarcoma is a malignant tumor that displays features of striated muscle differentiation. It is uncommon in mature adults but is the most frequent soft tissue sarcoma of children and young adults.

PATHOLOGY: Most cases of rhabdomyosarcoma can be classified in one of four subtypes. In addition to their light microscopic features, all subtypes of rhabdomyosarcoma show immunohistochemical evidence of skeletal muscle differentiation. Tumors may express nonspecific myoid markers, such as actin and desmin, but most demonstrate at least focal expression of skeletal muscle–specific markers, such as the transcription factors myogenin and MyoD1.

EMBRYONAL RHABDOMYOSARCOMA: This form is most common in children between 3 and 12 years old and frequently involves the head and neck, genitourinary tract and

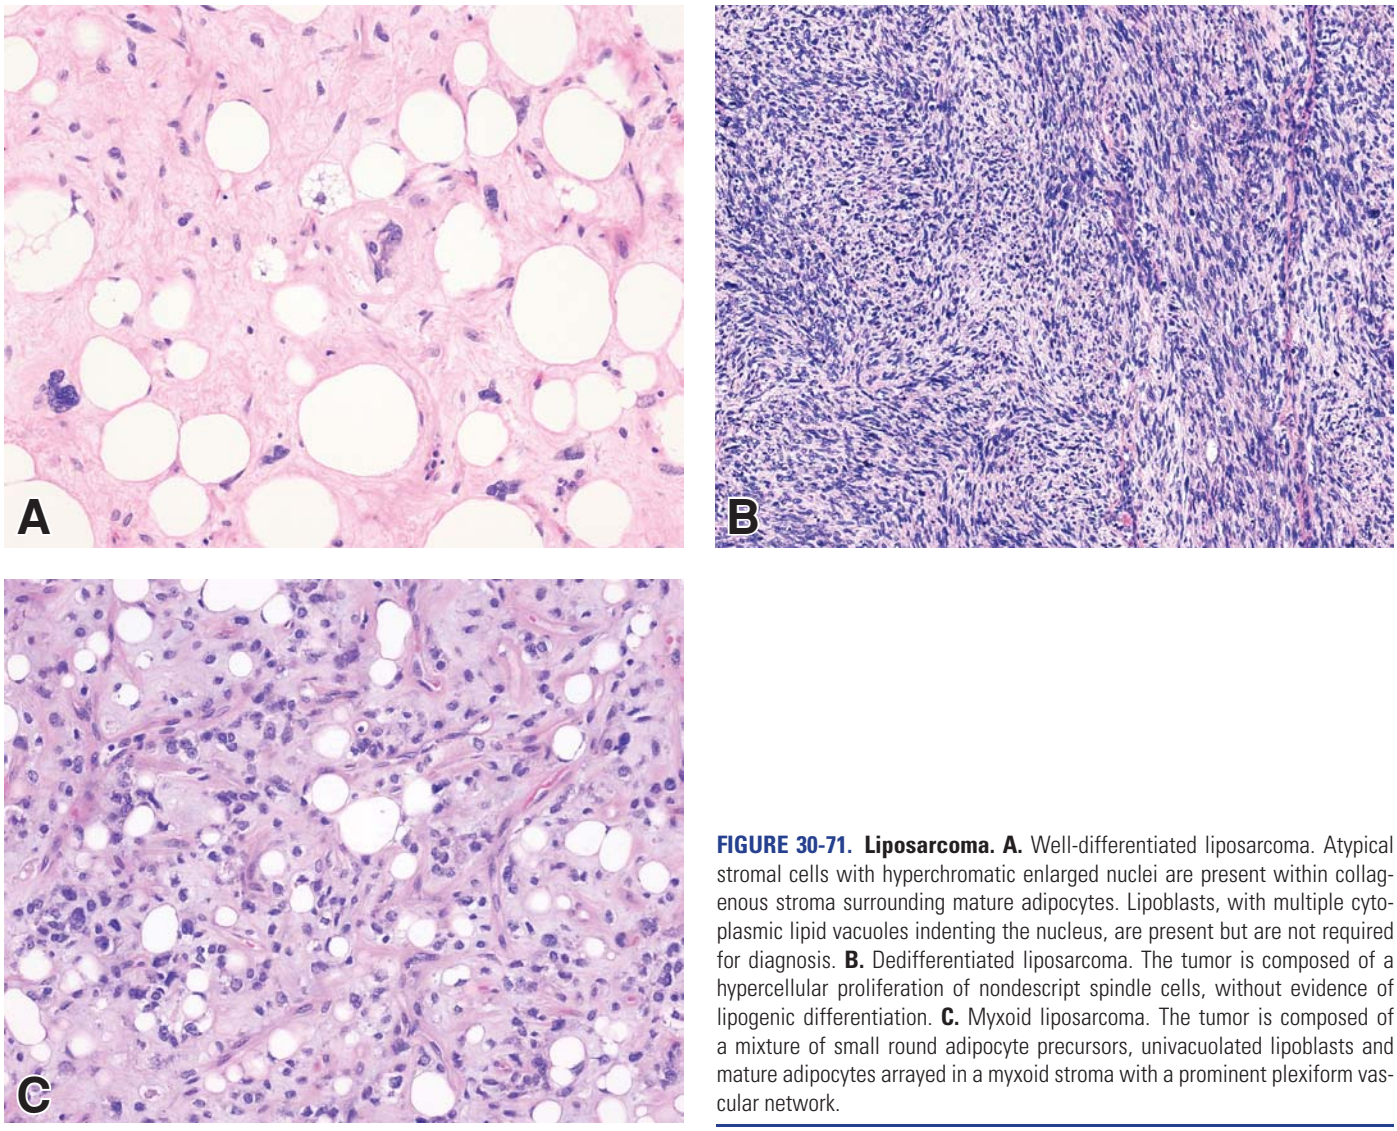

FIGURE 30-71. Liposarcoma. A. Well-differentiated liposarcoma. Atypical stromal cells with hyperchromatic enlarged nuclei are present within collagenous stroma surrounding mature adipocytes. Lipoblasts, with multiple cytoplasmic lipid vacuoles indenting the nucleus, are present but are not required for diagnosis. **B.** Dedifferentiated liposarcoma. The tumor is composed of a hypercellular proliferation of nondescript spindle cells, without evidence of lipogenic differentiation. **C.** Myxoid liposarcoma. The tumor is composed of a mixture of small round adipocyte precursors, univacuolated lipoblasts and mature adipocytes arrayed in a myxoid stroma with a prominent plexiform vascular network.

retroperitoneum. Its appearance varies from that of a highly differentiated tumor containing rhabdomyoblasts, with large eosinophilic cytoplasm and cross-striations (Fig. 30-72A), to that of a poorly differentiated small cell neoplasm.

BOTRYOID EMBRYONAL RHABDOMYOSARCOMA: This tumor, also known as **sarcoma botryoides,** is distinguished by the formation of polypoid, grape-like tumor masses. Microscopically, the malignant cells are scattered in an abundant myxoid stroma. Botryoid foci may occur in any type of embryonal rhabdomyosarcoma, but they are most common in tumors of hollow visceral organs, including the vagina (see Chapter 24) and urinary bladder.

ALVEOLAR RHABDOMYOSARCOMA: This neoplasm occurs less frequently than the embryonal type and principally affects young people between ages 10 and 25; rarely, it may be seen in elderly patients. It is most common in the upper and lower extremities, but it can also be distributed in the same sites as the embryonal type. Typically, club-shaped tumor cells are arranged in clumps that are outlined by fibrous septa. The loose arrangement of the cells in the center of the clusters generates an "alveolar" pattern (Fig. 30-72B). The tumor cells exhibit intense eosinophilia, and occasional multinucleated giant cells are identified. Malignant rhabdomyoblasts, recognizable by their cross-striations, occur less commonly in the alveolar variant than in embryonal rhabdomyosarcoma, being present in only 25% of cases.

MOLECULAR PATHOGENESIS: Most alveolar rhabdomyosarcomas express *PAX3-FOXO1* or *PAX7-FOXO1* gene fusions, resulting from t(2;13)(q35;q14) or t(1;13)(p36;q14) translocations, respectively. In patients with localized tumors, the type of fusion does not correlate with the clinical outcome. However, in the presence of metastatic disease, *PAX3-FOXO1*–positive tumors have a worse prognosis than do *PAX7-FOXO1*–positive ones.

PLEOMORPHIC RHABDOMYOSARCOMA: The least common form of rhabdomyosarcoma is found in the skeletal muscles of older individuals, often in the thigh. This tumor differs from the other types of rhabdomyosarcoma in the pleomorphism of its irregularly arranged cells and can be categorized as a type of adult undifferentiated pleomorphic sarcoma. Large, granular, eosinophilic rhabdomyoblasts, together with multinucleated giant cells, are common. Cross-striations are virtually nonexistent.

The historically dismal prognosis associated with most rhabdomyosarcomas has improved in the past two decades

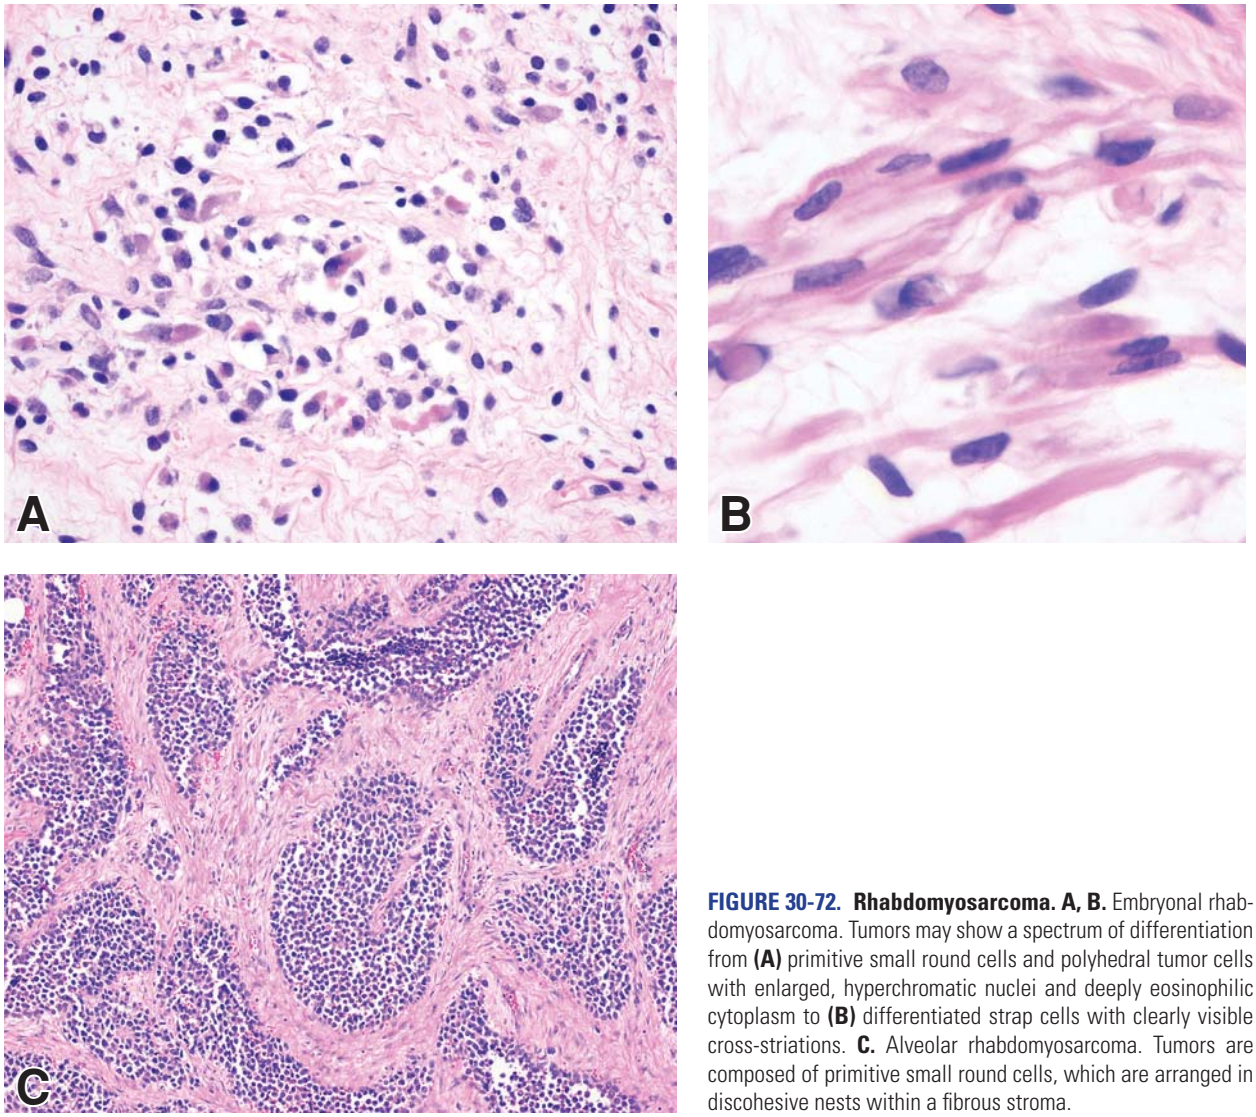

FIGURE 30-72. Rhabdomyosarcoma. A, B. Embryonal rhabdomyosarcoma. Tumors may show a spectrum of differentiation from **(A)** primitive small round cells and polyhedral tumor cells with enlarged, hyperchromatic nuclei and deeply eosinophilic cytoplasm to **(B)** differentiated strap cells with clearly visible cross-striations. **C.** Alveolar rhabdomyosarcoma. Tumors are composed of primitive small round cells, which are arranged in discohesive nests within a fibrous stroma.

as a result of the introduction of combined therapeutic modalities, including surgery, radiation therapy and chemotherapy. Today, more than 80% of patients with localized or regional disease are cured. Factors indicating a worse prognosis include age older than 10, tumor size greater than 5 cm, alveolar and pleomorphic histologic subtypes and advanced stage of disease.

SMOOTH MUSCLE TUMORS

These tumors are characterized histologically by fascicles of spindled cells with brightly eosinophilic cytoplasm, cylindrical nuclei and immunohistochemical expression of smooth muscle actin, muscle-specific actin and desmin.

LEIOMYOMA: This benign soft tissue tumor usually arises in sites associated with normal smooth muscle, including erector pili muscles in the dermis, blood vessel walls in subcutaneous or deep somatic tissues and the muscular wall of the esophagus or uterus. Leiomyomas appear as firm, gray-white, well-circumscribed nodules. Dermal or subcutaneous tumors may be painful. Microscopically, they are composed of intersecting fascicles of uniform spindled cells with cigar-shaped nuclei and very low mitotic activity. Some display prominent blood vessels (angiomyoma). Simple excision is curative.

LEIOMYOSARCOMA: This malignant soft tissue neoplasm is an uncommon tumor of adults that typically arises from the wall of blood vessels in the soft tissue of the extremities or in retroperitoneum. Macroscopically, leiomyosarcomas tend to be well circumscribed but are larger and softer than leiomyomas and often exhibit necrosis, hemorrhage and cystic degeneration. Histologically, the tumor cells are arranged in broad, intersecting fascicles. Well-differentiated tumor cells have elongated nuclei and eosinophilic cytoplasm; poorly differentiated ones show marked increased cellularity and severe cytologic atypia (Fig. 30-73). Leiomyosarcoma is differentiated from leiomyoma mainly by cellularity, atypia, mitotic activity and necrosis, which also indicates the prognosis. Most leiomyosarcomas eventually metastasize, although dissemination may occur as late as 15 or more years after resection of the primary tumor. Leiomyosarcomas have complex chromosomal rearrangements and numerous somatic mutations, but no characteristic alterations have been documented. Retroperitoneal tumors have a poor prognosis.

EBV-associated smooth muscle tumors are a distinctive subgroup of smooth muscle tumors that occur in

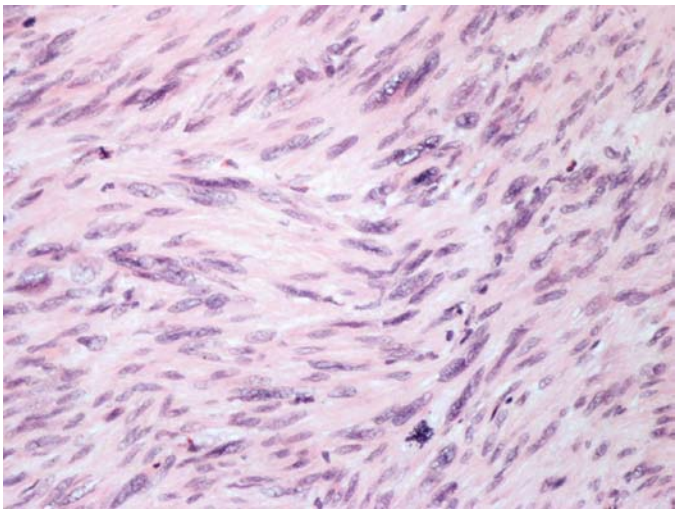

FIGURE 30-73. Leiomyosarcoma. The tumor is composed of spindle cells with elongated, hyperchromatic nuclei; a variable degree of pleomorphism; and frequent mitoses.

immunocompromised patients, mostly children and young adults who are infected with HIV or are status post–organ transplant. The tumors may be multifocal or multicentric. Their histologic appearance is variable and all display a degree of mitotic activity and numerous intralesional T lymphocytes. Death from these tumors is rare, but most patients have persistent disease.

VASCULAR TUMORS

Benign vascular tumors (hemangiomas) are among the most common soft tissue tumors and are the most frequent neoplasms of infancy and childhood. By contrast, angiosarcomas account for less than 1% of all sarcomas and are more common in older adults. Vascular tumors are discussed in detail in Chapter 16.

SYNOVIAL SARCOMA

Synovial sarcoma is a highly malignant soft tissue tumor characterized by translocations between chromosomes

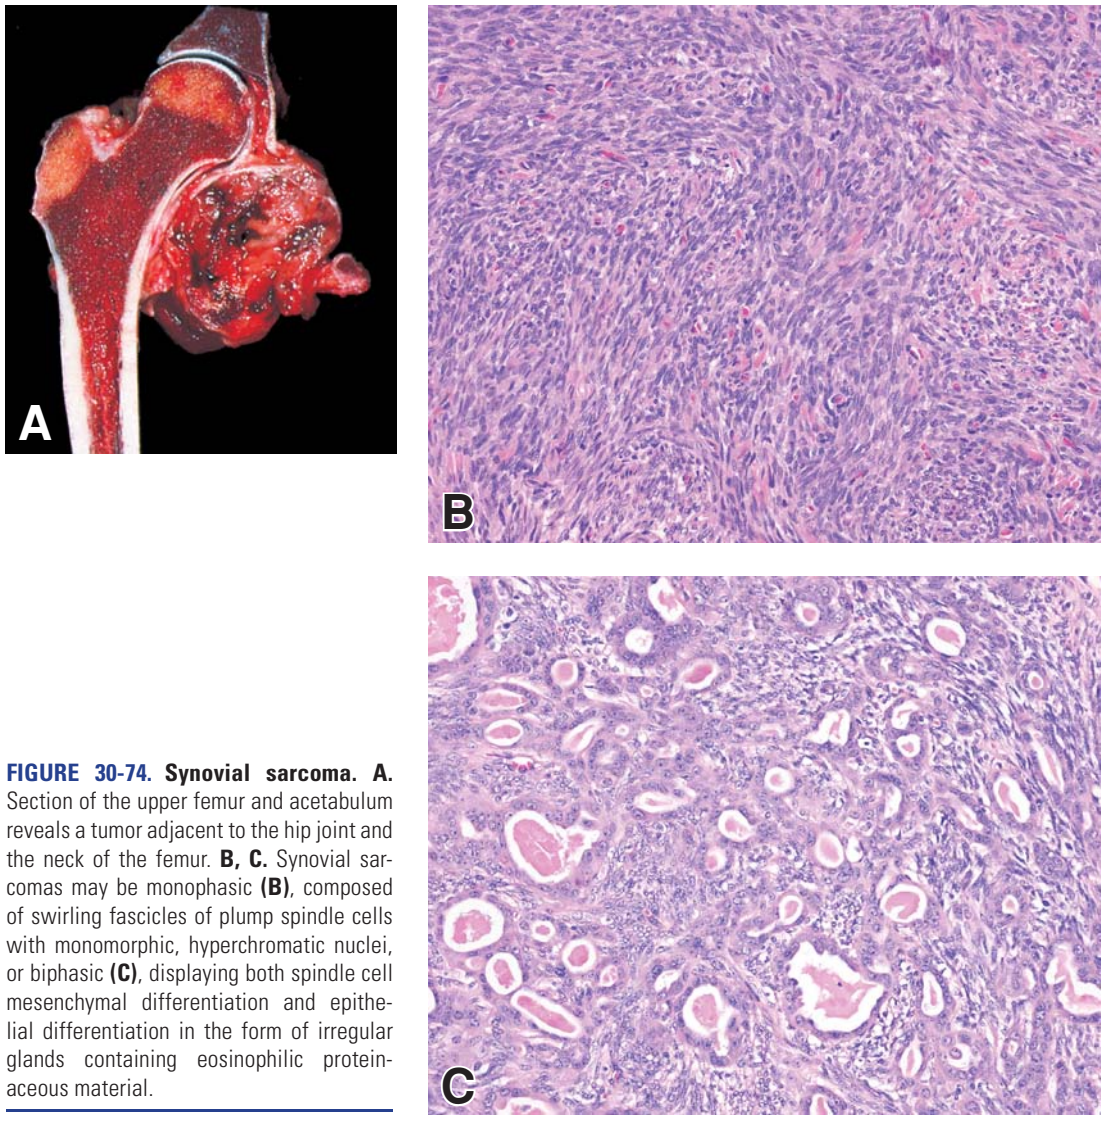

FIGURE 30-74. Synovial sarcoma. A. Section of the upper femur and acetabulum reveals a tumor adjacent to the hip joint and the neck of the femur. **B, C.** Synovial sarcomas may be monophasic **(B)**, composed of swirling fascicles of plump spindle cells with monomorphic, hyperchromatic nuclei, or biphasic **(C)**, displaying both spindle cell mesenchymal differentiation and epithelial differentiation in the form of irregular glands containing eosinophilic proteinaceous material.

X and 18. They may arise anywhere in the body but are commonly located in deep soft tissues near joints, tendon sheaths or joint capsules. Synovial sarcomas occur principally in young adults and usually present as a painful mass in the extremity.

Despite the name, synovial sarcomas neither arise from synovial tissues nor show synoviocyte differentiation. Expression of TLE1, a transcription factor associated with cell fate determination, is characteristic and may account for the dual epithelial and mesenchymal differentiation often seen in synovial sarcoma.

MOLECULAR PATHOGENESIS: Synovial sarcomas display a specific, balanced chromosomal translocation involving chromosomes X and 18 [t(x;18)(p11.2;q11.2)]. This translocation results in fusion of the *SS18/SYT* (synteny) gene on chromosome 18 to the *SSX* gene (a transcriptional repressor) on the X chromosome, leading to production of a hybrid protein, SS18-SSX1, SS18-SSX2 or, rarely, SS18-SSX4. The SS18-SSX2 protein is associated with a better prognosis if the disease is localized.

PATHOLOGY: On gross examination, synovial sarcomas are usually circumscribed, round or multilobular masses attached to tendons, tendon sheaths or the exterior wall of the joint capsule (Fig. 30-74A). The tumors tend to be surrounded by a glistening pseudocapsule and in many instances are cystic. Areas of hemorrhage, necrosis and calcification may be seen. They range from small nodules to masses of 15 cm or more in diameter, the average being 3–5 cm.

Microscopically, synovial sarcoma is classically described as having a **biphasic pattern** (Fig. 30-74B). Fluid-filled glandular spaces lined by epithelium-like tumor cells are embedded in a sarcomatous, spindle cell background. These elements vary in proportion, distribution and cellular differentiation, with the spindle cells usually considerably more numerous than the glandular elements. If the epithelial component is lacking, the tumor is referred to as **monophasic synovial sarcoma**. Although monophasic synovial sarcoma resembles fibrosarcoma, its atypical spindle cells are plumper and swirled with a "school of fish" appearance, rather than being arranged in a herringbone pattern. Calcifications may be conspicuous within the tumor. Poorly differentiated morphology imparts a poorer prognosis. Synovial sarcoma usually expresses cytokeratin or epithelial membrane antigen, further evidence of epithelial differentiation.

The recurrence rate of synovial sarcoma is high, and metastases occur in over 60% of cases. The 5-year survival rate is 50%, and those who die usually have extensive lung metastases.

EMBRYOLOGY AND ANATOMY

The myoblast is a primitive cell that fuses with other myoblasts to form a cylindrical multinucleated myotube. The periphery of the myotube rapidly accumulates myofibrils, containing myosin and actin, which become arrayed in the cross-banded pattern characteristic of striated muscle (Fig. 31-1). The myofiber has a distinctive ultrastructural architecture (Fig. 31-2).

The myotube matures completely when it is innervated by the terminal axon of a lower motor neuron. Before innervation, the sarcolemma of the myotube contains diffusely distributed nicotinic receptors for acetylcholine on its surface membrane. Upon innervation, these receptors become highly concentrated at the motor endplate. An individual muscle fiber is innervated by only a single nerve ending, but each motor neuron innervates many muscle fibers. After innervation, the myofiber nuclei move from the center to arrange themselves in a regular pattern beneath the sarcolemma (Fig. 31-3A). Mature skeletal muscle cells are syncytia (multiple nuclei within a single cytoplasm) and can be several centimeters in length.

Muscle fibers responsible for movement are **extrafusal fibers,** while those in stretch receptors (muscle spindle organs, Fig. 31-3C) are **intrafusal fibers**. ***In most primary myopathies, the damage affects extrafusal fibers but not intrafusal fibers.***

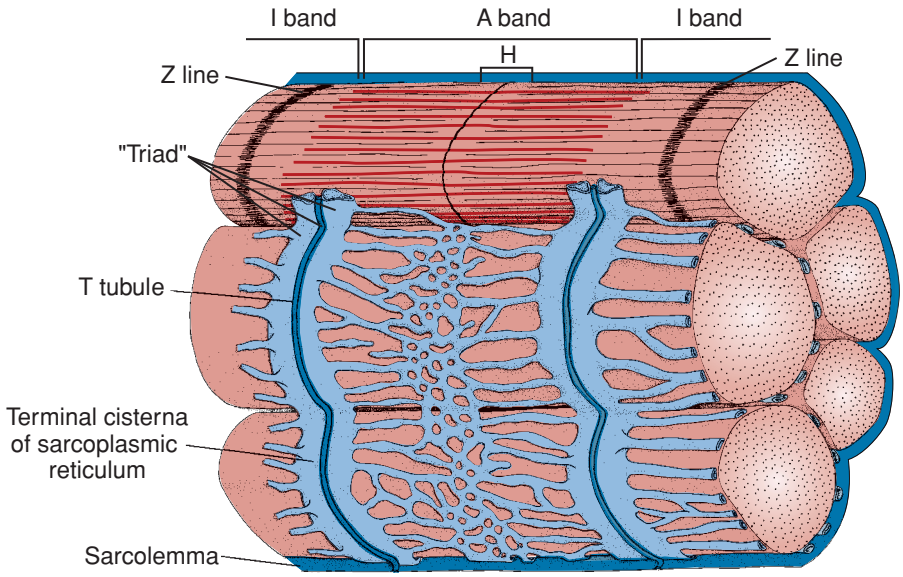

FIGURE 31-1. Normal striated muscle. Cross-striations of striated muscle are created by the arrangement of the myofilaments of the myofibril (compare to Fig. 31-2). The dark A band results from the thick myosin filaments and the thinner, partially overlapping actin filaments. In the middle portion of the myosin filaments where the actin does not overlap, there is a lighter band called the H zone or H band. In the middle of the H band, the center of each myosin filament thickens, forming intermolecular bridging with the adjacent myosin filament and giving rise to the M line (see Fig. 31-2). The finer actin filaments are anchored on the dark Z disk of the lighter I band. With contraction, the myosin filaments pull the actin filaments, causing the H zone to disappear, the I band to shrink and the A band to remain the same. The mitochondria are scattered throughout the sarcoplasm among the myofibrils. The endoplasmic reticulum (sarcoplasmic reticulum) forms an extensive, complex tubular network with periodic dilations (cisternae) around each myofibril. The cisternae are closely apposed to the transverse tubules, which are derived from the cell membrane (sarcolemma) and form a transverse network, which resembles chicken wire, around each myofibril, giving extensive communication between the internal and external environments. A triad consists of a T tubule and adjacent terminal cisternae of the sarcoplasmic reticulum.

Thus, muscle spindle organs, which are usually inconspicuous in routine histologic preparations, become relatively more prominent as extrafusal fibers disappear.

Myofiber Structure

The myofiber consists of distinct functional units (Figs. 31-1 and 31-2):

- **Sarcomere:** The functional myofibril unit, extending from one Z band to the next.
- **Z band:** A distinct electron-dense band that anchors the thin actin filaments.
- **I band:** Zone where actin filaments extend from the Z band into the A band.
- **A band:** Structure composed of the thick myosin filaments. Actin filaments overlap myosin filaments to a variable extent, depending on the degree of muscle contraction. The thin filaments form a hexagonal array around each thick filament (best seen in cross-section).
- **H zone:** Pale region in the midportion of the A band where actin filaments end.
- **M line:** Zone of intermolecular bridging and thickening of myosin filaments at the midline of the A band, which forms a thin, slightly darker electron-dense band.

During contraction, actin filaments slide past myosin filaments. The sliding actin filaments advance farther into the A band, decreasing sarcomere length. As a result, the I band and H zone shorten, while the A band remains nearly constant. There are many filamentous proteins that make up the sarcomeres, and multiple proteins that anchor sarcomeres to the sarcolemma. These proteins may be mutated or abnormally regulated in muscular dystrophies (see below).

The **sarcoplasmic reticulum** surrounds each myofibril and forms an elaborate membranous network with irregular dilations (cisternae) juxtaposed to a transverse tubular network derived from the sarcolemma (Fig. 31-1). The **transverse tubular system** (T-tubule system) is arranged across the fiber like chicken wire, each ring wrapping around an individual myofibril. This arrangement allows an electrical stimulus to proceed along the muscle fiber surface and become diffusely and rapidly internalized via the transverse tubular system. The electrical signal is translated into a chemical signal between the transverse tubule and the cisternae of the sarcoplasmic reticulum. This process releases calcium from the sarcoplasmic reticulum into the vicinity of myofibrils, triggering muscle contraction.

The lower motor neurons and the fibers they innervate are the **motor units,** which vary in size. In limb muscles, one motor unit can include several hundred myofibers. By contrast, each motor unit of extraocular muscles may have only 20 myofibers. Eye muscles are also exceptional in that one fiber may have more than one motor endplate.

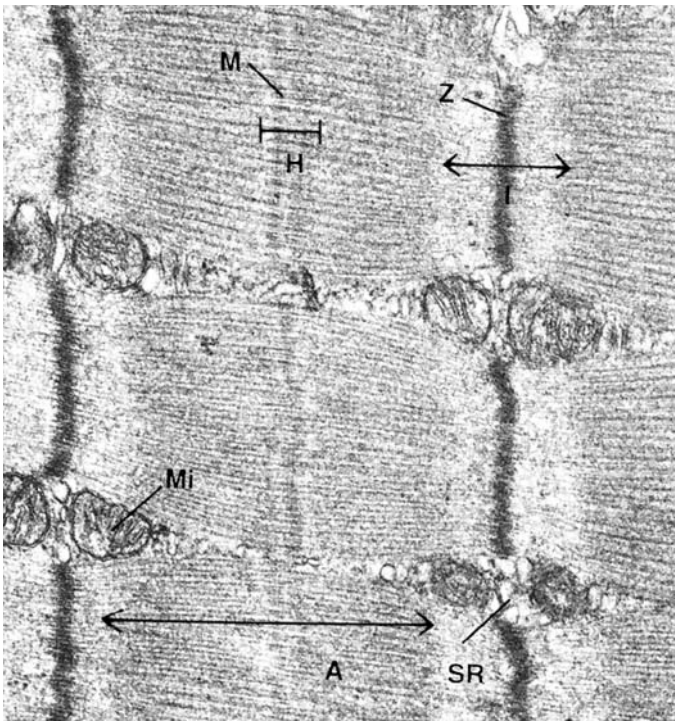

FIGURE 31-2. Normal muscle. This electron micrograph of the biceps muscle demonstrates the ultrastructure of the sarcomere. The thin dark band, the Z disk (*Z*), bisects the broad, pale I band (*I*), a zone composed of the thin actin filaments. The broad, dark band, made up of the thick myosin filaments and overlapping actin filaments, is the A band (*A*). The middle of the A band consists of the pale H zone (*H*), which in turn is bisected by a slightly darker M line (*M*), representing a zone of intermolecular bridging of myosin. Small membrane-bound vesicles compose the sarcoplasmic reticulum (*SR*) and the transverse tubules. Pairs of mitochondria (*Mi*) tend to be located between myofibrils at the level of the I bands.

Myofibers Are Classified as Slow Twitch or Fast Twitch

After innervation, a characteristic metabolic profile develops for different muscle fibers. Muscle fiber types are broadly classified by the rate of contraction and fatigueability, as type I or type II, or slow-twitch fibers and fast-twitch fibers, respectively. These can be further subdivided into slow twitch, fatigue resistant (type I); fast twitch, fatigue resistant (type IIA); and fast twitch, fatigue sensitive (type IIB). There are also type IIC fibers, which are an immature fiber type. In lower mammals, some muscles are deep red (type I), while others are pale (type II).

TYPE I FIBERS (RED, SLOW TWITCH): If a nerve stimulates a dark (red) muscle, the resulting contraction is slower and more prolonged than when a nerve excites a pale (white) muscle. For this reason, red muscles have been classified as "slow twitch." Type I fibers tend to have more mitochondria and more myoglobin, the red, oxygen-storing pigment. Krebs cycle enzymes and electron-transport-chain carrier proteins are all more abundant in slow-twitch muscle than in fast-twitch muscle. The alkaline histochemical reaction for myosin adenosine triphosphatase (ATPase) gives a crisp distinction between the two fiber types. Type I fibers stain poorly at high (alkaline) pH, but type II fibers stain darkly (Fig. 31-3B).

Functionally, type I muscles have a greater capacity for long, sustained contractions and resist fatigue. A training program that increases endurance produces little change in *size* of type I fibers, but conditioning of these fibers causes mitochondrial proliferation and increased capacity for generating energy.

TYPE II FIBERS (WHITE, FAST TWITCH): Stimulating type II fibers elicits faster, shorter and stronger contractions than with type I fibers. Glycogen, phosphorylase and other enzymes that produce energy by anaerobic glycolysis are present in higher concentrations in white muscle. Type II muscle fibers are used for rapid, brief contractions, and

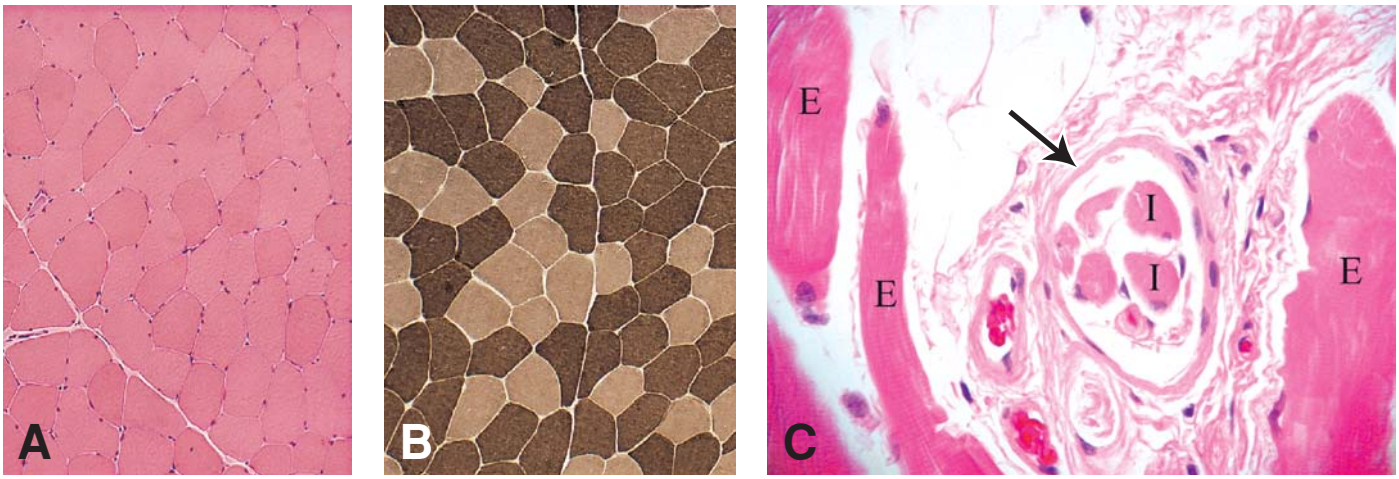

FIGURE 31-3. Normal muscle. A. Hematoxylin and eosin stain. In this transverse frozen section of the vastus lateralis, the polygonal myofibers are separated from each other by an indistinct, thin layer of connective tissue, the endomysium. The thicker band of connective tissue, the perimysium, demarcates a bundle or fascicle of fibers. All of the nuclei in this field are located at the periphery of the cells. Satellite cell nuclei are contained within the basement membrane of the muscle cell and cannot be distinguished from those of the myofibers by light microscopy. **B. Myofibrillar (myosin) ATPase.** Type I fibers are pale, at high (alkaline) pH; type II fibers are dark. Note the intermixture of fiber types. **C. Muscle spindle organ (stretch receptor).** The *arrow* marks the capsule of the muscle spindle organ. *I* = intrafusal fibers; *E* = extrafusal fibers.

hypertrophy during strength training. Type II fibers hypertrophy in response to androgenic steroids and undergo selective atrophy after disuse.

A good way to remember the distinction between fiber types is to consider a chicken. The breast muscles are pale (white) compared to those of the back or legs. The breast muscles are fast twitch since they pull down the wings during flight (granted, domesticated chickens have been bred to be too heavy to fly), while the darker muscles of the legs and back correspond to slow-twitch fibers since their function includes sustained contraction against gravity: standing and maintaining posture.

The lower motor neuron influences fiber type. During embryonic development, early muscle cells begin to express type-specific contractile proteins before muscle is innervated. Thus, the phenotype of a myofiber seems to be a programmed characteristic of the cell, rather than one induced by the nerve supply. However, the kind of innervation can alter the types of myofibers. For example, after denervation injury, reinnervation of a slow-twitch muscle (type I) by a nerve from a fast-twitch muscle (type II) causes the newly innervated type I fibers to resemble type II fibers. It is thought that the pattern or rate of discharge of lower motor neurons plays an important role in this process. Because lower motor neurons can determine fiber type, it follows that all muscle fibers in a given motor unit are of the same type. A cross-section of muscle stained with alkaline ATPase reaction (see above) shows a random mixture of fiber types (Fig. 31-3B), because motor units interdigitate extensively with each other.

In humans, no muscles are composed exclusively of one fiber type. However, proportions of fiber types vary from muscle to muscle. For example, the soleus muscle mainly contains (≥80%) type I fibers. The pattern of fiber types in a given muscle is apparently genetically determined and varies between people. Some evidence indicates that changing the use of a muscle through lengthy, intensive training may alter the pattern of muscle fiber types.

MUSCLE BIOPSY: Since normal muscle patterns are more constant within a specific muscle, the same muscles are biopsied from case to case. Samples from the quadriceps femoris or biceps brachii are suitable for biopsy diagnosis in most primary muscle diseases (myopathies). Biopsies of the sural nerve and gastrocnemius muscle are often done if a peripheral neuropathy is suspected. However, as some neuromuscular conditions are more focal, locations for muscle biopsies vary.

Biopsy sampling of a moderately affected muscle is most informative. Muscles that are uninvolved may show few or no pathologic changes, while very weak muscles may be end stage—largely replaced by fat and fibrous connective tissue (Fig. 31-4).

Evaluation of a muscle biopsy typically includes formalin-fixed, frozen and glutaraldehyde-fixed tissue (the latter for potential electron microscopy). Several frozen section histochemical stains are used, many of which measure enzymatic activity using colorimetric assays. Unlike immunohistochemical stains that tell whether a protein is present or not, histochemical stains allow visualization of an enzyme's function. Some of the usual histochemical reactions used to evaluate skeletal muscle are:

- **Nonspecific esterase:** Important for identifying denervation atrophy and the presence of neuromuscular junctions.
- **NADH-tetrazolium reductase (NADH-TR):** Type I fibers appear dark owing to abundant mitochondria. This stain is useful in identifying central cores and signs of denervation.
- **Succinate dehydrogenase (SDH):** Sensitive histochemical index of mitochondrial proliferation due to mutations of mitochondrial DNA.
- **Cytochrome C oxidase:** Fibers containing abnormal mitochondria lacking the final enzyme of the electron transport chain will fail to stain.
- **Alkaline phosphatase:** Regenerating fibers are selectively stained.
- **Periodic acid–Schiff (PAS):** Helpful in identifying glycogen and diagnosing glycogen storage diseases (see below).
- **Oil red orcein (oil red O):** Marks neutral lipid and is particularly useful in assessing lipid storage myopathies such as carnitine deficiency (see below).
- **Modified Gomori trichrome stain:** Versatile stain in evaluating myopathies. It helps in assessing nemaline bodies, rimmed vacuoles of inclusion body myositis and "ragged red fibers" (see below).
- **Acid phosphatase stain:** Identifies lysosomal activity within muscle fibers and macrophages.
- **Myosin ATPase:** Depending on the pH, helps to differentiate fiber types.

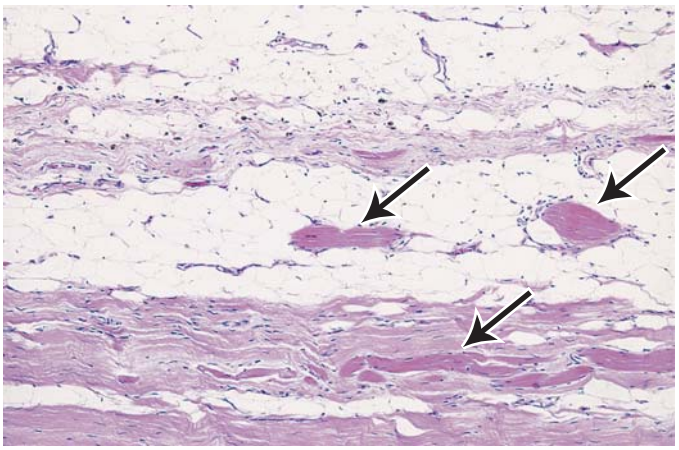

FIGURE 31-4. End-stage neuromuscular disease. In this section of the deltoid muscle stained by hematoxylin and eosin, skeletal muscle has been largely replaced by fibrofatty connective tissue. The few surviving muscle fibers have a deeper eosinophilia than does the abundant collagenous component (*arrows*).

GENERAL PATHOLOGIC REACTIONS

Necrosis is a common response of myofibers to injury in primary muscle diseases **(myopathies)**. Widespread acute necrosis of skeletal muscle fibers **(*rhabdomyolysis*)** releases cytosolic proteins, including myoglobin, into the circulation, which may lead to myoglobinuria and cause acute renal failure. In many human myopathies, segmental necrosis occurs along the length of a fiber, with intact muscle flanking the site of damage (Fig. 31-5). The injury quickly elicits two responses: influx of blood-borne macrophages into the necrotic cytoplasm and activation of satellite cells, a population of dormant myoblasts nearby each fiber. As monocytes gradually phagocytose necrotic debris and remove it, satellite

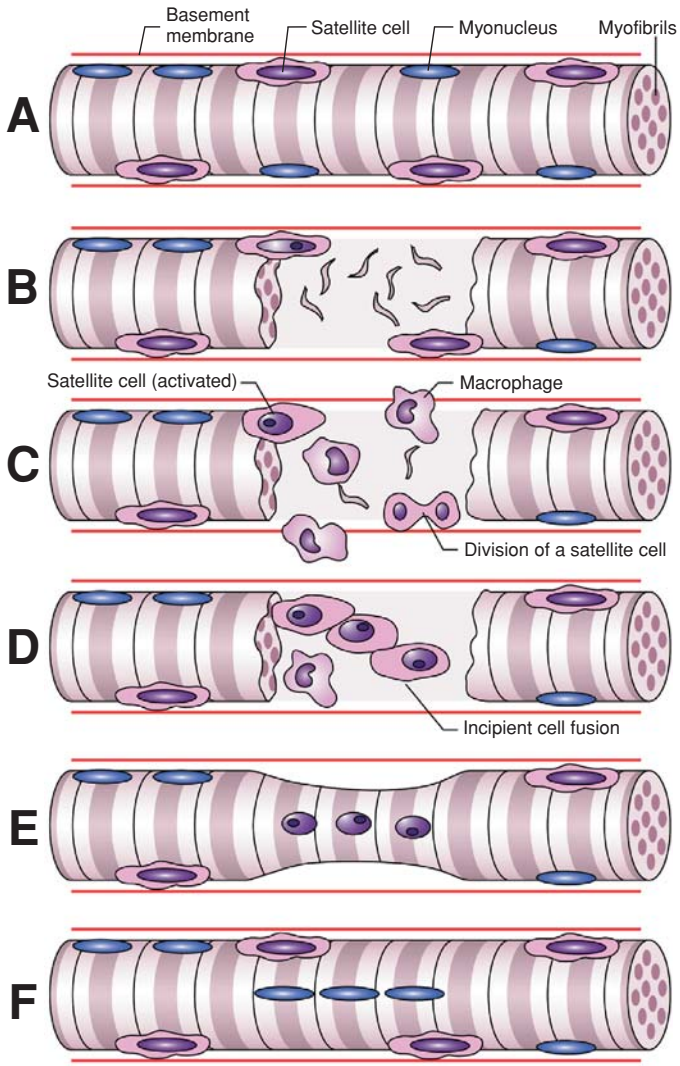

FIGURE 31-5. Segmental necrosis and regeneration of a muscle fiber. **A.** A normal muscle fiber contains myofibrils and subsarcolemmal nuclei and is covered by a basement membrane. Scattered satellite cells are situated on the surface of the sarcolemma, inside the basement membrane. These cells are dormant myoblasts, capable of proliferating and fusing to form differentiated fibers. They constitute 3%–5% of the nuclei, as observed in a cross-section of skeletal muscle. **B.** In many muscle diseases (e.g., Duchenne muscular dystrophy or polymyositis), injury to the muscle fiber causes segmental necrosis with disintegration of the sarcoplasm, leaving a preserved basement membrane and nerve supply (not shown). **C.** The damaged segment attracts circulating macrophages that penetrate the basement membrane and begin to digest and engulf the sarcoplasmic contents (myophagocytosis). Regenerative processes begin with the activation and proliferation of the satellite cells, forming myoblasts within the basement membrane. Macrophages gradually leave the site of injury with their load of debris. **D.** At a later stage, the myoblasts are aligned in close proximity to each other in the center of the fiber and begin to fuse. **E.** Regeneration of the fiber segment is prominent, as indicated by the large, pale, vesicular, centrally located nuclei. **F.** The fiber is nearly normal except for a few persistent central nuclei. Eventually, the normal state **(A)** is restored.

cells proliferate and become active myoblasts. Within 2 days, they begin to fuse to each other and to the ends of the intact fiber remnants, to form a joining multinucleated segment. This regenerating fiber is narrower than the parent fiber and has basophilic cytoplasm (owing to increased ribosomes) and large, vesicular nuclei with prominent nucleoli arranged in long chains (see below).

Regeneration can restore normal structure and function of muscle fibers within a few weeks after a single episode of injury. With subacute or chronic disorders, fiber necrosis proceeds concurrently with fiber regeneration, gradually leading to atrophy of muscle fibers and fibrosis.

MUSCULAR DYSTROPHY

In the middle of the 19th century, physicians discovered that progressive weakness of voluntary muscles could be caused by either a disorder of the nervous system or primary muscle degeneration. The latter was called **muscular dystrophy**. It was found to be frequently hereditary (or at least familial) and relentlessly progressive. Muscles from these patients showed fiber necrosis, with regeneration, progressive fibrosis and infiltration by fatty tissue (Fig. 31-4). Little or no inflammation was seen. Subsequently, many variants of this type of muscle disease were found, and hereditary, progressive, noninflammatory degenerative conditions of muscle have been classified.

Duchenne and Becker Muscular Dystrophies Are Severe, Progressive, X-Linked Diseases

Duchenne muscular dystrophy is characterized by progressive degeneration of muscles, particularly in the pelvic and shoulder girdles. It is the most common noninflammatory myopathy in children. A milder form of the disease is known as **Becker muscular dystrophy** (see Chapter 6 for the genetics of both diseases). Serum creatine kinase is usually greatly increased in both conditions.

MOLECULAR PATHOGENESIS: Duchenne and Becker muscular dystrophies are caused by several mutations in a large gene on the short arm of the X chromosome (Xp21). This gene encodes **dystrophin,** a 427-kd protein at the inner sarcolemma surface. Dystrophin links the subsarcolemmal cytoskeleton to the exterior of the cell via a transmembrane complex of proteins and glycoproteins that binds to laminin (Fig. 31-6). If it is absent or greatly decreased, often owing to deletions of the gene (Fig. 31-7), the normal interaction between the sarcolemma and extracellular matrix is absent. This may cause the observed increase in osmotic fragility of dystrophic muscle, excessive influx of calcium ions and release of soluble muscle enzymes such as creatine kinase into the serum. Breakdown of the sarcolemma precedes muscle cell necrosis, and the basal lamina seems to separate from the sarcolemma early in the course of Duchenne muscular dystrophy.

Dystrophin genes may show point mutations, deletions or duplications, leading to altered, usually truncated, proteins. Some mutated proteins may retain sufficient function to localize correctly to the muscle fiber surface but may distribute abnormally at the cell surface (Fig. 31-7). Such partly active proteins tend to produce less severe disease. Some patients have mutations affecting transmembrane proteins or glycoproteins that normally link the cytoskeleton and extracellular matrix (Table 31-1; Fig. 31-6). In them, dystrophin may be decreased or abnormally localized because its binding partners are abnormal, thus complicating diagnosis (see below).

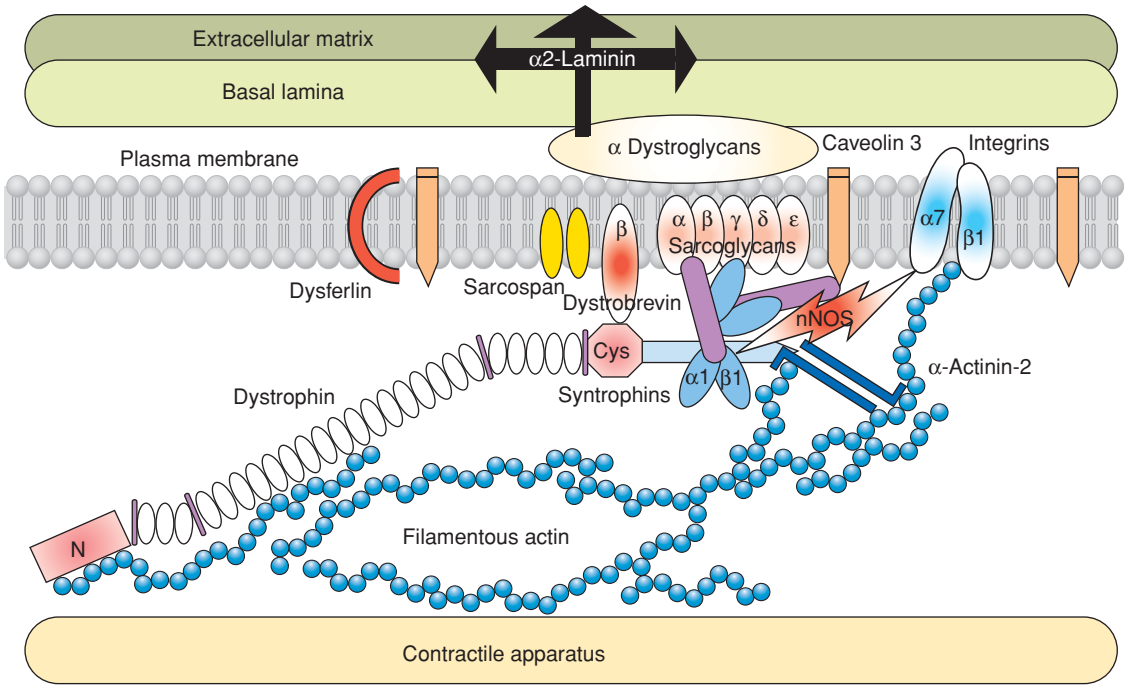

FIGURE 31-6. Diagrammatic representation of proteins linking dystrophin to the plasma membrane and the contractile apparatus. Several of these linking proteins are associated with known myopathies (Table 31-1).

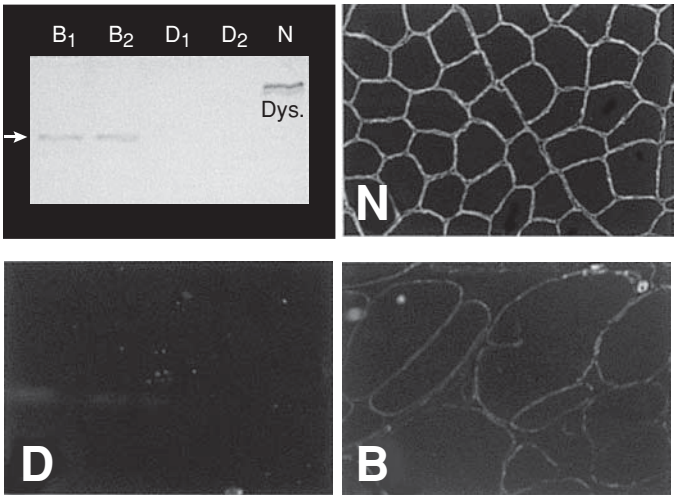

FIGURE 31-7. Dystrophin analysis in Duchenne and Becker muscular dystrophies. Immunofluorescence stain for dystrophin. The sections illustrate a normal subject (*N*), a patient with Duchenne muscular dystrophy (*D*) and one with Becker muscular dystrophy (*B*). Dystrophin is normally concentrated at the surface membrane of every muscle fiber, but in Duchenne muscular dystrophy, the protein is absent or is only barely detected in a small proportion of muscle fibers. Becker muscular dystrophy exhibits hypertrophic muscle fibers with reduced expression of dystrophin. The immunoblot (*upper left*) of normal muscle shows a band near the top of the gel corresponding to the 427-kd protein dystrophin. Dystrophin is undetectable in Duchenne muscular dystrophy (two patients, D_1, D_2). In Becker muscular dystrophy, a weaker band has migrated farther down the gel relative to the normal protein, and it corresponds to a smaller, truncated protein (two patients, B_1, B_2). The combined analysis (immunolocalization and immunoblot) of the dystrophin protein is diagnostic of this group of dystrophies (*dystrophinopathies*).

Because Duchenne muscular dystrophy is inherited as an X-linked recessive disease, the abnormal gene is passed from heterozygous carrier mothers. About 30% of cases are due to spontaneous somatic mutation. Until recently, female carriers were best detected by repeatedly measuring serum creatine kinase, which is moderately increased in 75% of heterozygotes. Expression of the carrier state is very variable, probably because of fluctuations in the random inactivation of the X chromosome. Dystrophin immunolocalization on muscle biopsy also identifies some carriers who show a characteristic mosaic pattern of deficient and normal myofibers. Molecular probes detect more than 2/3 of people who carry large deletions.

PATHOLOGY: Duchenne muscular dystrophy causes relentless necrosis of muscle fibers, continuous effort at repair and regeneration and progressive fibrosis. Degeneration eventually outstrips the regenerative capacity of the muscle. The number of muscle fibers then progressively decreases, to be replaced by fibrofatty connective tissue. In the end stage, skeletal muscle fibers disappear almost completely (Fig. 31-4), but muscle spindle fibers (intrafusal fibers) are relatively spared.

Early in the disease, necrotic fibers and regenerating fibers tend to occur in small groups, together with scattered, large, hyalinized dark fibers. The latter are overly contracted and are thought to precede fiber necrosis (Figs. 31-8 and 31-9). Breakdown of the sarcolemma is one of the earliest ultrastructural changes. Macrophages invade necrotic fibers and reflect a scavenging function rather than an inflammatory process.

CLINICAL FEATURES: Polymerase chain reaction (PCR) analysis of genomic DNA establishes the diagnosis of Duchenne dystrophy. In practice,

TABLE 31-1
LIMB-GIRDLE MUSCULAR DYSTROPHIES

Limb-Girdle Muscular Dystrophies[a]	Defective Protein	Subcellular Location
LGMD1A	Myotilin	Sarcomere
LGMDIB	Lamin	Nuclear envelope

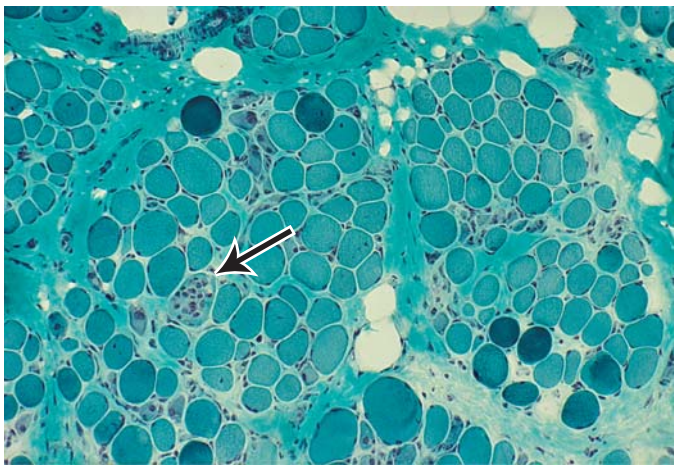

FIGURE 31-9. Duchenne muscular dystrophy. Modified Gomori trichrome stain. A section of vastus lateralis muscle shows necrotic muscle fibers, some of them invaded by macrophages (*arrow*). Dark-staining, enlarged fibers represent overly contracted fibers. Green amorphous material between the fascicles of muscle represents fibrosis. Calcium influx across the defective surface membrane overwhelms mechanisms that maintain a low resting Ca^{2+} concentration and triggers excessive contraction. There is conspicuous perimysial and endomysial fibrosis.

this method only detects large deletions of the gene. About 30% of patients have small rearrangements or point mutations and are evaluated by muscle biopsy, which shows little or no detectable dystrophin by immunoblot or immunohistochemistry. If there is an affected family member, prenatal diagnosis using chorionic villi may be useful.

Boys with Duchenne muscular dystrophy have markedly increased serum creatine kinase levels from birth and morphologically abnormal muscle, even in utero. Clinical weakness is not detectable during the first year but is usually evident by 3 or 4 years of age, mainly around pelvic and shoulder girdles (proximal muscle weakness). It progresses relentlessly. "Pseudohypertrophy" (enlargement of a muscle when muscle fibers are replaced by fibroadipose tissue) of calf muscles eventually develops. Patients are usually wheelchair bound by age 10 and bedridden by 15. Death is usually from complications of respiratory insufficiency caused by muscular weakness or cardiac arrhythmia due to

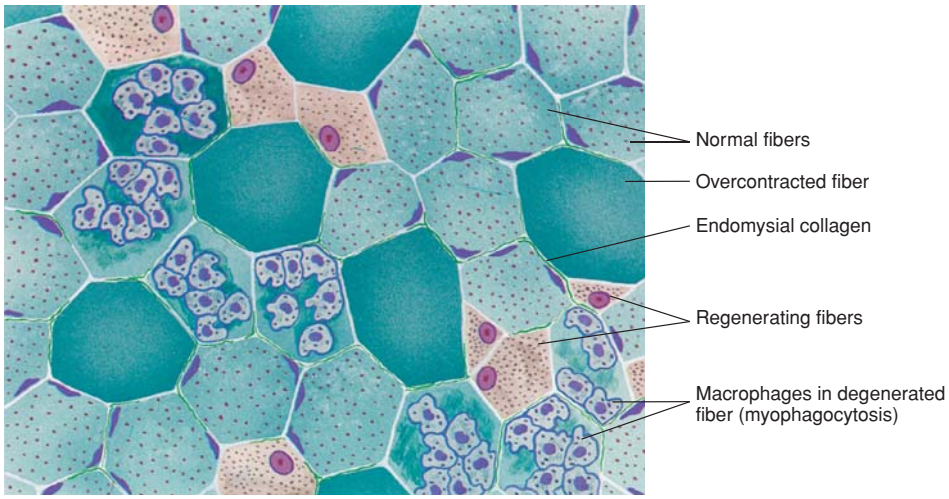

FIGURE 31-8. Duchenne muscular dystrophy. The pathologic changes in skeletal muscle (illustration of modified Gomori trichrome stain). Some fibers are slightly larger and darker than normal. These represent overcontracted segments of sarcoplasm situated between degenerated segments. Other fibers are packed with macrophages (myophagocytosis), which remove degenerated sarcoplasm. Other fibers are smaller than normal and have granular sarcoplasm. These fibers have enlarged, vesicular nuclei with prominent nucleoli and represent regenerating fibers. Developing endomysial fibrosis is represented by the deposition of collagen around individual muscle fibers. The changes are those of a chronic, active noninflammatory myopathy.

myocardial involvement. Other extraskeletal manifestations include gastrointestinal dysfunction (from degeneration of smooth muscle) and intellectual impairment. Many boys with Duchenne dystrophy show variably severe mental retardation, apparently due to lack of dystrophin in the central nervous system (CNS).

While the clinical presentation of patients with Becker muscular dystrophy is typically milder and of later onset, affected individuals often have exercise intolerance with muscle cramping, occasional rhabdomyolysis and myoglobinuria. Unlike Duchenne muscular dystrophy, in which dystrophin is usually absent, in Becker dystrophy dystrophin is present as a truncated protein (Fig. 31-7).

Limb-Girdle Muscular Dystrophies Are Caused by Mutations in Diverse Proteins

Limb-girdle muscular dystrophies (LGMDs) are a group of disorders with several defective proteins and modes of inheritance (Table 31-1). Defects in many proteins have been implicated, but these patients show similar clinical features that include pelvic and shoulder girdle weakness. Onset may be in childhood or adulthood, with variable muscle weakness. Patients may have difficulty walking, running or rising from a sitting position. Cardiac involvement is common. The histology resembles all muscular dystrophies, but some variants show unusual features including inflammation (LGMD2B, Miyoshi myopathy) and rimmed vacuoles (LGMD1A) like those seen in inclusion body myositis (see below). As a result, proper diagnosis requires detailed clinical histories, plus immunohistochemical, immunoblotting and genetic tests. LGMD (2C through 2F) are also known as the sarcoglycanopathies (Fig. 31-6).

Congenital Muscular Dystrophies Present in the Perinatal Period

These diseases are characterized by hypotonia, weakness and contractures (Table 31-2). Depending on the variant, patients may also present with a leukoencephalopathy (white matter brain disease), brain malformations and eye involvement.

Pathologically, these diseases resemble other muscular dystrophies, with variable fibrosis and fatty infiltration of muscle. Many of these disorders reflect mutations in extracellular matrix proteins (e.g., collagens, laminin, integrins) or abnormal glycosylation of α-dystroglycan (α-dystroglycanopathies) and sarcoplasmic reticulum (rigid spine muscular dystrophy). Some affected proteins also cause certain limb-girdle muscular dystrophies, albeit with different mutations.

Nucleotide Repeat Syndromes May Cause Muscular Dystrophies

Several human genetic diseases are caused by abnormal numbers of intragenic oligonucleotide repeats. Myotonic dystrophy and oculopharyngeal muscular dystrophy are trinucleotide repeat syndromes with very different muscle pathologies. Both, however, exhibit "anticipation" (i.e., increasingly earlier ages at onset and more severe symptoms in successive generations, as numbers of repeats increase; see Chapter 6).

Myotonic Dystrophy Is the Most Common Adult Muscular Dystrophy

Myotonic dystrophy is an autosomal dominant disease characterized by slowed muscle relaxation (myotonia), progressive muscle weakness and wasting. Its prevalence is about 14 per 100,000, although minimally affected individuals are hard to diagnose, so this estimate may be low. Age at onset and severity of symptoms vary greatly. Myotonic dystrophy may be either adult onset or congenital.

MOLECULAR PATHOGENESIS: The two forms of myotonic dystrophy (DM1, DM2) both follow autosomal dominant inheritance and reflect mutations in different genes. DM1 is due to expansion of a CTG repeat near the 3′ end of the DM protein

TABLE 31-2
CONGENITAL MYOPATHIES CAUSED BY ABNORMALITIES IN THE SARCOLEMMA OR EXTRACELLULAR MATRIX

Congenital Muscular Dystrophy (CMD)	Protein	Location and/or Function of Protein
Merosin-deficient CMD	Laminin α2	Extracellular matrix
Ullrich syndrome	Collagen VI	Extracellular matrix
Integrin α7 deficiency	Integrin α7	Plasma membrane
Fukuyama CMD	Fukutin	Possible substrate for glycosyltransferase
Muscle-eye-brain	POMGnT1 (*O*-mannose β-1,2-*N*-acetylglucosaminyl-tranferase	Glycosyltransferase
Walker-Warburg syndrome	POMT1 (protein-*O*-mannosyl-transferase) Fukutin-related protein	Glycosyltransferase Possible phosphor-sugar transferase
Rigid spine syndrome	Selenoprotein N1	Glycoprotein of the endoplasmic reticulum

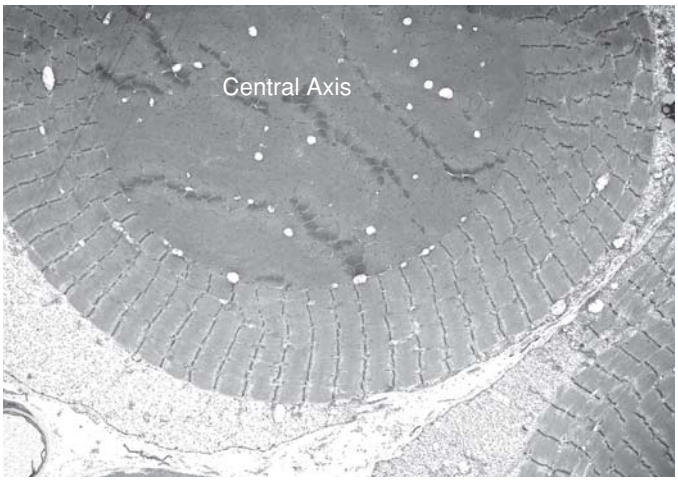

FIGURE 31-10. Ring fiber. Electron micrograph (magnification ×1900). The outer sarcomeres are oriented perpendicular to the axis of the myofiber.

kinase (DMPK) gene, which encodes a serine-threonine kinase. Normally, there are fewer than 30 copies of this repeat, but in minimally affected myotonic dystrophy patients, there may be 50 or more copies. The greater the number of repeats (sometimes as many as 4000), the more severe the disorder. The mechanism of injury brought about by expansion of CTG repeats in myotonic dystrophy, as in other trinucleotide repeat disorders, is not clearly understood at present (see Chapter 1). DM2 is caused by expansion of the tetranucleotide repeat CCTG in the first intron of the ZNF9 gene.

PATHOLOGY: Pathology in adult myotonic dystrophy is highly variable, even in muscles from the same patient. Most patients show type I fiber atrophy and type II fiber hypertrophy. In contrast, most muscle disorders show relative type II fiber atrophy. Internally situated nuclei are a constant feature. The ATPase reaction shows many ring fibers, with circumferential concentration of heavily stained sarcoplasm. In these fibers, outer sarcomeres are circumferential, instead of their usual longitudinal arrangement along the fiber axis (Fig. 31-10). Necrosis and regeneration, although occasionally present, are not prominent (as they are in Duchenne muscular dystrophy).

Muscles in congenital myotonic dystrophy show myofiber atrophy, frequent central nuclei and failure of fiber differentiation. These features closely resemble those of the X-linked recessive type of myotubular myopathy (see below).

CLINICAL FEATURES: People with DM1 experience slowly progressive muscle weakness and stiffness, principally in the distal limbs (proximal weakness is more common in DM2). Facial and neck weakness as well as ptosis are typical of DM1, but less common in DM2. Extraskeletal features sometimes present in myotonic dystrophy include frontal balding, gonadal atrophy, cataracts, personality degeneration and endocrine abnormalities. Cardiac arrhythmias and, less often, cardiomyopathy may occur. A few patients exhibit involvement of smooth muscle, with disorders of the gastrointestinal tract, gallbladder and uterus.

Diagnosis is based on clinical features, family history and characteristic electromyography, which exhibits myotonic discharges. Identifying an expanded CTG repeat (DM1) or CCTG (DM2) is predictive in utero and can be diagnostic in patients.

Congenital myotonic dystrophy is seen only in children of women with DM1 who themselves show symptoms of myotonic dystrophy. Affected infants have severe muscle weakness at birth. Myotonia is inconspicuous or absent but appears in later childhood. Many of these patients suffer mental retardation. Congenital DM2 has not been identified.

Oculopharyngeal Muscular Dystrophy Usually Presents in Adults

Oculopharyngeal muscular dystrophy (OPMD) is typically diagnosed in middle age (over 45 years) and mostly shows autosomal dominant inheritance. However, an autosomal recessive form does exist. Patients develop slowly progressive eyelid ptosis and dysphagia and weakness of other muscle groups including the face and limbs. The autosomal dominant form is prevalent among French Canadians in Quebec and Bukhara Jews (formerly from central Asia), now living in Israel. Both autosomal dominant and recessive forms are due to abnormally increased numbers of GCG repeats in the poly(A) binding protein nuclear 1 gene (PABPN1), but differ in where these increased repeats are within the gene. Biopsies show intranuclear inclusions, rimmed vacuoles and filamentous inclusions similar to those in inclusion body myositis (see below). Unlike the latter, the intranuclear inclusions contain 8.5-nm filaments.

Facioscapulohumeral Muscular Dystrophy Usually Presents in Childhood

Facioscapulohumeral muscular dystrophy (FSHD) is a relatively common muscular dystrophy, inherited as an autosomal dominant disease that begins in childhood or young adulthood. Patients suffer from facial and shoulder girdle weakness. Scapular winging is prominent. Other muscles may also be affected. Life expectancy is usually normal, and extraskeletal involvement includes bundle branch block, hearing loss and retinal vasculopathy. FSHD is caused by deletion of part of a repetitive DNA fragment in the subtelomeric region of chromosome 4q: affected patients have fewer repeats than normal. Chronic inflammation is prominent, resembling an inflammatory myopathy such as polymyositis (see below), but does not correlate with the disease course. A detailed clinical history is essential to making the proper diagnosis; otherwise, a patient with muscle weakness and a lymphocytic inflammatory infiltrate could easily be misdiagnosed as suffering from polymyositis.

CONGENITAL MYOPATHIES

A newborn occasionally shows generalized hypotonia, with decreased deep tendon reflexes and muscle bulk. Many of these children have a difficult perinatal period because of pulmonary complications of weak respiration. Many of the muscle diseases already described are "congenital" in the sense that they are due to mutations present at birth. However, such disorders are not clinically evident until much later. In contrast, congenital myopathies, as described here, are evident at birth. Some have progressive "malignant"

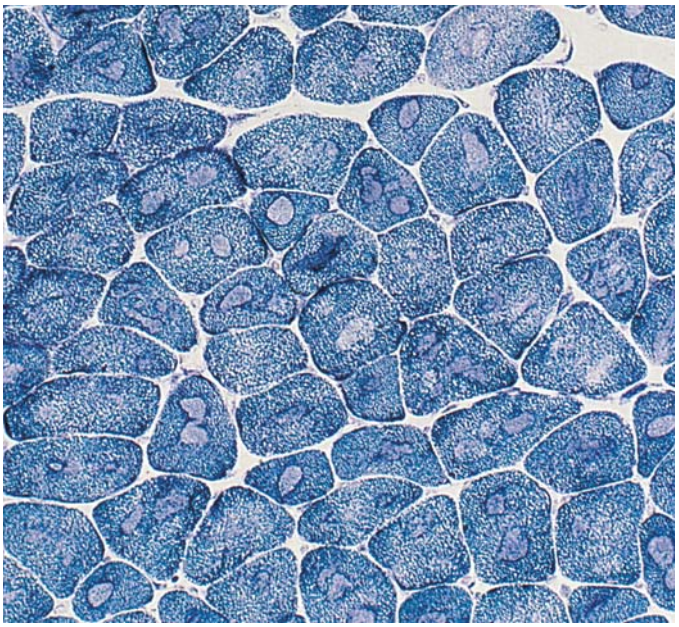

FIGURE 31-11. Central core disease. A section of vastus lateralis muscle stained for NADH-tetrazolium reductase shows a distinct circular zone of pallor in the center of most muscle fibers. A thin zone of excessive staining surrounds the core lesion. All of the myofibers in this case were type I, as demonstrated by the myofibrillar ATPase stain (not shown). Note the close resemblance of the core lesions to the target formations found in the muscle fibers of neurogenic disorders (Fig. 31-23).

hypotonia, which results in death within the first year of life, for example, **Werdnig-Hoffman disease** and **infantile acid maltase deficiency (Pompe disease)**.

In other hypotonic patients, hypotonia may persist with little or no progression. These people become ambulatory and live a normal life span, although sometimes with secondary skeletal complications of hypotonia such as severe scoliosis. Muscle from these patients rarely reveals distinctive structurally abnormal myofibers. Three of the most common forms of congenital myopathies are **central core disease** (Fig. 31-11), **nemaline (rod) myopathy** (Fig. 31-12)

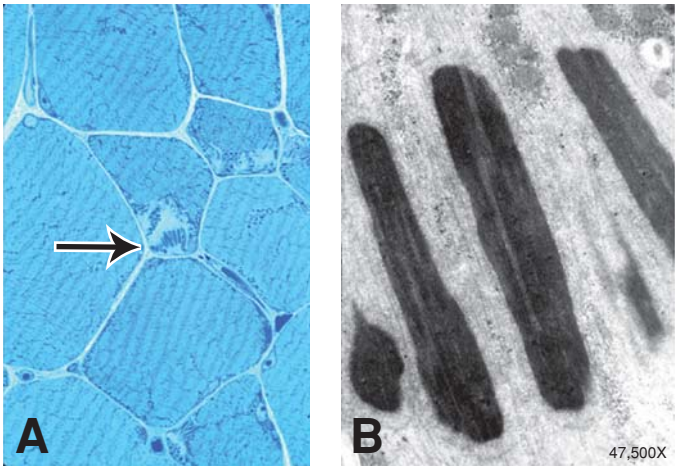

FIGURE 31-12. Rod (nemaline) myopathy. A. Muscle fibers contain dark aggregates of rods (toluidine blue, 1000×). **B.** An electron micrograph of the same biopsy shows that the structures are rod shaped and are derived from the Z disk (47,500×).

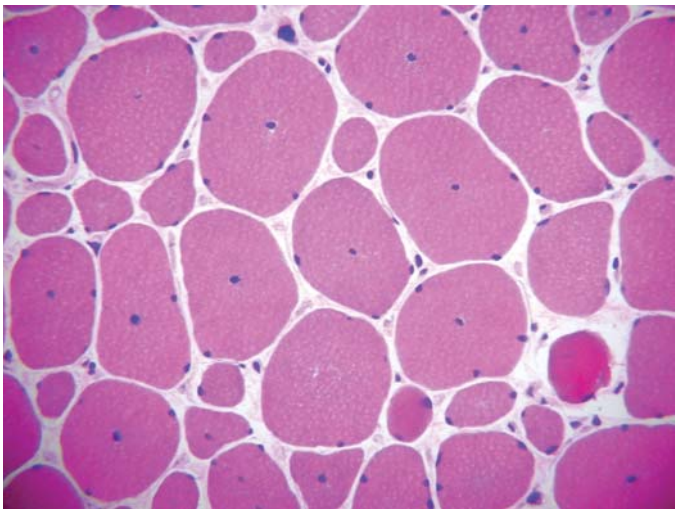

FIGURE 31-13. Central nuclear myopathy. Hematoxylin and eosin stain. Many muscle fibers contain a single central nucleus, and most of the affected muscle fibers are abnormally small. In addition, there are radiating spokes emanating from the central nuclei. These fibers resemble the late myotubular stage of fetal development of skeletal muscle.

and **central nuclear myopathy** (Fig. 31-13). All show congenital hypotonia, decreased deep tendon reflexes, decreased muscle bulk and delayed motor milestones. In all three conditions, abnormal muscle morphology is usually limited to type I fibers, with type I fiber predominance in some disorders and type I hypotrophy in others. Often, type I fibers are unusually predominant, or possibly, type II fibers fail to develop. There is no active myofiber necrosis or fibrosis, and patients have normal serum creatine kinase.

Central Core Disease Is an Autosomal Dominant Condition with Congenital Hypotonia and Proximal Muscle Weakness

MOLECULAR PATHOGENESIS: Afflicted patients have decreased deep tendon reflexes and delayed motor development. The disease has been traced to a mutation on the long arm of chromosome 19 (19q13.1) that codes for the ryanodine receptor, the calcium release channel of the sarcoplasmic reticulum. Occasional cases are sporadic or show autosomal recessive inheritance. Typical patients become ambulatory, but muscle strength remains less than normal.

PATHOLOGY: There is a striking predominance of type I fibers, often showing a central zone of degeneration with loss of NADH-TR reaction staining (Fig. 31-11) and extending the entire length of the fiber. By electron microscopy, mitochondria and other membranous organelles are lost in the central cores, with or without myofibril disorganization. Membranous organelles tend to condense around the margin of the central core. The periphery of the fiber is unremarkable.

Central core anomalies may resemble the target fibers seen in active denervating conditions (see below), although target fibers typically have dark rims around the areas of pallor and there is no evidence of denervation in central core disease.

Mutations of the ryanodine receptor 1 gene also cause **malignant hyperthermia,** a potentially fatal disorder that is triggered by succinylcholine and some anaesthetic agents, particularly halothane. It is characterized by hyperpyrexia and rhabdomyolysis (see Chapter 8). Central core disease and malignant hyperthermia may coexist in some patients, so patients with central core disease may be at risk for malignant hyperthermia. However, patients with malignant hyperthermia often have no abnormal histologic changes. Malignant hyperthermia is suspected by family history and confirmed by an in vitro caffeine-halothane contraction test.

Rod Myopathy Sarcoplasmic Inclusions Derive from Z Bands

Rod myopathy includes a group of diseases in which rod-like inclusions accumulate within skeletal muscle sarcoplasm. The tangled, thread-like appearance of the inclusions led to the original name, "nemaline" myopathy. In reality, they are clusters of rod-shaped structures.

MOLECULAR PATHOGENESIS: Autosomal dominant and recessive inheritance is described. Genes responsible for rod myopathy include nebulin (most common), skeletal muscle α-actin, α- and β-tropomyosin and slow troponin T. Mutations in the ryanodine receptor gene may also lead to nemaline rod formation.

PATHOLOGY: There is variable predominance of type I fibers containing rod-shaped structures in their sarcoplasm. Aggregates of these inclusions often occur in subsarcolemmal regions, near nuclei. They are brilliant, red to dark red, using modified Gomori trichrome stain, or blue on toluidine blue stain (Fig. 31-12A), but are often not visible with hematoxylin and eosin. The inclusions are rod shaped and arise from the Z band, which they resemble ultrastructurally (Fig. 31-12B).

Rods are described in several neuromuscular diseases, including denervation atrophy, muscular dystrophy and inflammatory myopathies. Experimental tenotomy (cutting a tendon) induces formation of rods in the muscle when the nerve supply remains intact. In rod myopathy, however, inclusions are the main pathologic feature. Other abnormalities (inflammation, denervation) are absent.

CLINICAL FEATURES: In the classic congenital form of rod myopathy, patients show congenital hypotonia, delayed motor milestones of variable clinical severity and secondary skeletal changes such as kyphoscoliosis. Some exhibit severe involvement of muscles of the face, pharynx and neck. Later-onset (childhood and adult) forms tend to be associated with some muscle degeneration, increased serum creatine kinase levels and a slowly or nonprogressive course.

Central Nuclear Myopathy and Myotubular Myopathy Resemble the Myotubular Stage of Embryogenesis

MOLECULAR PATHOGENESIS AND CLINICAL FEATURES: Central nuclear myopathy is a group of clinically and genetically heterogeneous inherited conditions in which skeletal muscle cells have centrally located nuclei. Autosomal recessive and autosomal dominant varieties are known. The latter tend to manifest in adolescence and show modestly increased serum creatine kinase. They progress slowly and, like rod myopathy, resemble the limb-girdle dystrophies (see above). Some patients exhibit a striking involvement of facial and extraocular musculature. Bilateral ptosis is almost always present. The gene responsible, dynamin 2, is involved in endocytosis, membrane trafficking and centrosome and actin assembly.

Myotubular myopathy is an X-linked disorder caused by myotubularin gene mutations. Myotubularin is a phosphatase expressed in most tissues and involved in phosphatidylinositol signaling. Clinically, myotubular myopathy is characterized by marked neonatal hypotonia and respiratory failure at birth. Pathologically, like central nuclear myopathy, there are centrally placed nuclei within both fiber types.

PATHOLOGY: Biopsies show predominance of type I fibers (Fig. 31-13), many of which are small and round, with a single central nucleus (hence the name of the disease). They resemble the myotubular stage in skeletal muscle embryogenesis. This apparent immature state suggests a possible defect in the nerve supply to the muscle fiber because the lower motor neuron normally promotes subsequent maturation of the fiber. However, lower motor neurons in these patients, including motor endplates, are not demonstrably abnormal.

Later-onset forms of myotubular myopathy are characterized morphologically by more mature muscle fibers, in which fibers are larger, have more numerous myofibrils and display single central nuclei that appear more mature.

INFLAMMATORY MYOPATHIES

Inflammatory myopathies are a heterogeneous group of acquired disorders, all of which feature symmetric proximal muscle weakness, increased serum levels of muscle-derived enzymes and nonsuppurative inflammation of skeletal muscle.

These are uncommon diseases, the annual incidence being 1 in 100,000. ***Dermatomyositis afflicts children and adults, but polymyositis almost always begins after 20 years of age***. Both disorders occur more often in females than males. In contrast, inclusion body myositis is usually a disease of men over age 50.

These myopathies are thought to have an autoimmune origin (see Chapter 11) because (1) they often occur in association with other autoimmune and connective tissues diseases, (2) the pathology suggests autoimmune cellular injury, (3) serum autoantibodies are detected and (4) polymyositis and dermatomyositis (but not inclusion body myositis) respond to immunosuppressive therapy. No specific target autoantigens in muscle or blood vessels have been identified, but antinuclear and anticytoplasmic antibodies against several different antigens exist in all.

The inflammatory myopathies are characterized by (1) the presence of inflammatory cells, (2) necrosis and phagocytosis of muscle fibers, (3) a mixture of regenerating and atrophic fibers and (4) fibrosis.

CLINICAL FEATURES: All inflammatory myopathies manifest as insidious proximal and symmetric muscle weakness, gradually increasing

over weeks to months. Patients have problems with simple activities that require use of proximal muscles, including lifting objects, climbing steps or combing hair. Dysphagia and difficulty in holding up the head reflect involvement of pharyngeal and neck-flexor muscles. Some patients with inclusion body myositis have distal muscle weakness of the limbs that equals or exceeds that of proximal muscles. In advanced cases, respiratory muscles may be affected. Interstitial lung disease may also compromise respiratory function in 10% of polymyositis and dermatomyositis patients. Myocardial involvement may also occur. Weakness progresses over weeks or months and leads to severe muscular wasting.

In Polymyositis Muscle Damage Is Mediated by Cytotoxic T Cells

MOLECULAR PATHOGENESIS: In polymyositis, there is no detectable microangiopathy as is seen in dermatomyositis (see below). In these disorders, healthy muscle fibers are initially surrounded by $CD8^+$ T lymphocytes (Fig. 31-14) and macrophages, after which the fibers degenerate. Unlike normal muscle, muscle cells in inflammatory myopathies express major histocompatibility complex (MHC) I antigens. This aberrant expression promotes an autoimmune reaction.

The pathogenetic role of autoantibodies against nuclear antigens and cytoplasmic ribonucleoproteins in muscle injury is unknown. Polymyositis often has detectable anti-Jo-1, an antibody against histidyl-transfer RNA (tRNA) synthetase, with concomitant interstitial lung disease, Raynaud phenomenon and nonerosive arthritis.

Viral infections may precede polymyositis, but virus cultures of muscle are negative. An inflammatory myopathy may also occur in many cases of HIV-1 infection, but the role of the virus is unclear.

PATHOLOGY: Inflammatory cells infiltrate connective tissue mostly within fascicles (i.e., endomysial inflammation) and invade apparently healthy muscle (Fig. 31-14). Angiopathy is absent. Isolated degenerating or regenerating fibers are scattered throughout fascicles. Perifascicular atrophy does not occur in polymyositis (see below).

Inclusion Body Myositis Is Characterized by β-Amyloid Deposits

Inclusion body myositis typically occurs in older patients (>50 years) and is the most common inflammatory myopathy of the elderly. It resembles polymyositis pathologically, showing single-fiber necrosis and regeneration, with predominantly endomysial cytotoxic T cells. Basophilic granular material is seen at the edge of vacuoles (rimmed vacuoles) within muscle fibers (Fig. 31-15A, B). These inclusions contain intracellular amyloid (Fig. 31-15C) that is immunoreactive for β-amyloid protein, the same type of amyloid as in senile plaques in Alzheimer disease. Other proteins associated with Alzheimer disease are also present including phosphorylated tau, α-synuclein, ubiquitin and presenilins (see Chapter 32). Parkin, which accumulates in hereditary Parkinson disease, and the prion precursor protein have also been localized to the inclusions.

The pathogenic role of these inclusions is unclear as similar neurodegenerative disease-associated protein accumulation has been observed in other rare myopathies (X-linked Emery-Dreifuss muscular dystrophy and myofibrillar myopathies) as well as in chronic denervation. By electron microscopy, the granules of rimmed vacuoles contain membranous whorls and adjacent distinctive filaments (Fig. 31-15D). Unique features of inclusion body myositis include Congo red–positive inclusions, the characteristic cytoplasmic (or rarely nuclear) filaments in muscle fibers and an inflammatory infiltrate, though the latter may be slight. An autosomal recessive hereditary form of the disease shows similar features but may present in late adolescence or adulthood. Despite the presence of inflammation, immunosuppressive therapy does not mitigate the disease, but intravenous immunoglobulin (IVIG) may be therapeutically useful.

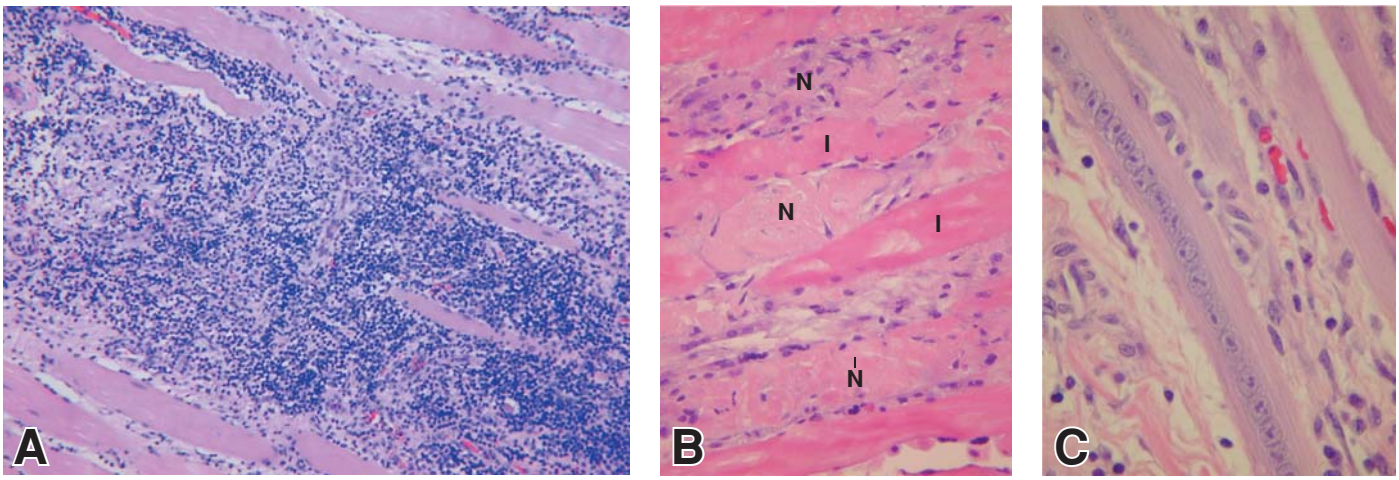

FIGURE 31-14. Polymyositis. A. Hematoxylin and eosin stain. A section of affected muscle shows an inflammatory myopathy. Mononuclear inflammatory cells infiltrate chiefly the endomysium. The field includes single-fiber necrosis. **B.** Region of healing inflammatory myopathy demonstrates intact fibers (*I*) and necrotic fibers (*N*). The uppermost necrotic fiber is heavily infiltrated with macrophages. **C.** Regenerating fiber displaying a linear array of enlarged centrally placed nuclei.

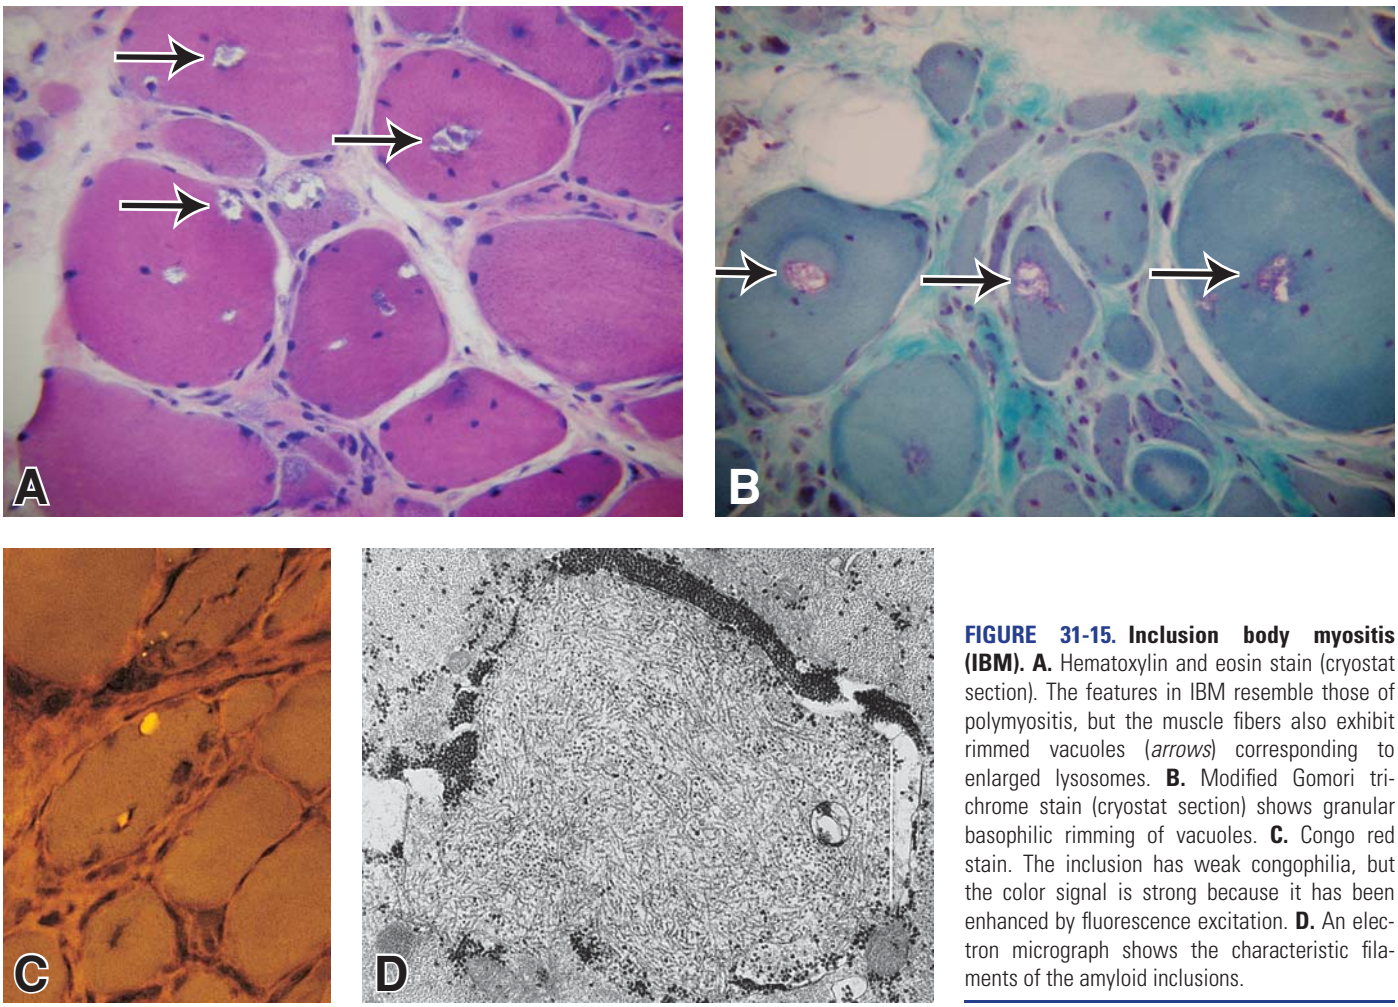

FIGURE 31-15. Inclusion body myositis (IBM). A. Hematoxylin and eosin stain (cryostat section). The features in IBM resemble those of polymyositis, but the muscle fibers also exhibit rimmed vacuoles (*arrows*) corresponding to enlarged lysosomes. **B.** Modified Gomori trichrome stain (cryostat section) shows granular basophilic rimming of vacuoles. **C.** Congo red stain. The inclusion has weak congophilia, but the color signal is strong because it has been enhanced by fluorescence excitation. **D.** An electron micrograph shows the characteristic filaments of the amyloid inclusions.

Dermatomyositis Is an Immune-Mediated Microangiopathy

Dermatomyositis differs from other myopathies in having a characteristic rash on the upper eyelids, face, trunk and sometimes elsewhere. It may occur alone or together with scleroderma, mixed connective tissue disease or other autoimmune conditions.

PATHOPHYSIOLOGY: This myopathy is characterized by (1) deposition of immune complexes of immunoglobulin G (IgG), IgM and complement components, including membrane attack complex C5b-9 in the walls of capillaries and other blood vessels; (2) microangiopathy with loss of capillaries; (3) signs of injury and atrophy of myofibers; and (4) perivascular infiltrates of B cells and $CD4^+$ helper T cells (Fig. 31-16). These features suggest that muscle injury in dermatomyositis is mainly mediated by complement-fixing cytotoxic antibodies against skeletal muscle microvasculature. Complement deposition in capillary walls preceding inflammation or damage to muscle fibers is the most specific finding. This microangiopathy is thought to lead to ischemic injury of individual muscle fibers and eventually to fiber atrophy. True infarcts may result from involvement of larger intramuscular arteries. The rash clinically distinguishes dermatomyositis from the other inflammatory myopathies due to the same microangiopathy.

PATHOLOGY: B and T lymphocytes infiltrate around blood vessels and in perimysial connective tissue, with a high $CD4^+$ (helper):$CD8^+$ (cytotoxic/suppressor) T-cell ratio. Immune complexes, including IgG, IgM and complement C5-9 membrane attack complex, in the walls of blood vessels (Fig. 31-16, inset) are associated with the microangiopathy. Perifascicular atrophy (one or more layers of atrophic fibers at the periphery of fascicles) is pathognomonic (Fig. 31-16) even if inflammation is lacking. The perifascicular atrophy is due to relative hypoperfusion of perifascicular zones.

Vasculitis in Skeletal Muscle May be Part of Systemic Vasculitides

Vasculitis can be present in skeletal muscle in polyarteritis nodosa (PAN), granulomatosis with polyangiitis, collagen

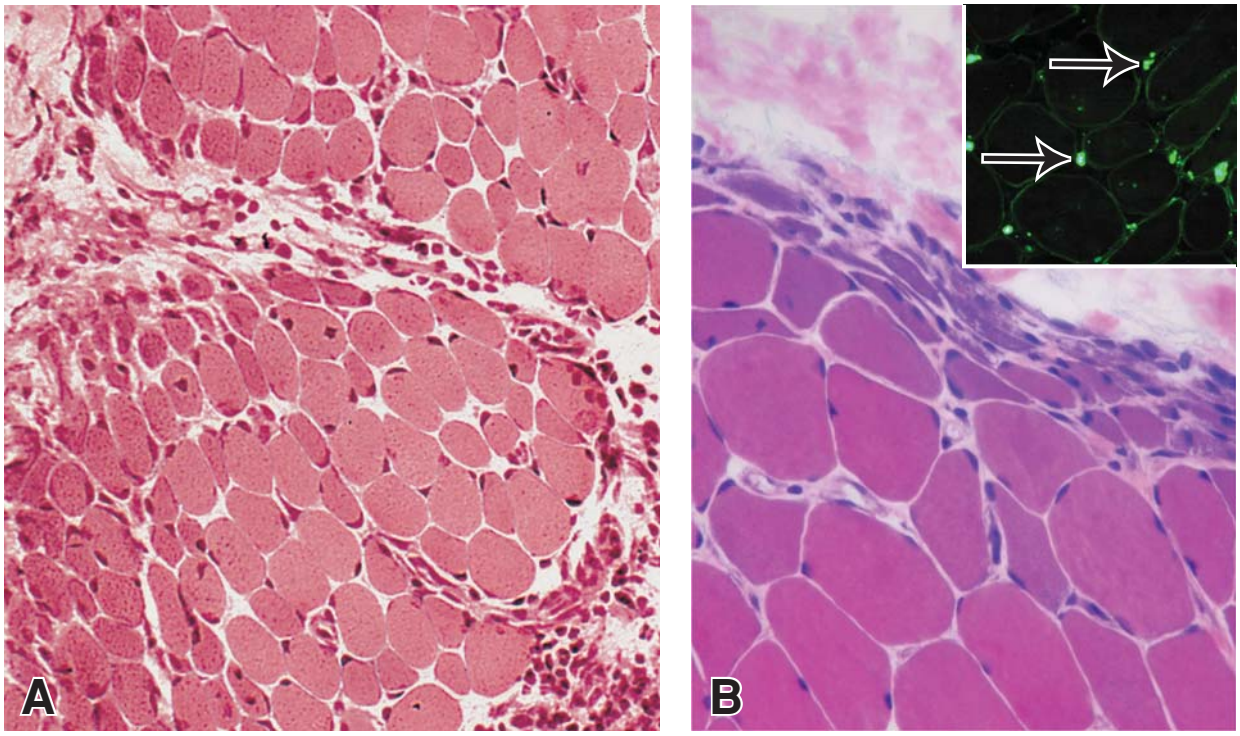

FIGURE 31-16. Dermatomyositis. A. Hematoxylin and eosin stain. The inflammatory cells infiltrate predominantly the perimysium rather than the endomysium. The periphery of muscle fascicles shows most of the muscle fiber atrophy and damage, resulting in a pattern of injury characteristic of dermatomyositis, termed *perifascicular atrophy.* **B.** High-magnification image of perifascicular atrophy demonstrating the flattening and shrinkage of fibers at the periphery of the fascicle. Immunofluorescence (*inset*) reveals that the walls of many capillaries display C5b-9 (membrane attack complex), reflecting the altered microvasculature typical of dermatomyositis.

vascular disease and immune-mediated hypersensitivity states. In such instances, skeletal muscle may show neurogenic changes (see below) secondary to nerve damage.

MYASTHENIA GRAVIS

Myasthenia gravis is an acquired autoimmune disease in which antibodies to the acetylcholine (Ach) receptor at the neuromuscular junction cause abnormal muscular fatigability. It occurs in all races and is twice as common in women as in men. The disease typically begins in young adults, but first presentations may vary from childhood to old age.

PATHOPHYSIOLOGY: In myasthenia gravis, antibodies bind the Ach receptor of the motor endplate. Complement activation leads to shedding of the Ach receptor–rich terminal portions of the folds of the neuromuscular junction. The bivalent IgG antibodies also cross-link receptor proteins that remain in the postsynaptic membrane. This accelerates Ach receptor endocytosis so much that the muscle cannot replace them. The combination of reduced postsynaptic membrane area, decreased numbers of Ach receptors per unit area and widened synaptic space impairs signal transmission and causes muscle weakness and abnormal fatigability. The antireceptor antibodies do not directly block Ach binding its receptor.

Most patients with myasthenia gravis have anti–Ach receptor antibodies and thymic hyperplasia. About 15% have an associated thymoma. Surgical removal of the hyperplastic thymic tissue or the thymoma often causes the myasthenia gravis to remit. Ach receptors are present on the surface of some thymic cells in thymoma and thymic hyperplasia. Thus, thymic T cells may trigger production of antireceptor antibodies.

PATHOLOGY: Light microscopy may reveal atrophy of type II muscle fibers and focal collections of lymphocytes within fascicles. However, electron microscopy shows that most muscle endplates are abnormal, even in muscles that are not weakened. Sarcolemmal secondary folds are simplified with breakdown, loss of the crests of the folds and widening of the clefts.

CLINICAL FEATURES: The clinical severity of the condition is quite variable, and symptoms tend to wax and wane as in other autoimmune diseases. Weakness of extraocular muscles is typically severe and causes ptosis and diplopia. Sometimes, myasthenia gravis may be limited to those muscles. More commonly, it progresses to other muscles (e.g., those associated with swallowing, the trunk and extremities). Patients with myasthenia gravis often have other autoimmune diseases.

The overall mortality from myasthenia gravis is about 10%, often because muscle weakness leads to respiratory

insufficiency. In addition to thymectomy, corticosteroids, methotrexate and anticholinesterase drugs are used, alone or in combination. Plasmapheresis reduces anti–Ach receptor antibody titers, but any consequent clinical improvements are short-lived.

INHERITED METABOLIC DISEASES

Skeletal muscle is dramatically affected by many endocrine and metabolic diseases, such as Cushing syndrome, Addison disease, hypothyroidism, hyperthyroidism (see Chapter 27) and conditions associated with hepatic or renal failure. Only primary hereditary abnormalities in metabolism of skeletal muscle resulting in abnormal muscular function are discussed here.

Glycogen Storage Diseases Are Genetic Disorders with Variable Effects on Muscle

Glycogen storage diseases (glycogenoses) are autosomal recessive, inherited, metabolic disorders characterized by an inability to degrade glycogen (see Chapter 6). There are many glycogenoses, but only some of them affect skeletal muscle. Only the most important glycogenoses affecting skeletal muscle will be described.

Type II Glycogenosis (Acid Maltase [α-1,4-Glucosidase] Deficiency, Pompe Disease)

MOLECULAR PATHOGENESIS: Various mutations affect muscle acid maltase activity and lead to distinctly different clinical syndromes. Acid maltase is a lysosomal enzyme that is expressed in all cells and participates in glycogen degradation. When the enzyme is deficient, glycogen is not broken down, accumulates within lysosomes and remains membrane bound (Fig. 31-17B).

PATHOLOGY: In all forms of glycogenosis due to acid maltase deficiency, the morphologic changes are distinctive and almost pathognomonic (Fig. 31-17A).

In the severe form, Pompe disease, muscle shows massive accumulation of membrane-bound glycogen. Myofilaments and other sarcoplasmic organelles disappear. There is very little regeneration, and apparently inactive satellite cells are present at the surfaces of muscle fibers that have been almost completely destroyed by the disease.

Late infantile, juvenile and adult-onset forms of type II glycogenosis are milder, with changes ranging from overt vacuolar myopathy to very subtle accumulation of membrane-bound glycogen particles only detectable by electron microscopy. Vacuoles seen by light microscopy are empty or contain glycogen.

CLINICAL FEATURES: Pompe disease occurs in neonates or young infants and is the most extreme form of acid maltase deficiency. Patients have severe hypotonia and areflexia and clinically resemble patients with Werdnig-Hoffmann disease (see below). Some have enlarged tongues and cardiomegaly and die of cardiac failure, usually within their first 2 years. Many tissues are affected, but skeletal and cardiac muscle, the CNS and the liver are most involved. The serum creatine kinase level is slightly to moderately increased. Later-onset forms of the disease entail milder, but relentlessly progressive, myopathy. Glycogen accumulates in other organs, but clinical expression of the disorder is usually limited to muscle.

Type III Glycogenosis (Debranching Enzyme Deficiency, Cori Disease, Limit Dextrinosis, Amylo-1,6-Glucosidase Deficiency)

MOLECULAR PATHOGENESIS: Type III glycogenosis is a rare, autosomal recessive disease of children or adults. Because the debranching enzyme is absent, phosphorylase can hydrolyze 1,4-glycosidic linkages of the terminal glucose chains of glycogen, but not beyond branch points. Hepatomegaly and growth retardation are the rule. Muscle symptoms vary, and the most severe and consistent involvement is related to liver dysfunction in children.

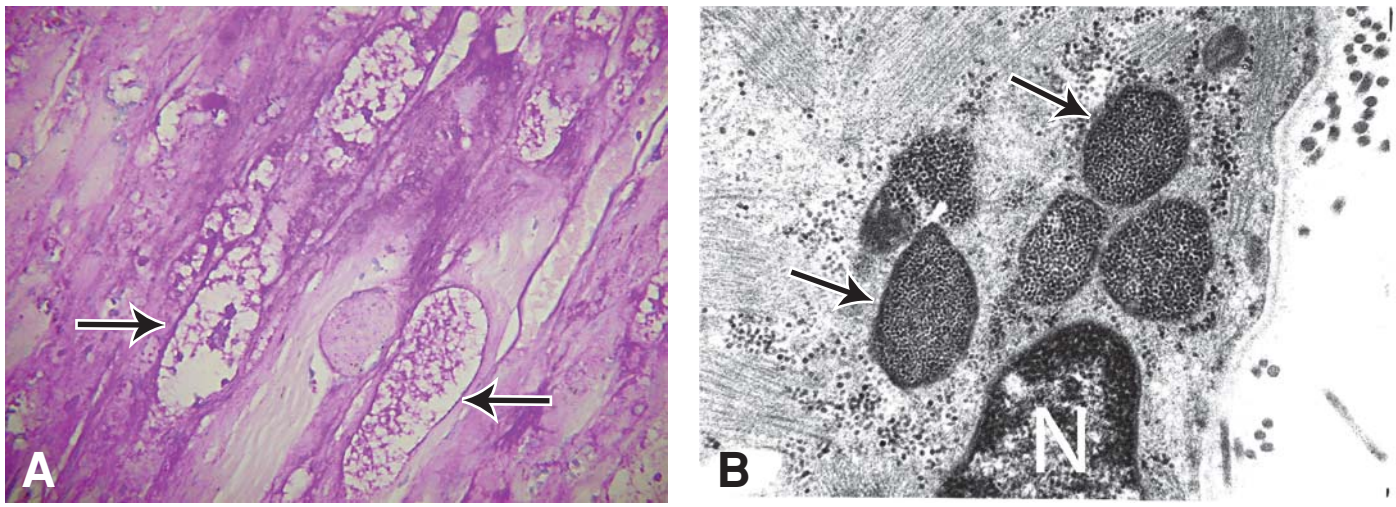

FIGURE 31-17. Acid maltase deficiency—adult onset. A. Periodic acid–Schiff (PAS) stain demonstrating large vacuoles filled with PAS-positive glycogen granules (*arrows*). **B.** Electron micrograph demonstrating membrane-bound glycogen granules (*arrows*). The structure marked *N* is a nucleus.

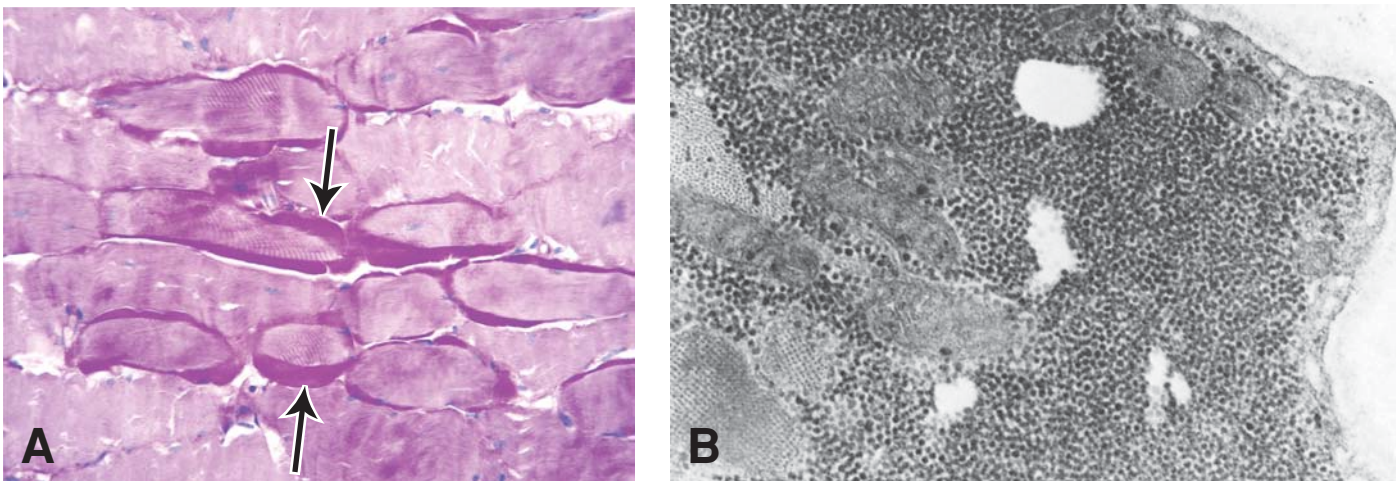

FIGURE 31-18. McArdle disease (myophosphorylase deficiency). A. Prominent periodic acid–Schiff (PAS)-positive glycogen accumulation in a subsarcolemmal distribution (*arrows*). **B.** An electron micrograph demonstrates an abnormal mass of glycogen particles just beneath the sarcolemma. The glycogen is not surrounded by a membrane, in contrast to the lysosomal glycogen storage of acid maltase deficiency.

Type V Glycogenosis (McArdle Disease, Myophosphorylase Deficiency)

MOLECULAR PATHOGENESIS: Type V glycogenosis is a more common metabolic myopathy that is usually not progressive or severely debilitating. The deficient enzyme, myophosphorylase, is specific for skeletal muscle. Without this enzyme, skeletal muscle glycogen cannot be cleaved at 1,4-glycosidic chains to produce glucose for energy production during physical exertion. Thus, muscles cramp with exercise. Patients also cannot produce lactate during ischemic exercise, which is the basis for a metabolic test for the condition.

PATHOLOGY: Tissue may appear completely normal, except for the absence of phosphorylase activity. However, there is usually subtle evidence of abnormal accumulation of glycogen granules within the sarcoplasm, mainly in the subsarcolemmal area (Fig. 31-18). The specific diagnosis can be made by a histochemical reaction for myophosphorylase but must be confirmed by biochemical assay of muscle enzyme activity or by DNA analysis. Electron microscopy will often demonstrate accumulation of non–membrane-bound glycogen.

CLINICAL FEATURES: Myophosphorylase deficiency need not seriously interfere with patients' lives. However, prolonged, vigorous exercise can lead to widespread myofiber necrosis and release of soluble muscle proteins like creatine kinase and myoglobin into the blood. This can cause myoglobinuria and renal failure.

Muscle biopsy should be performed several weeks after an episode of symptoms to allow regeneration of the muscle.

Type VII Glycogenosis (Phosphofructokinase Deficiency, Tarui Disease)

MOLECULAR PATHOGENESIS: Phosphofructokinase (PFK) deficiency is less common than McArdle disease but causes the same syndrome. PFK converts fructose-6-phosphate to fructose-1,6-diphosphate and is a key enzyme in the Embden-Meyerhof pathway. In muscle, this enzyme has four identical subunits (M_4), while in erythrocytes, it has two different (M and L) subunits, each encoded separately. Genetic lack of the muscle subunit thus leads to complete absence of muscle PFK activity but reduces erythrocyte PFK by 50%. In red blood cells, the remaining active enzyme is composed of four normal L subunits.

Patients with type VII glycogenosis often have slight anemia or low-grade hemolysis, but muscle histology resembles that in McArdle disease, save that phosphorylase activity is present. By contrast, histochemistry shows little or no PFK. The diagnosis is substantiated by biochemical assay of enzyme activity in muscle.

Lipid Myopathies Are Caused by Defective Fat Metabolism

A muscle biopsy from a patient with exercise intolerance or muscle weakness may sometimes show excess neutral lipids. This occurs in several metabolic disorders of lipid metabolism, more than a dozen of which are known. In brief, lipid myopathies may involve deficiencies in (1) fatty acid transport into mitochondria (carnitine deficiency syndromes, carnitine palmityl transferase deficiency), (2) several enzymes that mediate β-oxidation of fatty acids, (3) respiratory chain enzymes and (4) triglyceride use. Only disorders involving carnitine metabolism are discussed here.

Carnitine Deficiency

Carnitine is synthesized in the liver and is present in large quantities in skeletal muscle. It is needed for long-chain fatty acid transport into mitochondria. Muscle carnitine deficiency is an autosomal recessive condition, with progressive proximal muscle weakness and atrophy, often with signs of denervation and peripheral neuropathy. Without carnitine, lipid droplets accumulate massively in the sarcoplasm outside mitochondria and are readily seen in muscle biopsies (Fig. 31-19). Sometimes oral carnitine therapy alleviates

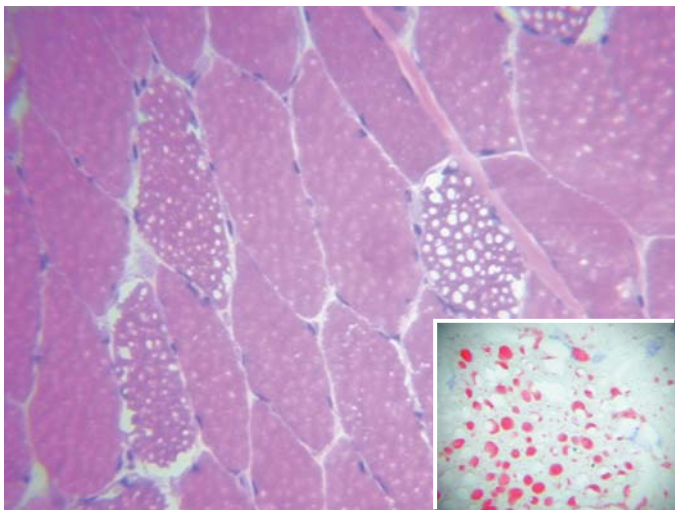

FIGURE 31-19. Lipid storage myopathy. Hematoxylin and eosin–stained frozen section. Numerous cytoplasmic vacuoles are present in the muscle fibers. Oil red-orcein stain (*inset*) demonstrates that the cytoplasmic vacuoles contain neutral lipid.

symptoms. Carnitine deficiency in skeletal muscle also occurs as part of a systemic disorder that can affect the CNS, heart and liver. Structural abnormalities of mitochondria may be present.

Carnitine Palmitoyltransferase Deficiency

Patients with carnitine palmitoyltransferase deficiency cannot metabolize long-chain fatty acids, owing to an inability to transport these lipids into mitochondria, where they undergo β-oxidation. After heavy exercise, these patients have muscular pain, which may progress to myoglobinuria. Prolonged fasting can produce the same symptoms. After such an episode, fibers regenerate and restore muscle structure. Biopsies are microscopically normal; the diagnosis requires biochemical assay for carnitine palmitoyltransferase activity.

In Mitochondrial Diseases Nuclear or Mitochondrial DNA May Be Mutated

Inherited defects of mitochondrial metabolism are uncommon but conceptually important disorders. Historically, diseases of muscle were recognized first and designated mitochondrial myopathies, but others affect both CNS and muscle and are known as **mitochondrial encephalomyopathies**. The nervous system, skeletal muscle, heart, kidney and other organs can be affected in different combinations as part of a multisystem disease.

Inherited diseases of mitochondria are divided into defects of **nuclear DNA** (nDNA) or **mitochondrial DNA** (mtDNA). Point mutations, deletions and duplications of mtDNA have been linked to several mitochondrial encephalomyopathies.

MOLECULAR PATHOGENESIS: The genes for most mitochondrial proteins are in nDNA, but mtDNA encodes 13 of the 80 polypeptides in respiratory chain complexes. Defects in these proteins lead to mitochondrial encephalomyopathies.

Unlike Mendelian inheritance of nDNA genes, mtDNA diseases are transmitted in maternal mtDNA, since mtDNA derives only from the oocyte. The zygote and its daughter cells have many mitochondria, each of which contains maternally derived mtDNA. Mutations in this DNA are passed on randomly to later generations of cells. During fetal or later growth, some cells may thus contain only mutant genomes (mutant homoplasmy), others will have only normal genomes (wild-type homoplasmy) and still others receive mixed populations of mutant and normal mtDNA (heteroplasmy). Clinical expression of a disease due to a mutation in mtDNA depends on the proportion of the total content of mitochondrial genomes that is mutant. ***The fraction of mutant mtDNA must exceed a critical value for a mitochondrial disease to be symptomatic.*** This threshold varies in different organs and is related to cellular energy requirements.

PATHOLOGY: In skeletal muscle, defects of mtDNA lead to accumulation of mitochondria, excessive numbers of which may appear as aggregates of reddish granular material in a subsarcolemmal location (underneath the myocyte plasma membrane) with modified Gomori trichrome stain (Fig. 31-20A). These are called **ragged red fibers** because these deposits have an irregular contour at the fiber periphery. Three subunits of complex IV (cytochrome oxidase) are encoded by mtDNA and are required for the assembled electron transport carrier to be functional. Pathogenic mutations of mtDNA may impair complex IV activity, so that ragged red fibers are often deficient in cytochrome oxidase activity (Fig. 31-20B). By contrast, they stain intensely for succinic dehydrogenase (SDH, complex II); this complex is exclusively encoded by nDNA (Fig. 31-20C). The increased SDH reflects mitochondrial proliferation. Such defects cause myofiber atrophy and accumulation of sarcoplasmic lipid and glycogen owing to impaired mitochondrial energy utilization. Ultrastructurally, mitochondria may display striking paracrystalline inclusions (Fig. 31-20D), ring-shaped mitochondria, spiral cristae and electron-dense deposits.

Increased ragged red fibers and cytochrome oxidase–negative fibers may also occur in elderly patients with unexplained muscle weakness ("mitochondrial cytopathy of old age"), presumably because numbers of mutant mitochondria increase with age. Ragged red fibers, cytochrome oxidase–negative fibers and intramitochondrial paracrystalline inclusions may suggest a mitochondrial disorder but are not specific, as similar changes occur in some muscular dystrophies, in inclusion body myositis and after certain drugs. Conversely, the absence of such changes does not exclude a mitochondrial disorder.

CLINICAL FEATURES: Clinical presentations of encephalomyopathies vary, but diseases may begin in children or adults. Some patients start with muscle weakness and then develop brain disorders. Others present with CNS disease, with or without overt muscle weakness, even though muscle biopsy shows mitochondrial pathology. Other organs, such as the heart (arrhythmias), are often affected as part of a multisystem disorder. The number of known mitochondrial disorders is increasing rapidly. The discussion below of major mitochondrial myopathies is a small sample.

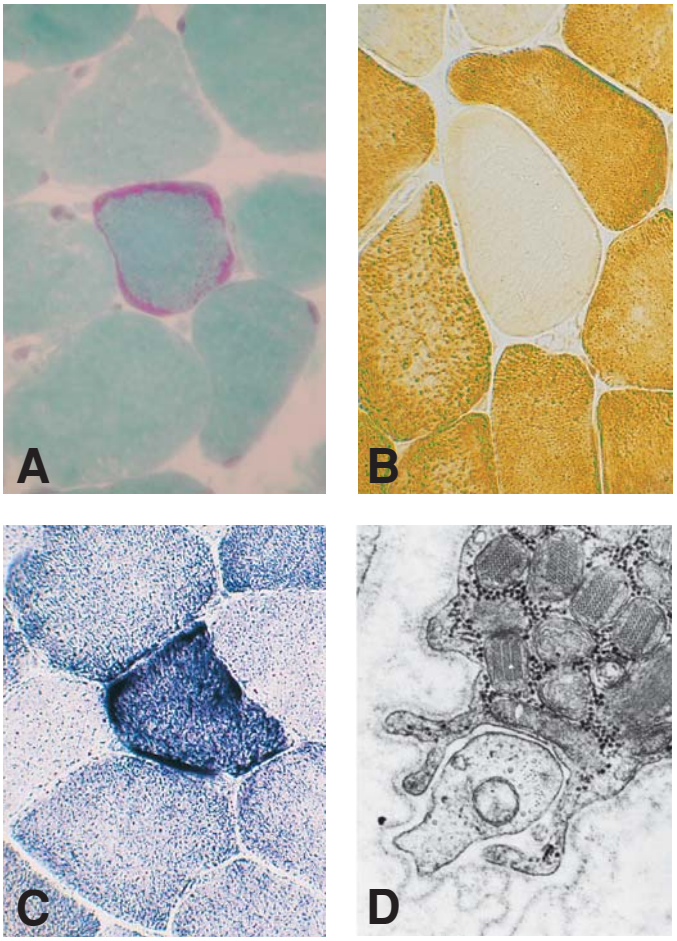

FIGURE 31-20. Mitochondrial myopathy caused by deletions of mitochondrial DNA (mtDNA). A. Modified Gomori trichrome. A ragged red fiber shows prominent proliferation of reddish, granular mitochondria, located chiefly in a subsarcolemmal region. **B.** A ragged red fiber displays lack of **histochemical staining for cytochrome oxidase** (central pale fiber). Three subunits of this electron-transport carrier are coded by mtDNA, and the mutations have interfered with function in this fiber. **C. Succinate dehydrogenase (SDH) stain.** A ragged red fiber shows overexpression of SDH, an enzyme that is entirely encoded by nuclear DNA (nDNA). **D.** An electron micrograph reveals mitochondria with ultrastructural abnormalities, including paracrystalline inclusions.

Three well-known neurologic syndromes include (1) **Kearns-Sayre syndrome** (progressive ophthalmoplegia, retinitis pigmentosum, cardiac arrhythmias, diabetes mellitus, cerebellar ataxia and multifocal neurodegeneration), (2) **MELAS** (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes) and (3) **MERRF** (myoclonic epilepsy and ragged red fibers). Most patients with Kearns-Sayre syndrome have large deletions of mtDNA that are usually nonfamilial. A related but clinically more benign condition, chronic progressive external ophthalmoplegia (CPEO), also has mitochondrial DNA deletions. Patients present with bilateral ptosis and weakness of eye muscles as in Kearns-Sayre syndrome. Such patients may progress to Kearns-Sayre syndrome. Clinically, the presence of cardiac arrhythmias in a CPEO patient predicts progression to Kearns-Sayre syndrome (KSS). The mitochondrial DNA deletions probably arise during oogenesis. All such affected people are heteroplasmic (i.e., they have a mixture of mutant and normal mitochondria) and the phenotype depends on the distribution and relative numbers of mutant mitochondria at birth. Despite the presence of these congenital mutations, symptoms typically appear in adulthood. More severe forms (KSS) present in the second decade.

Progressive external ophthalmoplegia (PEO) is an autosomal dominant disorder characterized by ophthalmoparesis and exercise intolerance with onset typically between ages 20 and 40. These patients have multiple mtDNA deletions that are secondary to mutations in a number of nuclear-encoded genes such as in DNA polymerase-γ (which replicates mitochondrial DNA), as well as mutations in mitochondrial DNA helicase or adenine nucleotide translocator-1. Thus, mutations in these nuclear-encoded genes subsequently produce mitochondrial DNA deletions. PEO and CPEO are similar pathologically. MELAS and MERRF usually involve point mutations in mitochondrial genes for tRNAs, mostly—but not exclusively—leucine tRNA (MELAS) and lysine tRNA (MERRF). Mitochondrial genetic disorders like MELAS and MERRF are inherited from maternal mtDNA. Other syndromes affecting mitochondrial proteins encoded by nuclear genes show autosomal (such as PEO) or X-linked patterns of inheritance.

Myoadenylate Deaminase Deficiency Causes Mild Weakness

MOLECULAR PATHOGENESIS: There are large amounts of adenosine monophosphate deaminase (AMP-DA) in skeletal muscle, particularly in type II fibers. AMP-DA is important in regulating purine nucleotide cycles and maintaining the adenosine triphosphate–to–adenosine diphosphate (ATP:ADP) ratio during exercise. A group of patients with mild proximal muscle weakness and exercise intolerance completely lack AMP-DA activity. It is a common, autosomal recessive condition, seen in 1%–2% of all muscle biopsies. AMP-DA deficiency may thus not actually be a separate disease, but one that is unmasked by other neuromuscular diseases.

Familial Periodic Paralysis Reflects Impaired Electrolyte Flux

Familial periodic paralysis encompasses several autosomal dominant disorders in which episodic muscular weakness or even complete paralysis is followed by rapid recovery. These reflect abnormalities in sodium and potassium fluxes into and out of muscle cells. During an attack, muscle fiber surfaces do not propagate action potentials, although calcium entry into the muscle fiber causes contraction. Muscle biopsies during an attack show no detectable abnormalities of recent onset. Later, permanent mild myopathic changes and sarcoplasmic vacuoles appear. These vacuoles are dilated or remodeled sarcoplasmic reticulum and transverse tubules. In some cases, a distinct subpopulation of fibers (type IIB) contains numerous tubular aggregates derived from the tubular network of the sarcoplasmic reticulum.

MOLECULAR PATHOGENESIS: These dyskalemic episodic weakness syndromes include hypokalemic and hyperkalemic periodic paralysis. The former type is linked to mutations in several genes

including a calcium channel (*CACNA1S*), a sodium channel (*SCN4A*) and a potassium channel (*KCNE3*). In the hyperkalemic form, the same sodium channel gene (*SCN4A*) is mutated, but the hyperkalemic form reflects a gain-of-function *SCN4A* mutation, while the hypokalemic form is due to a loss-of-function mutation in the same sodium channel gene. A previously described normokalemic periodic paralysis syndrome is now considered a variant of hyperkalemic periodic paralysis and demonstrates mutations in *SCN4A*.

RHABDOMYOLYSIS

Rhabdomyolysis is dissolution of skeletal muscle fibers and release of myoglobin into the blood. This may cause myoglobinuria and acute renal failure. The disorder may be acute, subacute or chronic. During acute rhabdomyolysis, muscles are swollen, tender and profoundly weak.

Episodes of rhabdomyolysis may be precipitated by diverse stimuli. They may complicate or follow bouts of influenza. Some patients develop rhabdomyolysis with apparently mild exercise and probably have some form of metabolic myopathy. A spectrum of muscle dysfunction, from pain (myalgia) to rhabdomyolysis, is also well known during treatment with statin cholesterol-lowering agents. Biopsies after recovery may show morphologically normal muscle. Rhabdomyolysis also may complicate heat stroke or malignant hyperthermia. Alcoholism is occasionally associated with either acute or chronic rhabdomyolysis.

Pathologically, rhabdomyolysis is an active, noninflammatory myopathy, with scattered muscle fiber necrosis and varying degrees of degeneration and regeneration. Macrophages, but no other inflammatory cells, are present in and around muscle fibers.

DENERVATION

The major differential diagnostic consideration in any patient with muscle weakness is whether the cause is myopathic or neurogenic. Myopathic conditions are those intrinsic to muscle and have been discussed above. Neurogenic causes of muscle weakness are due to denervation. The pathology of denervation reflects lesions of lower motor neurons and/or axons. Muscle biopsy detects lower motor neuron lesions, but patterns of denervation do not identify the cause of the lesion. The morphology may indicate whether denervation is recent or chronic but does not distinguish between, for example, amyotrophic lateral sclerosis, a disorder of motor neurons, and neuropathy due to diabetes mellitus. Lesions of upper motor neurons, as in multiple sclerosis or stroke, lead to paralysis and atrophy but leave lower motor neurons intact. Pathologic changes thus reflect nonspecific diffuse atrophy rather than denervation atrophy.

When a skeletal muscle fiber becomes separated from contact with its lower motor neuron, it invariably atrophies, owing to progressive loss of myofibrils. On cross-section, atrophic fibers are characteristically angular, as though compressed by surrounding normal muscle fibers (Fig. 31-21). If a fiber is not reinnervated, atrophy progresses to complete loss of myofibrils, with nuclei condensing into aggregates. In the end stage, muscle fibers disappear and are replaced chiefly by adipose tissue.

Early in denervation, fibers are irregularly scattered, angular and atrophic. As the disease progresses, these fibers are first seen in small clusters of several fibers, and then in progressively larger groups (Fig. 31-21B). They stain excessively darkly for nonspecific esterase (Fig. 31-22) and NADH-TR, in contrast to atrophy caused by disuse or wasting. Groups of denervated fibers include both type I and type II fibers: **denervating conditions are not selective for only one type of motor neuron**.

"Target fibers" (Fig. 31-23) are seen transiently in 20% of cases of denervation. This change occurs during or shortly after denervation or reinnervation and indicates that the process is active. The lesion consists of central pallor of the muscle fiber, which is surrounded by a condensed zone, in turn surrounded by a normal zone of sarcoplasm. Target fibers are difficult to see with hematoxylin and eosin stain, but the NADH-TR stain shows greatly reduced staining in the central zone, reflecting reduced or absent mitochondria.

Denervation is always followed by an effort at reinnervation. If denervation proceeds slowly, reinnervation may keep pace. New sprouting nerve endings make synaptic contact with the muscle fiber at the site of the previous motor endplate. As in the myotubular phase of embryogenesis, nicotinic Ach receptors (extrajunctional receptors) cover muscle fibers soon after denervation. This denervated state induces sprouting of new nerve endings from adjacent surviving nerves. With reinnervation, extrajunctional receptors again disappear from the sarcolemma, except at the point of synaptic contact.

In a chronic denervating condition, reinnervation of each surviving motor unit gradually enlarges. As a specific type of lower motor neuron takes over innervation of a given field of fibers, fiber groups of one type are seen adjacent to groups of another type. This pattern, called **fiber-type grouping,** is pathognomonic of denervation followed by reinnervation (Fig. 31-21C).

Patients with striking fiber–type grouping often have symptoms of muscle cramping in addition to progressive muscular weakness. After a single episode of denervation, such as in poliomyelitis, reinnervation often leads to remarkable recovery of strength. Years later, one sees conspicuous-type grouping, with scattered pyknotic nuclear clumps. In such cases, there are neither angular atrophic fibers nor target fibers.

If denervation continues after development of fiber-type grouping, large motor units become atrophic. Such **grouped atrophy** (Fig. 31-21D) is characteristic of chronic denervating disorders such as amyotrophic lateral sclerosis (ALS).

Occasionally, one fiber type (either type I or type II) predominates over the other, in **type predominance**. There is frequently evidence of denervation. In such cases, reinnervation may favor one type of lower motor neuron over another.

Muscle fibers may uncommonly be lost or regenerate in neuropathic conditions. Then, muscle degeneration causes a modest increase in serum creatine kinase levels. This occurs in slowly progressive forms of spinal muscular atrophy (e.g., Kugelberg-Welander disease, Kennedy disease [X-linked spinobulbar muscular atrophy]).

Spinal Muscular Atrophy Reflects Progressive Degeneration of Anterior Horn Cells

This disease is, strictly speaking, not a primary muscle disorder but is usually included in discussions of skeletal muscle pathology since it represents a major consideration in the differential diagnosis of childhood or infantile weakness. ***Spinal***

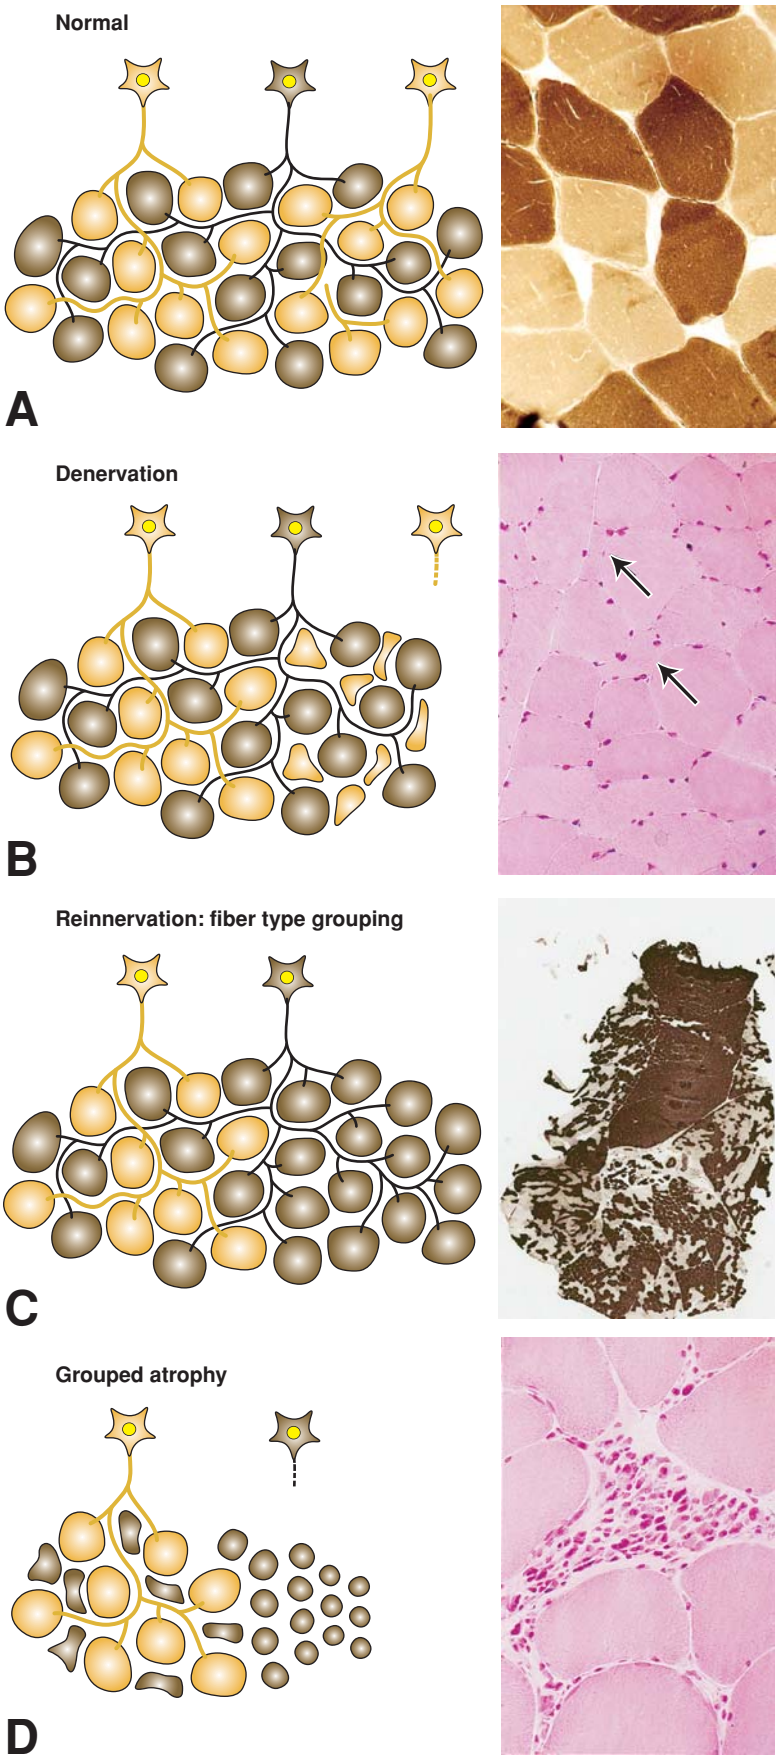

FIGURE 31-21. Denervation/reinnervation. A. As shown in the photomicrograph, the normal intermixed distribution of type I (*pale*) and type II (*dark*) muscle fibers is shown by staining for ATPase. In the drawing, two neurons (*pale*) innervate type I muscle fibers, and two neurons (*dark*) supply type II fibers. **B.** Denervation; hematoxylin and eosin stain. With early (mild) denervation, portions of the axonal tree degenerate, resulting in angular atrophy of scattered type I and II muscle fibers (*arrows*). **C.** Reinnervation; myofibrillar ATPase. As neurons degenerate, surviving neurons sprout more nerve endings and reinnervate some of the denervated fibers. These reinnervated fibers become either type I or type II, according to the type of neuron that reinnervates them. This process results in fewer, but larger, motor units and the appearance of clusters of fibers of one type adjacent to clusters of the other type, a pattern called "type grouping." The photomicrograph demonstrates type grouping. This field would appear normal except for a few atrophic fibers if it were stained with hematoxylin and eosin. **D.** With more advanced (severe, chronic) denervation, entire lower motor neurons or numerous axonal processes degenerate, causing small groups of angular atrophic fibers (grouped atrophy) to appear as illustrated in the photomicrograph.

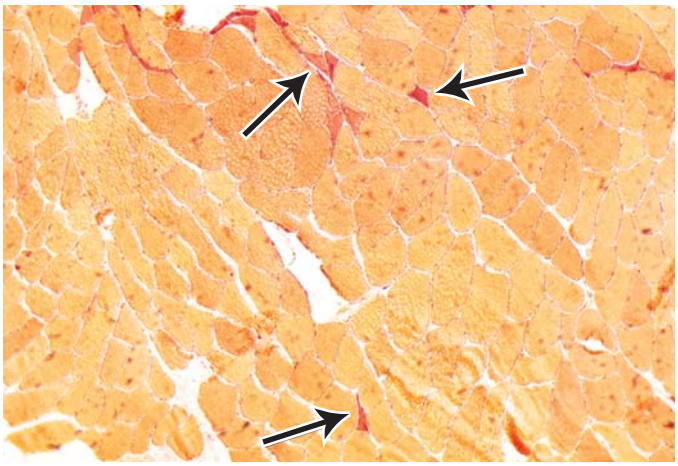

FIGURE 31-22. Denervation. In this frozen section of the biceps muscle subjected to the nonspecific esterase reaction, a few irregularly scattered, angular, atrophic fibers (*arrows*) are excessively dark stained. This pattern is highly characteristic of atrophy due to denervation.

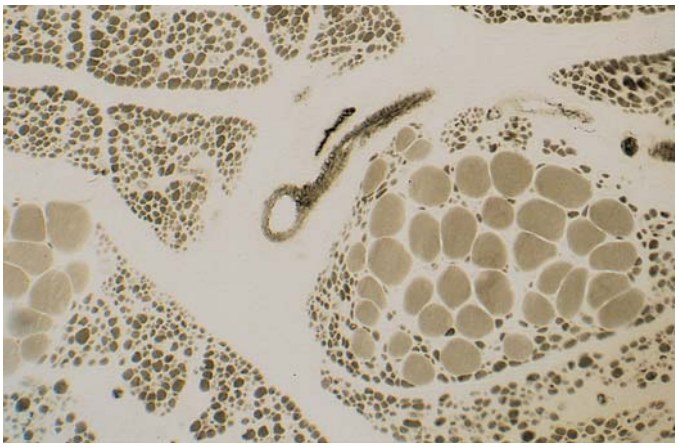

FIGURE 31-24. Werdnig-Hoffman disease (infantile spinal muscular atrophy). This cross-section of skeletal muscle stained for myofibrillar ATPase is derived from an infant with severe hypotonia. It shows groups of extremely atrophic, rounded type I and type II fibers and clusters of markedly hypertrophied pale type I fibers.

muscular atrophy (SMA) is the second most common lethal autosomal recessive disorder after cystic fibrosis. Childhood SMA is classified into type I **(Werdnig-Hoffmann disease),** type II (intermediate) and type III **(Kugelberg-Welander disease)**. The survival motor neuron gene (5q11.2-13.3) is mutated in these related syndromes, mostly as a result of deletion.

WERDNIG-HOFFMANN DISEASE (INFANTILE SPINAL MUSCULAR ATROPHY): In ***Werdnig-Hoffmann disease, infants show progressive and severe weakness*** and seldom survive beyond 1 year of life. Denervation seems to begin in utero after motor units are established. The histology is virtually pathognomonic (Fig. 31-24). Groups of minute, rounded, atrophic fibers are still identifiable with the ATPase reaction as being either type I or type II. There are also fascicles of normal muscle fibers and almost invariably clusters of hypertrophied type I fibers. In addition to the absent survival motor neuron gene, a second gene (neuronal apoptosis inhibitory protein gene) has also been implicated in the pathogenesis of Werdnig-Hoffmann disease.

KUGELBERG-WELANDER DISEASE (JUVENILE SPINAL MUSCULAR ATROPHY): ***This variant is a later-onset form of SMA and is not necessarily progressive.*** These patients had often been designated as having limb-girdle muscular dystrophy, but the electromyographic pattern of denervation helps to make the diagnosis. Muscle biopsies show type grouping and other evidence of a neurogenic disorder but can resemble a myopathy in a small sample because of coexisting necrotic fibers and regenerating fibers.

KENNEDY DISEASE (X-LINKED SPINOBULBAR MUSCULAR ATROPHY): An X-linked adult-onset form of spinobulbar muscular atrophy (Kennedy disease) is associated with trinucleotide repeat (CAG) expansion in the androgen receptor. As a result, anterior horn cells (motor neurons) degenerate, and the testes atrophy.

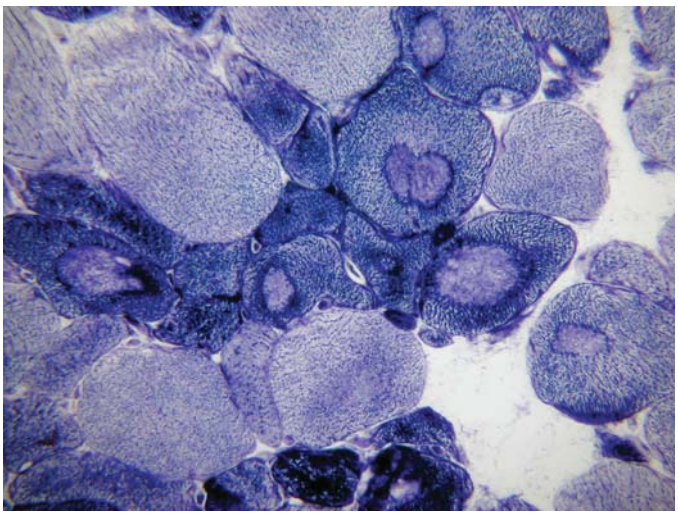

FIGURE 31-23. Target fiber. A cross-section of striated muscle treated with the NADH-tetrazolium reductase (NADH-TR) stain demonstrates several "target fibers," a characteristic feature of some cases of denervation. Because the enzyme reaction creates a product (formazan) that selectively fixes to membranous organelles, the centers of the target areas appear devoid of mitochondria and sarcoplasmic reticulum. The myofibrils may or may not be intact.

TYPE II FIBER ATROPHY

A commonly misinterpreted pathologic pattern in muscle biopsy specimens is atrophy from disuse, wasting, upper motor neuron disease and corticosteroid toxicity. This diffuse, nonspecific atrophy is a selective angular atrophy of type II fibers and may resemble denervation atrophy on hematoxylin and eosin stain. However, ATPase stains show that all angular atrophic fibers are type II (Fig. 31-25) and do not stain heavily by nonspecific esterase or NADH-TR reactions. Type II fiber atrophy is common and is often related to a more chronic problem.

STEROID MYOPATHY: Corticosteroid therapy can cause muscle weakness with type II atrophy. This may cause confusion clinically, as patients with polymyositis often receive large doses of corticosteroids. If such a patient's weakness worsens, the physician must decide if this development represents relapse of polymyositis, requiring more corticosteroids, or if it represents steroid myopathy, in which case steroid dosage should be reduced.

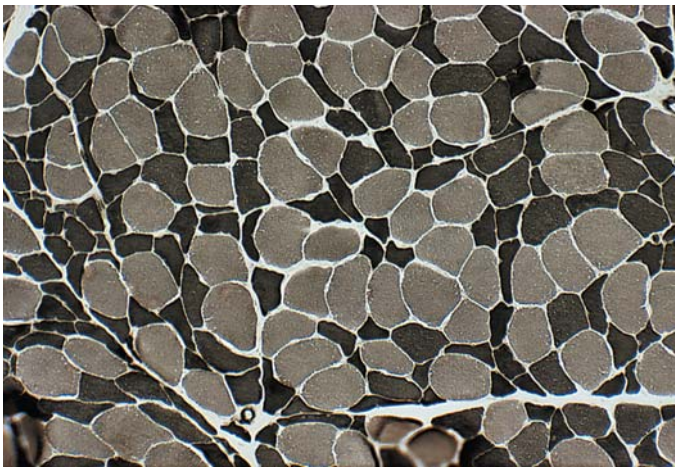

FIGURE 31-25. Type II fiber atrophy. This biopsy of the vastus lateralis muscle was taken from a 48-year-old man with proximal muscle weakness because of endogenous corticosteroid toxicity (Cushing syndrome). Virtually all of the angular atrophic fibers are type II. This form of atrophy closely mimics denervation atrophy when visualized with the hematoxylin and eosin stain.

Patients with corticosteroid toxicity do not have increased serum creatine kinase levels and biopsies show selective atrophy of type II fibers, without muscle fiber degeneration and inflammation. By contrast, in recurrent polymyositis, biopsy shows fiber degeneration and inflammation, with increased serum creatine kinase.

CRITICAL ILLNESS MYOPATHY

If patients on high-dose steroids and neuromuscular blocking agents experience severe weakness despite removal of paralyzing agents, they may have **critical illness myopathy,** also known as **myosin heavy-chain depletion syndrome**. These patients show loss of thick myosin filaments from muscle fibers (Fig. 31-26). The underlying mechanism of the myosin depletion is unclear, though myosin thick filaments reappear with discontinuation of corticosteroids, and muscle strength returns.

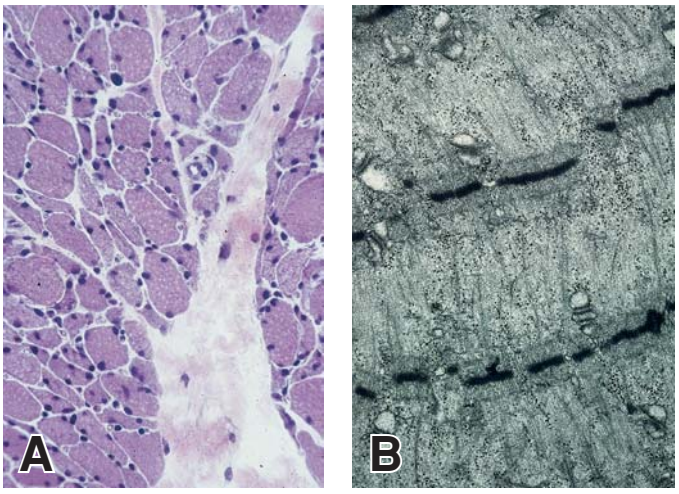

FIGURE 31-26. Critical illness myopathy. A. The condition frequently shows atrophic muscle with angular fibers (hematoxylin and eosin). **B.** By electron microscopy, there is marked loss of thick myosin filaments, while α-actin (thin) filaments are intact (compare to Fig. 31-2).

The Peripheral Nervous System

ANATOMY

The peripheral nervous system (PNS) is external to the brain and spinal cord and includes (1) cranial nerves III–XII, (2) dorsal and ventral spinal roots, (3) spinal nerves and their continuations and (4) ganglia. Peripheral nerves carry somatic motor, somatic sensory, visceral sensory and autonomic fibers.

Somatic motor and preganglionic autonomic axons arise from neuronal cell bodies within the CNS. Sensory and postganglionic autonomic axons originate from neuronal cell bodies within ganglia located on cranial nerves, dorsal roots and autonomic nerves. Neurons, satellite cells of the ganglia and all Schwann cells are derived from neural crest.

Endoneurial connective tissue surrounds individual nerve fibers, which are bundled into fascicles by a **perineurial sheath**. Epineurial connective tissue binds the fascicles together and contains nutrient arteries. A blood-nerve barrier (BNB), located in endoneurial capillaries and the perineurial sheath, and analogous to the blood-brain barrier, protects peripheral nerves, but not ganglia. There are no lymphatic vessels in nerve fascicles.

Peripheral nerve axons may be myelinated or unmyelinated (Fig. 31-27). Myelinated axons are 1–20 μm in diameter.

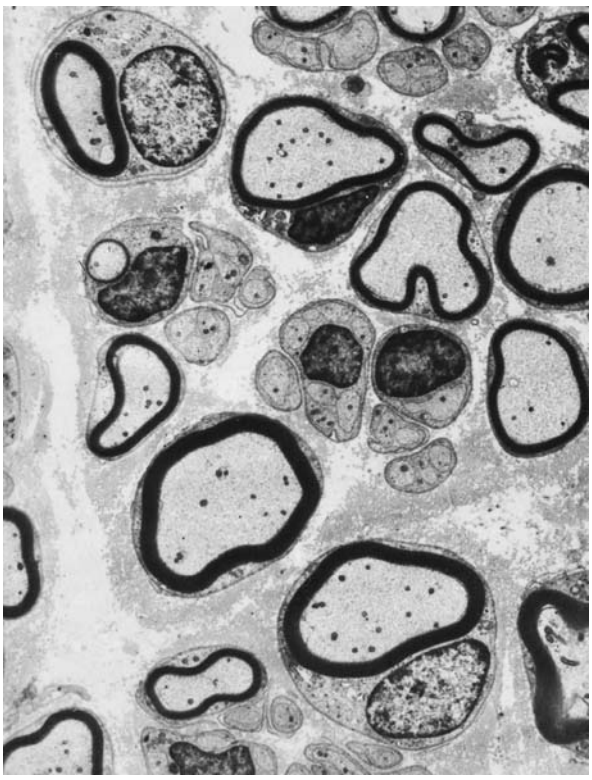

FIGURE 31-27. Structure of peripheral nerve. Electron micrograph of a peripheral nerve shows myelinated fibers interspersed with groups of unmyelinated fibers. Note that unlike myelinated axons, several unmyelinated axons may share a Schwann cell.

Unmyelinated ones, at 0.4–2.4 μm, are much smaller. Myelin is made from Schwann cell plasmalemma and is necessary for optimal nerve conduction. The lipids in Schwann cell–derived PNS myelin and oligodendrocyte-derived CNS myelin are similar, but their proteins differ substantially. Myelin protein zero (MPZ) and peripheral myelin protein 22 (PMP22) are only in the PNS. Schwann cells surround both myelinated and unmyelinated fibers. The axon determines whether the Schwann cell produces myelin. Myelin sheath thickness, internodal length (i.e., distance between two nodes of Ranvier) and conduction velocity are proportional to axonal diameter.

REACTIONS TO INJURY

Peripheral nerve fibers show only a limited number of reactions to injury (Fig. 31-28). The major types of nerve fiber damage are axonal degeneration and segmental demyelination. PNS fibers differ from those in the CNS by being able to regenerate and remyelinate to recover function.

Axonal Degeneration Reflects Injury to Axons or Neuronal Cell Bodies

Degeneration (necrosis) of the axon occurs in many neuropathies and may be limited to distal axons or involve both axons and neuronal cell bodies (Fig. 31-29A). Immediately after the axon degenerates, the myelin sheath breaks down and Schwann cells proliferate. The latter initiate myelin degradation, which is completed by macrophages that infiltrate the nerve within 3 days after axonal degeneration. If injury is restricted to the distal axon, regenerating axons may sprout within 1 week from the intact, proximal axonal stump. There are several types of axonal degeneration.

DISTAL AXONAL DEGENERATION: In many neuropathies, axon degeneration is initially limited to the distal ends of larger, longer fibers (**dying-back neuropathy** or **distal axonopathy**) (Fig. 31-28B). Peripheral neuropathies characterized by distal axonal degeneration typically present clinically as distal ("length-dependent" or "glove-and-stocking") neuropathies.

In this setting, neuron cell bodies and proximal axons stay intact. Axons may thus regenerate and nerve function may return if the cause of the distal axonal degeneration is removed. This must occur before the dying-back degeneration reaches the proximal axon and causes the neuronal cell body to die. In some dying-back neuropathies, the axonal degeneration involves both the axon directed peripherally from the dorsal root ganglion neuron and the axon directed centrally to the spinal cord dorsal columns. These centrally

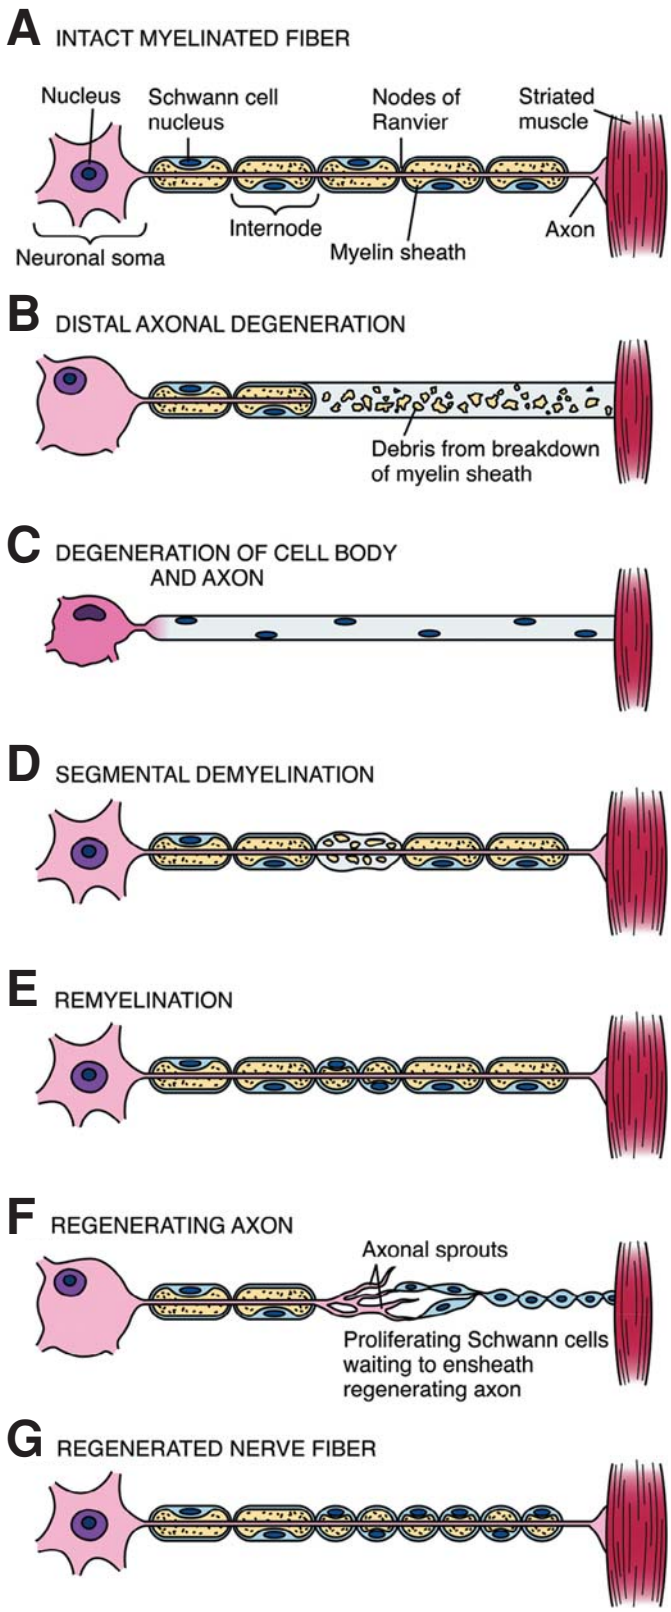

FIGURE 31-28. Basic responses of peripheral nerve fibers to injury. A. Intact myelinated fiber. The axon is insulated by the Schwann cell–derived myelin sheaths. **B. Distal axonal degeneration.** The distal axon has degenerated, and myelin sheaths associated with the distal axon have secondarily degenerated. The striated muscle shows denervation atrophy. **C. Degeneration of cell body and axon.** Degeneration involves the neuronal cell body and its entire axon. The myelin sheaths associated with the axon have also degenerated. **D. Segmental demyelination.** The myelin sheath associated with one Schwann cell has degenerated, leaving a segment of axon uncovered by myelin. The underlying axon remains intact. **E. Remyelination.** Proliferating Schwann cells cover the demyelinated segment of the axon and elaborate new myelin sheaths. The remyelinating Schwann cells have short internodal lengths. **F. Regenerating axon.** Regenerating axons sprout from the distal end of the disrupted axon. Ideally, the regenerating axons reinnervate the distal nerve stump, where they will be ensheathed and myelinated by Schwann cells of the distal stump. **G. Regenerated nerve fiber.** The regenerated portion of the axon is myelinated by Schwann cells with short internodal lengths. The striated muscle is reinnervated.

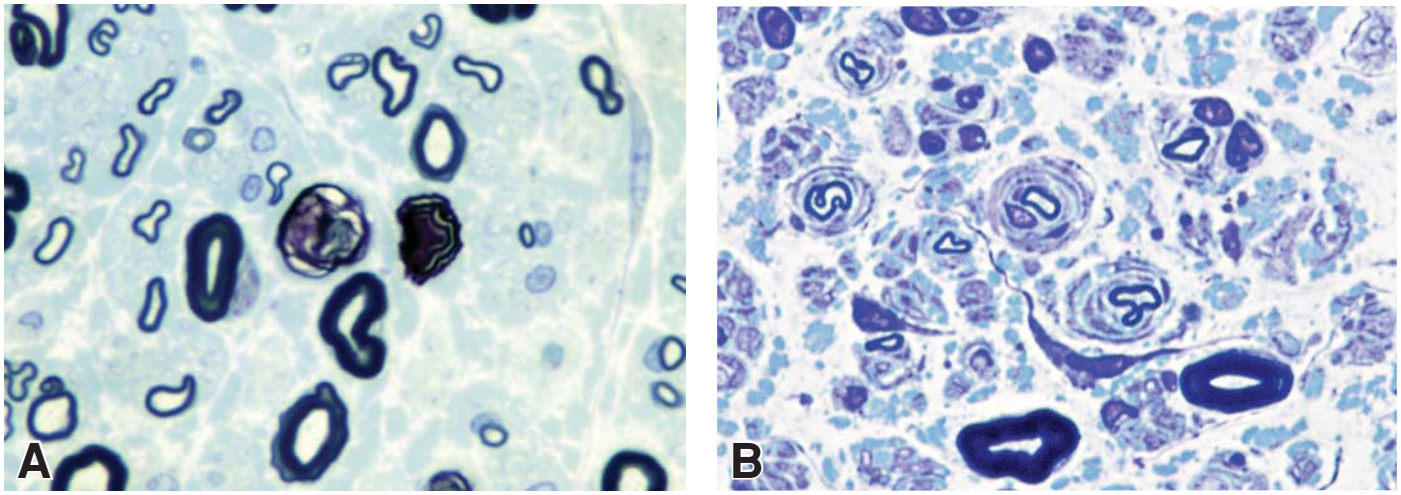

FIGURE 31-29. A. Axonal degeneration in an axonal neuropathy. Photomicrograph of a plastic-embedded cross-section of sural nerve shows two degenerating myelinated fibers in the center of the field. The degenerating fibers' axons are gone, and their myelin sheaths are reduced to rounded masses of myelin debris. In most axonal neuropathies, this axonal degeneration is limited to the distal axon. **B. Onion bulbs in chronic inflammatory demyelinating polyneuropathy.** Photomicrograph of a plastic-embedded cross-section of sural nerve shows several remyelinating axons with thin myelin sheaths in the center of the field. The remyelinating axons are surrounded by multiple concentric layers of Schwann cell cytoplasm, which resemble the concentric rings of a sectioned onion. Onion bulb formation is common in neuropathies with recurrent episodes of demyelination and remyelination.

directed axons, like other axons in the CNS, have little capacity for regeneration.

NEURONOPATHY: Axonal degeneration may result from death of a neuronal cell body, as in an autoimmune dorsal root ganglionitis (Fig. 31-28C). Peripheral neuropathies with selective damage to neuronal cell bodies are **neuronopathies** and are much rarer than distal axonopathies. Death of the neuronal cell body precludes axonal regeneration, making recovery impossible.

WALLERIAN DEGENERATION: This term describes axonal degeneration in a nerve distal to a transection or crush of the nerve. If the injury is not too proximal, the nerve may regenerate.

In Segmental Demyelination the Myelin Sheath Breaks Down but the Underlying Axon Remains Viable

Loss of myelin from one or more internodes (segments) along a myelinated fiber indicates Schwann cell dysfunction (Fig. 31-28D). This may be due either to direct injury to the Schwann cell or myelin sheath **(primary demyelination)** or to underlying axonal abnormalities **(secondary demyelination)**.

Loss of the myelin sheath does not cause the underlying axon to degenerate. Macrophages infiltrate the nerve and clear the myelin debris. Degeneration of the internodal myelin sheath is followed sequentially by Schwann cell proliferation, then remyelination of the demyelinated segments and finally functional recovery. Remyelinated internodes have shortened internodal lengths (Fig. 31-28E). Repeated episodes of segmental peripheral nerve demyelination and remyelination, as occurs in chronic demyelinating neuropathies, cause supernumerary Schwann cells that encircle the axons **(onion bulbs)** to accumulate (Fig. 31-29B) and cause clinically evident nerve enlargement **(hypertrophic neuropathy)**.

PERIPHERAL NEUROPATHIES

A peripheral neuropathy is a process that affects the function of one or more peripheral nerves. It may be restricted to the PNS, involve both the PNS and CNS or affect multiple organ systems. Peripheral neuropathies occur in all age groups and may be hereditary or acquired.

There are many causes of peripheral neuropathy (Table 31-3), but ***diabetes mellitus is the most common cause of generalized peripheral neuropathy in the United States.*** Other common causes include hereditary disorders, alcoholism, chronic renal failure, neurotoxic drugs, autoimmune diseases, paraproteinemia, nutritional deficiencies, infections, cancer and trauma.

PATHOLOGY: Pathologic findings in most neuropathies are limited to axonal degeneration, segmental demyelination or both. If axonal degeneration predominates, the neuropathy is an **axonal neuropathy;** if segmental demyelination predominates, it is called a **demyelinating neuropathy.** ***Most (80%–90%) neuropathies are axonal and of the dying-back type (distal axonal neuropathy).*** Electrophysiologic studies often help to distinguish axonal and demyelinating neuropathies. Nerve conduction velocity is typically near normal in axonal neuropathies but is impaired in demyelinating neuropathies. The distinction between axonal and demyelinating neuropathies is useful clinically. Axonal neuropathies have many causes, but demyelinating neuropathies have a limited number of etiologies. The latter are most likely to be hereditary or immunologically mediated.

The histopathology of many neuropathies does not indicate the underlying cause, so that clinicopathologic correlation is usually needed to establish causation. Less often, a specific etiology may be seen, for example, necrotizing arteritis (vasculitic neuropathy), granulomatous inflammation (leprosy, sarcoid), amyloid deposits

TABLE 31-3
ETIOLOGIC CLASSIFICATION OF NEUROPATHIES

Immune-mediated neuropathies
Acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barré syndrome)
Acute motor (and sensory) axonal neuropathy (axonal form of Guillain-Barré syndrome)
Fisher syndrome
Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)
Multifocal motor neuropathy
Dorsal root ganglionitis (sensory neuronopathy)
Immunoglobulin M (IgM) paraproteinemia-associated demyelinating neuropathy
Vasculitic neuropathy (systemic vasculitis, connective tissue disease, cryoglobulinemia)
Metabolic neuropathies
Diabetic polyneuropathy and mononeuropathies
Uremic neuropathy
Critical illness polyneuropathy
Hypothyroid neuropathy
Acromegalic neuropathy
Nutritional neuropathies
Neuropathy associated with deficiency of vitamin B_1, B_6, B_{12} or E
Copper deficiency myeloneuropathy
Alcoholic neuropathy
Toxic and drug-induced neuropathies (see Table 31-4)
Amyloid neuropathy (AL amyloidosis and familial amyloid polyneuropathy)
Hereditary neuropathies (see Tables 31-5 and 31-6)
Neuropathies associated with infections
Leprosy
HIV
Cytomegalovirus
Hepatitis B and C (vasculitic neuropathy or CIDP)
Herpes zoster
Lyme disease
Diphtheria (toxic neuropathy)
Paraneoplastic neuropathy
Sarcoid neuropathy
Radiation neuropathy
Traumatic neuropathy
Chronic idiopathic axonal polyneuropathy

(amyloid neuropathy), abnormalities of the myelin sheath (IgM paraproteinemic neuropathy, hereditary neuropathy with liability to pressure palsies) or abnormal accumulations within Schwann cells (leukodystrophy) or axons (giant axonal neuropathy).

CLINICAL FEATURES: The major clinical manifestations of peripheral neuropathy are muscle weakness and atrophy, sensory loss, paresthesia, pain and autonomic dysfunction. Motor, sensory and autonomic functions may be equally or preferentially affected. Predominant involvement of large-diameter sensory fibers affects position and vibration sense, while injury to small-diameter fibers hinders pain and temperature sensation. A neuropathy may be acute (days to weeks), subacute (weeks to months) or chronic (months to years). It may affect one nerve **(mononeuropathy)** or several **(mononeuropathy multiplex),** dorsal root ganglia **(sensory neuronopathy)** or nerve roots **(radiculopathy),** and may involve multiple peripheral nerves **(polyneuropathy),** or nerve roots and peripheral nerves **(polyradiculoneuropathy)**.

Peripheral Neuropathy Can Complicate Types 1 and 2 Diabetes Mellitus

Diabetic neuropathy may manifest as a distal sensorimotor polyneuropathy, autonomic neuropathy, mononeuropathy or mononeuropathy multiplex. The mononeuropathies may involve cranial nerves (cranial neuropathy), nerve roots or proximal peripheral nerves. ***Distal, predominantly sensory, polyneuropathy is the most common form of diabetic neuropathy.***

ETIOLOGIC FACTORS: How nerve fiber injury occurs in diabetes is unknown (see Chapter 13). It has long been held that the distal symmetric polyneuropathy is due to the metabolic abnormalities of diabetes, while the mononeuropathies are caused by nerve ischemia from small-vessel disease. However, local nerve ischemia also probably contributes to the symmetric polyneuropathy.

PATHOLOGY: The distal symmetric polyneuropathy of diabetes is characterized by a mixture of axonal degeneration and segmental demyelination, with the former predominating. Axonal loss involves fibers of all sizes but may preferentially affect large myelinated fibers **(large-fiber neuropathy)** or small myelinated fibers and unmyelinated fibers **(small-fiber neuropathy)**. Occasional neuronal loss in dorsal root ganglia and anterior horns most likely reflects centripetal progression of dying-back axonal degeneration, rather than a neuronopathy.

Uremic Neuropathy Often Complicates Chronic Renal Failure

Uremic neuropathy is a distal sensorimotor axonal polyneuropathy seen in half of patients with chronic renal failure, and causing both distal axonal degeneration and segmental demyelination. The former predominates and mainly affects large-diameter fibers. The mechanism is not known, but uremic neuropathy often stabilizes or improves with long-term dialysis and resolves after renal transplantation.

Critical Illness Polyneuropathy Develops in Many Severely Ill Patients

It is associated with sepsis and multiorgan failure. The acute, predominantly motor, neuropathy may first be apparent when a patient in the intensive care unit cannot be weaned from ventilatory support. A **critical illness myopathy** may also occur in these patients. The pathogenesis is obscure.

Neuropathy Is a Frequent Complication of Alcoholism

Alcoholic neuropathy is a distal sensorimotor axonal polyneuropathy, attributable to nutritional deficiencies and/or a direct toxic effect of ethanol on the PNS. Peripheral nerves show loss of nerve fibers from axonal degeneration of the dying-back type.

Nutritional Neuropathy Is an Axonal Polyneuropathy with Multiple Causes

Nutritional neuropathy is associated with deficiencies in vitamins (B_1, B_6, B_{12} or E) or copper. Copper deficiency may be a result of malnutrition, total parenteral nutrition, excessive ingestion of zinc or bariatric surgery. Isoniazid therapy for tuberculosis interferes with pyridoxine (vitamin B_6) metabolism and may cause vitamin B_6 deficiency neuropathy. It is unclear if the chronic axonal neuropathy sometimes seen in celiac disease is due to malnutrition or reflects the underlying autoimmune process.

Acute Inflammatory Demyelinating Polyradiculoneuropathy Is Immune Mediated

Acute inflammatory demyelinating polyradiculoneuropathy (AIDP) is an acquired, immune-mediated neuropathy that often follows bacterial, viral or mycoplasmal infections. It may also follow immunization or surgery. Usually, there is an antecedent upper respiratory or gastrointestinal infection. Commonly associated infectious agents include *Campylobacter jejuni*, cytomegalovirus, Epstein-Barr virus and *Mycoplasma pneumoniae*. AIDP is the most common cause in children and adults of the **Guillain-Barré syndrome,** which is an acute symmetric neuromuscular paralysis that often begins distally and ascends proximally. Sensory and autonomic disturbances may also occur, and 5% of cases present with ophthalmoplegia, ataxia and areflexia **(Fisher syndrome)**. Muscular paralysis may cause respiratory embarrassment, and autonomic involvement may lead to cardiac arrhythmias, hypotension or hypertension. The neuropathy begins to resolve 2–4 weeks after onset, and most patients recover. Characteristically, the cerebrospinal fluid (CSF) has increased protein but few white blood cells (albuminocytologic dissociation). The increased protein level is attributable to inflammation of spinal roots. The pathogenesis of the immunologically mediated demyelination is unknown.

AIDP may affect all levels of the PNS, including spinal roots (polyradiculoneuropathy), ganglia, craniospinal nerves and autonomic nerves. The distribution of lesions varies. Involved regions show endoneurial infiltrates of lymphocytes and macrophages, segmental demyelination and relative axonal sparing. Lymphoid infiltrates are often perivascular, but there is no true vasculitis. Macrophages are frequently adjacent to degenerating myelin sheaths and can strip off and phagocytose superficial myelin lamellae. Such macrophage-mediated demyelination is rare in other neuropathies.

Guillain-Barré syndrome may also be caused by an immune-mediated axonal neuropathy **(acute motor axonal neuropathy** or **acute motor and sensory axonal neuropathy)**. The axonal form of this disorder is much less common than the demyelinating type in North America and Europe but is more common in Asia. The axonal form often follows *C. jejuni* infection and shows serum antiganglioside antibodies (anti-GM_1 and others). Molecular mimicry between an antigenic component of the infectious agent and a component of the peripheral nerve may elicit a cross-reactive immune response that leads to axonal injury. Antiganglioside antibodies (anti-GQ1b and others) are also common in Fisher syndrome.

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is similar to AIDP but has a protracted course, with multiple relapses or slow continuous progression, and usually lacks evidence of antecedent infection. The neuropathy may occur sporadically (idiopathic CIDP) or be associated with paraproteinemia, HIV infection, chronic active hepatitis, connective tissue disease, inflammatory bowel disease or Hodgkin lymphoma. The demyelinating neuropathy is symmetric, sensorimotor and proximal and distal. Rarely, it may present as a multiple mononeuropathy **(multifocal acquired demyelinating sensory and motor neuropathy)**. Nerves and nerve roots in CIDP may show many onion bulbs owing to recurring episodes of demyelination, Schwann cell proliferation and remyelination (Fig. 31-29B). The pathogenesis of this immune-mediated neuropathy is obscure.

Multifocal motor neuropathy is a rare, slowly progressive, demyelinating mononeuropathy multiplex that may be mistaken clinically for motor neuron disease. There is often an associated increased titer of anti-GM_1 antibodies. This demyelinating neuropathy is immune mediated but is considered distinct from CIDP.

Dorsal Root Ganglionitis Is an Immune-Mediated Sensory Neuronopathy

This inflammatory ganglionopathy typically manifests as a subacute or chronic sensory polyneuropathy with sensory ataxia. The pathogenesis of this immune-mediated sensory neuronopathy is unknown. The disorder may occur sporadically **(idiopathic sensory neuronopathy),** in association with Sjögren syndrome or as a paraneoplastic sensory neuronopathy. The latter is often associated with anti-Hu antibodies (antineuronal autoantibodies) and may accompany a paraneoplastic encephalomyelitis. Dorsal root ganglia show infiltration by lymphocytes and loss of sensory neurons.

Vasculitis Causes Mononeuropathy Multiplex

Necrotizing arteritis may involve the epineurial arteries of nerves as a manifestation of systemic vasculitis (polyarteritis nodosa, Churg-Strauss syndrome, Wegener granulomatosis, microscopic polyangiitis), connective tissue disease (rheumatoid arthritis, systemic lupus erythematosus, Sjögren syndrome) or cryoglobulinemia, HIV infection or cancer. In

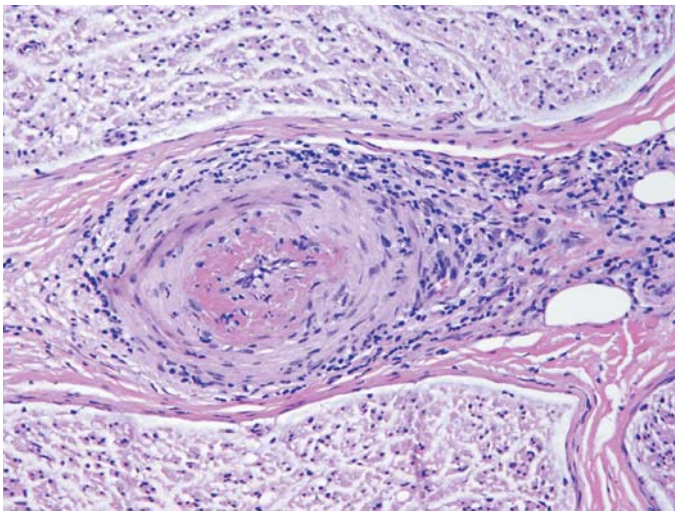

FIGURE 31-30. Vasculitic neuropathy in a patient with polyarteritis nodosa and mononeuropathy multiplex. Photomicrograph of a cross-section of a sural nerve reveals an inflamed epineurial artery with fibrinoid necrosis of its wall. The resultant nerve ischemia causes axonal degeneration.

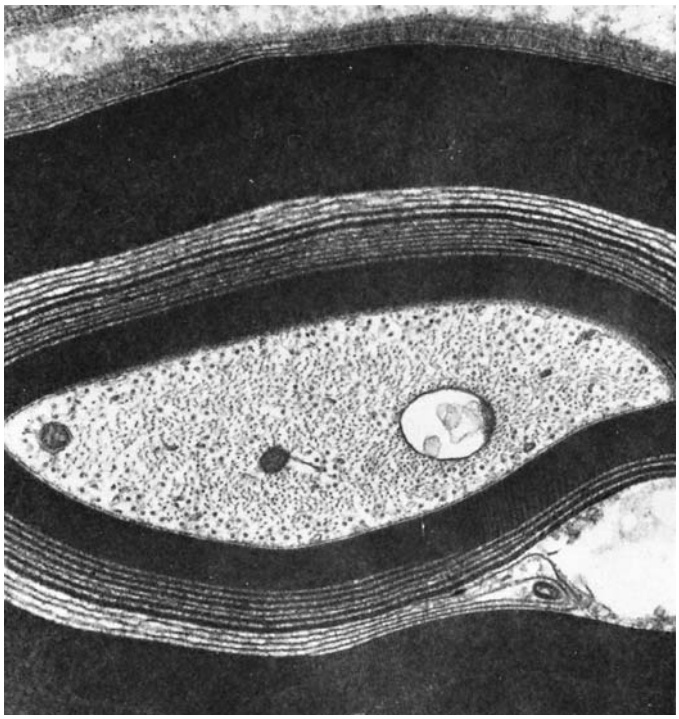

FIGURE 31-31. Anti–myelin-associated glycoprotein (MAG) IgM paraproteinemic demyelinating neuropathy. An electron micrograph shows a myelinated fiber with multiple, abnormally widely spaced, myelin lamellae from a patient with an IgM monoclonal gammopathy of unknown significance and a chronic demyelinating neuropathy. Widely spaced myelin is a characteristic ultrastructural feature of anti-MAG paraproteinemic neuropathy.

one third of cases of vasculitic neuropathy, the necrotizing arteritis appears limited to the PNS **(nonsystemic vasculitic neuropathy)**. The ischemic neuropathy is characterized pathologically by axonal degeneration (Fig. 31-30).

Monoclonal Gammopathies May Cause Neuropathy

Monoclonal gammopathies, whether of undetermined significance (MGUS; see Chapter 26) or due to plasma cell myeloma, may cause amyloid neuropathy, cryoglobulinemia-associated vasculitic neuropathy or chronic demyelinating polyneuropathy. Chronic demyelinating polyneuropathy often occurs with an IgM MGUS or Waldenström macroglobulinemia, in which the IgM paraprotein binds myelin-associated glycoprotein (MAG). Anti-MAG antibodies may thus precipitate demyelination. Anti-MAG neuropathy is characterized by extensive segmental demyelination, a variable number of onion bulbs, axonal loss and a distinctive widening of myelin lamellae (Fig. 31-31).

Paraproteinemic neuropathy may rarely present as POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and skin changes). Such patients show elevated serum levels of vascular endothelial growth factor (VEGF) and a plasma cell disorder.

Neuropathy Complicates Light-Chain and Familial Amyloidoses

In addition to its effects on sensory and motor nerves, amyloid infiltration of the PNS often leads to prominent autonomic dysfunction. The disorder may be hereditary but more often complicates light-chain amyloidosis (AL) in primary systemic amyloidosis or multiple myeloma. Familial amyloidosis is usually caused by a point mutation in the transthyretin gene (see Chapter 15), although mutations of the apolipoprotein A1 or gelsolin genes are inculpated in some cases.

Amyloid deposits in endoneurial and epineurial extracellular spaces and vascular walls in peripheral nerves, dorsal root ganglia and autonomic ganglia. Loss of myelinated and unmyelinated fibers ensues. Nerve-fiber damage may reflect direct mechanical injury of nerve fibers and ganglion cells by amyloid deposits, nerve ischemia caused by amyloid infiltration of vasa nervorum or both.

Systemic amyloidosis may also cause **carpal tunnel syndrome,** a chronic entrapment neuropathy of the median nerve at the wrist. Nerve entrapment results from amyloid infiltration of the flexor retinaculum. Carpal tunnel syndrome also occurs in many other settings, including occupational injuries, hypothyroidism, acromegaly, chronic renal failure (dialysis-related β_2-microglobulin amyloidosis), pregnancy and rheumatoid arthritis.

Paraneoplastic Neuropathies Often Precede Discovery of a Cancer

Paraneoplastic nervous system diseases include polyneuropathy, chronic encephalomyelitis, necrotizing myelopathy, cerebellar degeneration and the Eaton-Lambert syndrome. Several different clinicopathologic types of paraneoplastic neuropathy have been defined.

- **Paraneoplastic sensorimotor polyneuropathy:** This distal polyneuropathy is the most common paraneoplastic neuropathy. It is characterized by axonal degeneration and demyelination, mainly the former. The cause of the nerve-fiber degeneration is unknown.
- **Paraneoplastic sensory neuronopathy:** Less commonly, a paraneoplastic subacute sensory neuronopathy may be

caused by dorsal root ganglionitis. Similar chronic inflammatory changes may also occur in the CNS **(paraneoplastic encephalomyelitis)**. Small cell carcinoma of the lung is the usual culprit. The sensory neuronopathy and encephalitis are thought to be immune mediated, largely by anti-Hu antibodies.

- **Inflammatory demyelinating polyradiculoneuropathy:** Immune-mediated acute or chronic inflammatory demyelinating polyradiculoneuropathy may be associated with cancer.
- **Paraneoplastic vasculitic neuropathy:** Vasculitic neuropathy may rarely complicate cancer.

Not all paraneoplastic neuropathies reflect remote effects of a distant neoplasm. Tumors may cause neuropathy by direct compression or infiltration of nerves or nerve roots. Cancer therapies may induce toxic or radiation-induced neuropathies.

Toxic Neuropathy Is Often Iatrogenic

A variety of environmental agents and industrial compounds cause peripheral neuropathy (Table 31-4), but most cases of toxic neuropathy result from drugs. Almost all toxic neuropathies are characterized by axonal degeneration, usually of the dying-back type. Notable exceptions are platinum compounds and pyridoxine, which produce a sensory neuronopathy, and buckthorn toxin and diphtheria toxin, which produce a demyelinating neuropathy. People with hereditary neuropathy (see below) may be especially vulnerable to drug-induced peripheral neuropathy.

TABLE 31-4
AGENTS ASSOCIATED WITH TOXIC NEUROPATHY

Drugs	Environmental and Industrial Agents
Amiodarone	Acrylamide
Bortezomib	Allyl chloride
Colchicine	Arsenic
Dapsone	Buckthorn toxin
Disulfiram	Carbon disulfide
Gold salts	Chlordecone
Isoniazid	Dimethylaminopropionitrile
Metronidazole	Diphtheria toxin
Misonidazole	Ethylene oxide
Nitrofurantoin	n-Hexane (glue sniffing)
Nucleoside analogs (antiretrovirals)	Methyl n-butyl ketone
Paclitaxel (taxanes)	Lead
Phenytoin	Mercury
Platinum compounds	Methyl bromide
Podophyllin	Organophosphates
Pyridoxine (vitamin B_6)	Polychlorinated biphenyls
Suramin	Thallium
Thalidomide	Trichloroethylene
Vincristine	Vacor

TABLE 31-5
INHERITED DISEASES ASSOCIATED WITH NEUROPATHY

Ataxia-telangiectasia
Abetalipoproteinemia
Acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria
Cerebrotendinous xanthomatosis
Fabry disease (α-galactosidase A deficiency)
Familial amyloid polyneuropathy (transthyretin, apolipoprotein A1, and gelsolin amyloidosis)
Friedreich ataxia
Giant axonal neuropathy
Hereditary motor and sensory neuropathies (Charcot-Marie-Tooth disease)
Hereditary motor neuropathies
Hereditary neuropathy with liability to pressure palsies
Hereditary sensory and autonomic neuropathies
Infantile neuroaxonal dystrophy
Leukodystrophies (metachromatic, globoid cell, and adrenoleukodystrophy)
Refsum disease (phytanic acid storage disease)
Tangier disease

The Most Common Chronic Neuropathies in Children Are Hereditary

Many inherited diseases may manifest as peripheral neuropathies (Tables 31-5 and 31-6), with the neuropathy being the sole manifestation of a hereditary disease or a part of a multisystem disease.

Charcot-Marie-Tooth Disease

MOLECULAR PATHOGENESIS: Charcot-Marie-Tooth disease (CMT) is a genetically and pathologically heterogeneous group of slowly progressive distal sensorimotor polyneuropathies that manifest in childhood or early adult life. It is the most common inherited neuropathy and among the most common inherited neurologic disorders, with a prevalence of 1 in 2500. CMT may be broadly divided into **demyelinating** and **axonal** types. **CMT1,** the most common form, is a chronic demyelinating

TABLE 31-6
CHARCOT-MARIE-TOOTH DISEASE (CMT) AND RELATED HEREDITARY MOTOR AND SENSORY NEUROPATHIES

Disease	Inheritance	Gene	Pathology
CMT1	Autosomal dominant	Peripheral myelin protein 22 (*PMP22*), myelin protein zero (*MPZ*) and others	Demyelinating neuropathy with onion bulbs; axonal loss also present
CMT2	Autosomal dominant	Mitofusin 2 and others	Axonal neuropathy
CMTX	X linked	Gap junction protein β1 (connexin 32)	Axonal loss, demyelination, and regenerating axons
Dejerine-Sottas syndrome (congenital hypomyelinating neuropathy)	Autosomal dominant or recessive	*PMP22, MPZ,* early growth response 2 (*EGR2*) and others	Demyelinating neuropathy with onion bulbs; axonal loss also present
Hereditary neuropathy with liability to pressure palsies (HNPP)	Autosomal dominant	*PMP22*	Demyelinating neuropathy with tomacula; axonal loss also present

polyneuropathy with onion bulbs and axonal loss. The less common **CMT2** variety shows distal axonal degeneration. CMT1 and CMT2 are autosomal dominant diseases. X-linked **(CMTX)** and autosomal recessive **(CMT4)** types are also described. Mutations in at least 30 different genes may cause a CMT phenotype. Classification is complex because mutations in diverse genes may produce the same phenotype, and different mutations in the same gene may lead to different phenotypes (Table 31-6). CMT1, the most common form, usually reflects heterozygous duplication of peripheral myelin protein 22 gene on chromosome 17. CMT2 is often caused by a mutation of the gene encoding a mitochondrial fusion protein, mitofusin 2. In CMTX, the gap junction protein β1 (connexin 32) gene on the X chromosome is altered.

Dejerine-Sottas syndrome (DSS, CMT3) resembles CMT1 but is much more severe, with onset in early infancy. Peripheral nerves show a severe demyelinating neuropathy with onion bulbs and axonal loss. Several genes are associated with this phenotype (Table 31-6).

Hereditary neuropathy with liability to pressure palsies (HNPP) typically manifests as recurrent mononeuropathies. Nerves show demyelination, distinctive sausage-shaped myelin sheath thickenings (tomacula) and axonal loss (tomaculous neuropathy). HNPP is associated with a heterozygous deletion of peripheral myelin protein 22 gene on chromosome 17.

Peripheral Neuropathies Commonly Complicate HIV-1 Infection

HIV-1 peripheral neuropathies may manifest clinically as a distal symmetric polyneuropathy, autonomic neuropathy, lumbosacral polyradiculopathy, mononeuropathy or mononeuropathy multiplex.

- **Distal symmetric polyneuropathy** is the most common type of neuropathy in HIV-positive patients. It usually occurs during the later stages of AIDS and is characterized by distal axonal degeneration. The pathogenesis of the axonal degeneration is obscure, and there is no effective therapy.
- **Inflammatory demyelinating polyradiculoneuropathy** in HIV-infected people may be acute (AIDP) or chronic (CIDP) and is immunologically mediated. It typically occurs after HIV infection, before the onset of AIDS. The neuropathy often responds to plasmapheresis, intravenous γ-globulin or corticosteroids.
- **Cytomegalovirus infection** of the PNS is responsible for some of the mononeuropathies and lumbosacral polyradiculopathies associated with AIDS.
- **Vasculitic neuropathy** may be a mononeuropathy and mononeuropathy multiplex in some patients with AIDS.
- **Toxic neuropathies** occur with several drugs that are used to treat AIDS (Table 31-4). Such antiretroviral-induced axonal neuropathies resemble HIV-associated distal symmetric polyneuropathy clinically.
- **Diffuse infiltrative lymphocytosis syndrome** may be complicated by an acute or subacute axonal polyneuropathy. Peripheral nerve shows perivascular $CD8^+$ lymphocytic infiltrates.

Chronic Idiopathic Axonal Polyneuropathy Occurs in Older Patients

No cause can be identified for peripheral neuropathy, even with careful investigation, in a quarter of patients, usually over age 50. Many of these patients have a slowly progressive, distal, sensory or sensorimotor, axonal polyneuropathy called chronic idiopathic axonal polyneuropathy (CIAP).

NERVE TRAUMA

Traumatic Neuromas Are Masses of Regenerating Axons and Scar Tissue

Traumatic neuromas form at the proximal stump of a nerve that has been disrupted physically. Within a week after transection of a peripheral nerve, regenerating axonal sprouts arise from the distal ends of the intact axons in the proximal nerve stump. If the severed ends of the proximal and distal nerve stumps are closely approximated, regenerating axonal sprouts may find and reinnervate the distal stump. Regenerating axons advance in the distal stump at a rate of about 1 mm/day. However, if the cut nerve ends are not closely apposed, or if there is an impediment (e.g., scar tissue) between the two stumps, regenerating sprouts may not

reinnervate the distal stump. In that case, the regenerating axons grow haphazardly into the scar tissue at the end of the proximal stump to form a painful swelling: a **traumatic** or **amputation neuroma**.

Morton Neuroma Is a Painful Lesion in the Foot

Morton neuroma (plantar interdigital neuroma) is a sausage-shaped swelling of the plantar interdigital nerve between the second and third or third and fourth metatarsal bones. It is probably caused by repeated nerve compression, causing endoneurial, perineurial and epineurial fibrosis rather than a mass of regenerating axons. It thus is not a true neuroma. The fibrotic nerve also shows nerve fiber loss and areas of myxoid degeneration. Morton neuroma is particularly common in women who wear high heels.

TUMORS

Primary PNS tumors are of neuronal or nerve sheath origin. The former (e.g., neuroblastoma and ganglioneuroma) usually arise from the adrenal medulla or sympathetic ganglia. The common nerve sheath tumors are schwannoma and neurofibroma.

Schwannomas Are Benign Neoplasms of Schwann Cells

They are typically slowly growing, encapsulated tumors that originate in cranial nerves, spinal roots or peripheral nerves (Fig. 31-32A). Schwannomas usually occur in adults and rarely become malignant.

VESTIBULAR SCHWANNOMA (ACOUSTIC SCHWANNOMA): Intracranial schwannomas account for 8% of all primary intracranial tumors. Most arise from the vestibular branch of the eighth cranial nerve within the internal auditory canal or at the meatus. They cause unilateral, sensorineural hearing loss; tinnitus; and vestibular dysfunction. The slowly growing tumor enlarges the meatus, extends medially into the subarachnoid space of the cerebellopontine angle **(cerebellopontine angle tumor)** and compresses the fifth and seventh cranial nerves, brainstem and cerebellum. The posterior fossa mass may also lead to increased intracranial pressure, hydrocephalus and tonsillar herniation. Most vestibular schwannomas are unilateral and are not associated with neurofibromatosis (see Chapter 6). Bilateral vestibular schwannomas are a defining feature of NF2. Biallelic inactivation of the *NF2* gene, a tumor suppressor gene on chromosome 22, may also cause sporadic vestibular schwannomas.

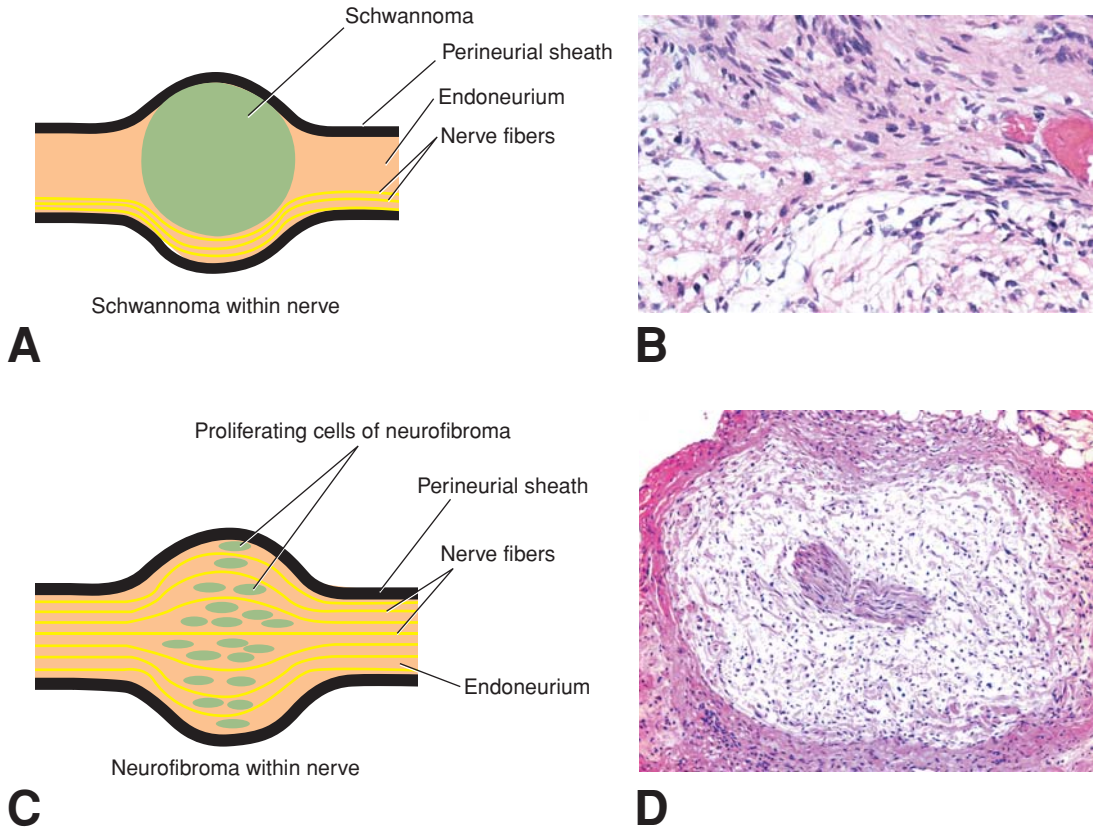

FIGURE 31-32. Growth patterns of schwannoma and neurofibroma within peripheral nerve. A. The cellular proliferation of the schwannoma is well circumscribed and pushes surviving nerve fibers to the periphery of the tumor. **B.** A photomicrograph of a schwannoma shows the characteristically abrupt transition between the compact Antoni type A histologic pattern (*top*) and the spongy Antoni type B histologic pattern (*bottom*). **C.** The cellular proliferation of the neurofibroma is interspersed among the surviving nerve fibers. **D.** Photomicrograph of neurofibroma shows that the proliferating spindle-shaped Schwann cells form small strands that course haphazardly through a myxoid matrix. A small cluster of surviving nerve fibers is in the center of the neurofibroma.

SPINAL AND PERIPHERAL SCHWANNOMAS: Spinal schwannomas are intradural, extramedullary tumors that arise most often from the dorsal (sensory) spinal roots. They produce radicular (root) pain and spinal cord compression. More peripherally located schwannomas usually arise on nerves of the head, neck and extremities.

PATHOLOGY: Schwannomas tend to be oval and well demarcated and vary from a few millimeters to several centimeters. The nerve of origin, if large enough, may be identifiable. The cut surface is firm and tan to gray, often with focal hemorrhage, necrosis, xanthomatous change and cystic degeneration. The proliferating Schwann cells form two distinctive histologic patterns (Fig. 31-32B).

- **Antoni A pattern** is characterized by interwoven fascicles of spindle cells with elongated nuclei, eosinophilic cytoplasm and indistinct cytoplasmic borders. Nuclei may palisade (line up in a picket fence–like pattern) in areas to form structures known as **Verocay bodies**.
- **Antoni B pattern** has spindle or oval cells with indistinct cytoplasm in a loose, vacuolated matrix.

Degenerative changes in schwannomas are common and include collections of foam cells, recent or old hemorrhage, focal fibrosis and hyalinized blood vessels. Scattered atypical nuclei are frequently encountered in schwannomas, but mitotic figures are uncommon.

Neurofibromas May Be Sporadic or Part of Neurofibromatosis Type 1

Neurofibromas are benign, slowly growing tumors of peripheral nerve, composed of Schwann cells, perineurial-like cells and fibroblasts. ***The Schwann cells are the neoplastic cells in these tumors.*** Neurofibromas should be distinguished from schwannomas because the former are associated with NF1 and may become malignant peripheral nerve sheath tumors.

Neurofibromas may be solitary or multiple and may arise on any nerve. They occur in children and adults. They mostly involve skin, subcutis, major nerve plexuses, large deep nerve trunks, retroperitoneum and gastrointestinal tract. Most **solitary cutaneous neurofibromas** are not part of NF1 and do not degenerate into sarcomas. The presence of multiple neurofibromas or one large plexiform neurofibroma strongly suggests NF1 and should prompt a search for other stigmata of the disease.

PATHOLOGY: Neurofibromas arising in large nerves are poorly circumscribed and fusiform (spindle shaped). A diffuse, intrafascicular growth of tumor within multiple nerve fascicles may so enlarge the fascicles that the nerve looks like a multistranded rope **(plexiform neurofibroma)**. Neurofibromas may involve long stretches of a nerve, making complete surgical excision impossible. When they arise from small nerves, the nerve of origin may not be apparent. Cutaneous neurofibromas originate from dermal nerves and are seen as soft nodular or pedunculated skin tumors.

These tumors are soft and light gray. Greatly enlarged, individual nerve fascicles of the plexiform neurofibroma may be prominent. Tumors arising in large nerves are characterized by endoneurial proliferation of spindle cells with elongated nuclei, eosinophilic cytoplasm and indistinct cell borders (Fig. 31-32D). The proliferating spindle cells include Schwann cells, fibroblasts and perineurial-like cells. Mast cells are also increased. An extracellular myxoid matrix, wavy bands of collagen and residual nerve fibers are interspersed among the spindle cells. The nerve fibers coursing through a neurofibroma contrasts with the pattern in schwannomas, in which nerve fibers are pushed peripherally into the tumor capsule (compare Fig. 31-32A, C). The neurofibromatous proliferation often extends beyond the nerve fascicle into adjacent tissue.

Some 5% of NF1-associated plexiform neurofibromas become malignant peripheral nerve sheath tumors. Increased cellularity, nuclear atypia and mitotic figures herald malignant transformation.

Malignant Peripheral Nerve Sheath Tumor

Malignant peripheral nerve sheath tumor (MPNST) is a poorly differentiated, spindle cell sarcoma of peripheral nerve of uncertain histogenesis. It may arise de novo or from malignant transformation of a neurofibroma. MPNST is most common in adults and typically arises in larger nerves of the trunk or proximal limbs. About half occur in patients with neurofibromatosis. There is an increased incidence of MPNST at sites of previous irradiation.

MPNSTs are unencapsulated, fusiform enlargements of a nerve. The tumors resemble fibrosarcomas, with closely packed spindle cells, nuclear atypia, mitotic figures and, often, foci of necrosis. MPNSTs are prone to local recurrence and blood-borne metastasis.

PARANEOPLASTIC SYNDROMES INVOLVING MUSCLE AND PERIPHERAL NERVES

Neurologic disorders are common in cancer patients, usually resulting from metastases or from endocrine or electrolyte disturbances. Vascular, hemorrhagic and infectious conditions affecting the nervous system are also common. However, additional neurologic complications of malignancies are known and may appear before the underlying tumor is detected. Many of these are mediated by autoimmune mechanisms.

Sensory Neuropathy and Encephalomyeloneuritis

Patients afflicted with this paraneoplastic syndrome complain of numbness and paresthesias and, conversely, variably acute aching and pain. These may be focal, but often affect all extremities over time, and are often complicated by disorders of gait, confusion and weakness. This syndrome may occur in patients with small cell lung cancer (SCLC; see Chapter 12) and is caused by circulating antibodies against Hu, an RNA-binding protein. High titers of anti-Hu antibodies are almost exclusively detected in people with SCLC. Lymphocytic infiltration of dorsal root ganglia is seen. Symptoms tend to be treatable when the primary tumor is treated.

Paraneoplastic Autonomic Neuropathies

These are rare, but affect a quarter of patients with anti-Hu antibodies, and may be the initial presentation of the tumor. Systems affected, sometimes severely, include vascular tone, bowel and bladder. Antibodies against the nicotinic acetylcholine receptor are sometimes responsible.

Opsoclonus-Myoclonus

Nonvoluntary spasms of ocular and other muscles characterize this syndrome. Among children, about half of cases of this disorder are associated with neuroblastoma. About 10% of adults with opsoclonus-myoclonus will have a malignancy, most often Hodgkin lymphoma.

Diseases of Upper and Lower Motor Neurons

These syndromes may be paraneoplastic in origin. Diverse tumor associations have been reported, the most frequent being lymphoproliferative diseases and anti-Hu antibodies. Weakness is the most common presenting symptom. As many as 10% of patients presenting with amyotrophic lateral sclerosis have internal malignancies.

Subacute Motor Neuropathy

This is a disorder of the spinal cord, characterized by slowly developing lower motor neuron weakness without sensory changes. It is so strongly associated with cancer that an intensive search for an occult neoplasm, often a lymphoma, should be made in patients who present with these symptoms.

Peripheral Neuropathies

An array of peripheral neuropathies may be paraneoplastic in origin. Sensorimotor neuropathy, most likely attendant to lung cancer, is not associated with detectable antibodies. Some types of lymphoproliferative disorders associated with paraproteins, especially the sclerosing variant of plasma cell myeloma, may develop peripheral neuropathies.

Neuromuscular Junction Disorders

The most common association is with thymomas. About 15% of patients with myasthenia gravis have thymomas, and about half of patients with thymomas suffer from myasthenia gravis. Autoantibodies against the nicotinic acetylcholine receptor are the principal cause of this syndrome.

Eaton-Lambert Syndrome

This syndrome is a paraneoplastic disorder that manifests as muscle weakness, wasting and fatigability of proximal limbs and trunk. Also called **myasthenic–myopathic syndrome,** it is usually associated with small cell lung carcinoma, but may also occur with other malignancies, and rarely in the absence of underlying cancer. Neurophysiologic evidence suggests a defect in Ach release at nerve terminals. IgG from patients can transfer the disease to mice. The pathogenic IgG autoantibodies target voltage-sensitive calcium channels expressed in motor nerve terminals and in the cells of the lung cancer. These calcium channels are necessary for Ach release and are greatly reduced in presynaptic membranes in these patients, thus reducing neuromuscular transmission. Lambert-Eaton syndrome responds to corticosteroid treatment.

Dermatomyositis

Dermatomyositis (see above) in middle-aged men is associated with increased risk of epithelial cancer, mostly lung carcinoma. However, polymyositis and inclusion body myositis have a reduced risk of an associated malignancy.

The Central Nervous System

The nervous system is the most complex organ system in the body. It is responsible for sensory processing and synthesis and motor control, and is the organ of thought, emotion and personality—in short, the basis of humanity itself. The vast majority of its operations occur without conscious supervision. Disorders of the central nervous system (CNS) strike at the core of our being as sentient organisms, and so inspire fear and dread. Diseases of the nervous system are common throughout the human life span and contribute substantially to mortality and morbidity: stroke, Alzheimer disease, mental retardation, traumatic brain and spinal cord injury, meningitis and tumors.

TOPOGRAPHY: The functions of the nervous system have fine topographic localization, so that focal disease processes can produce myriad signs and symptoms that permit a skilled clinician to locate the affected site precisely. In addition, most neurons are organized in functional arrays, which, if damaged, cause some of the most vexing neurodegenerative and neuropsychiatric disorders. Selective vulnerability of different nervous system cells and CNS regions to specific disease processes is one of the most profound unresolved enigmas of neurologic illnesses. For example, Huntington

disease primarily causes degeneration of neurons in the caudate nuclei; Parkinson disease targets the nigrostriatal system; amyotrophic lateral sclerosis (ALS) selectively singles out upper and lower motor neurons of the cerebrum, brainstem and spinal cord. Some infectious diseases prefer certain targets: poliomyelitis involves anterior horn cells of the spinal cord and motor nuclei of the brainstem, while herpes simplex virus preferentially affects the temporal lobes. Vascular and demyelinating diseases also have regional preferences within the CNS, as do some brain tumors. The basis of topographic vulnerability and protection for most such diseases is obscure.

AGE: The nervous system is affected by neurologic disorders throughout the life span, but individual diseases commonly affect selected age groups. Thus, inborn errors of metabolism such as Tay-Sachs disease, the leukodystrophies and several posterior fossa tumors mainly occur in childhood. Youthful reckless exuberance leads to a spike in traumatic brain and spinal cord injury in teens and young adults that subsides with maturity, only to return with the infirmities of age. Multiple sclerosis shows a strong preference for young adults, rarely beginning before puberty or after age 40. Neuropsychiatric disorders such as schizophrenia often appear in late adolescence and young adulthood when the brain undergoes striking neurodevelopmental changes. Huntington disease typically strikes youthful and middle-aged adults, while Parkinson disease and stroke occur late in life. Alzheimer disease tends to affect aged brains.

CELLS OF THE NERVOUS SYSTEM

The diversity and complexity of the CNS is reflected at all levels in its organization, from the morphologic and functional subspecialization of the many unique cellular constituents to the regional localization of sensory, motor and cognitive functions.

GRAY MATTER AND THE NEUROPIL: Gray matter includes all regions of the CNS rich in neurons: cerebral and cerebellar cortices, basal ganglia and central gray matter of the spinal cord. Gray matter consists of cell bodies (perikarya) of neurons and supporting glial cell nuclei, plus the intervening delicate interwoven meshwork of neuronal and glial cell processes, the **neuropil** (Fig. 32-1). Circumscribed collections of neuronal cell bodies that share a common functional task are referred to as "nuclei."

WHITE MATTER: White matter consists of compact bundles **(tracts, fascicles)** of myelinated axons with many oligodendrocytes and interspersed astrocytes (Fig. 32-2).

NEURONS: The morphology of neuronal subtypes in the gray matter varies due to functional subspecialization, ranging from large motor and primary sensory neurons to tiny "granular cell" neurons (Fig. 32-3A). For example, pigmented neurons, which occur only in specific brainstem nuclei, are distinguished by cytoplasmic brown neuromelanin pigment, a byproduct of catecholaminergic neurotransmitter synthesis (Fig. 32-3B). These clusters of pigmented catecholaminergic neurons are so dense as to be visible to the naked eye in the midbrain (substantia nigra) and pons (locus ceruleus).

ASTROCYTES: Astrocytes outnumber neurons at least 10:1 and play a critical supportive role in regulating the CNS microenvironment. They are also one of two primary CNS cell types that respond to many CNS insults (the other being microglia). Astrocytes responding to acute injury upregulate synthesis of glial fibrillary acidic protein (GFAP) and assemble it into intracytoplasmic intermediate filaments, resulting in prominent cell bodies and cytoplasmic processes (Fig. 32-4A). With advancing age, astrocyte peripheral processes may accumulate spherical inclusion bodies, corpora amylacea. These are glucose polymers that are especially numerous in subpial, subependymal and perivascular sites and in olfactory tracts (Fig. 32-4B). Cytoplasmic strap-like densities, Rosenthal fibers (Fig. 32-4C), appear in long-standing astrogliosis as densely compacted glial intermediate filaments with entrapped cytosol proteins.

OLIGODENDROGLIA: Oligodendroglia produce and maintain CNS axon myelin sheaths, and so are CNS counterparts of Schwann cells in the peripheral nervous system.

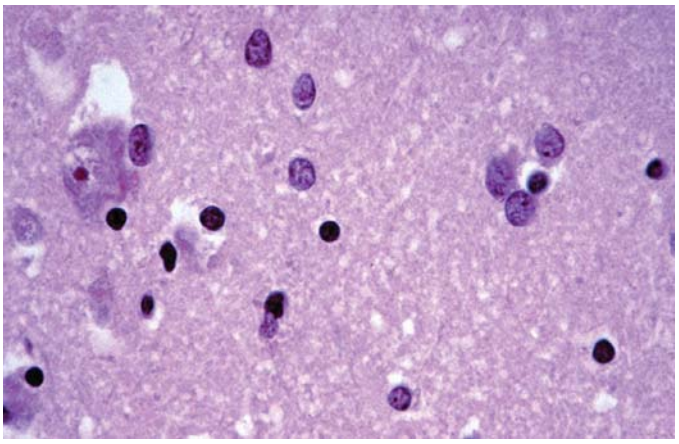

FIGURE 32-1. Gray matter and the neuropil. Gray matter by definition contains neuronal cell bodies. In addition, the nuclei of supporting glial cells, astrocytes and satellite oligodendroglia, are also present. The remaining finely fibrillar background meshwork is called the neuropil and consists of intimately intermingled axons, dendrites and astrocytic cytoplasmic processes.

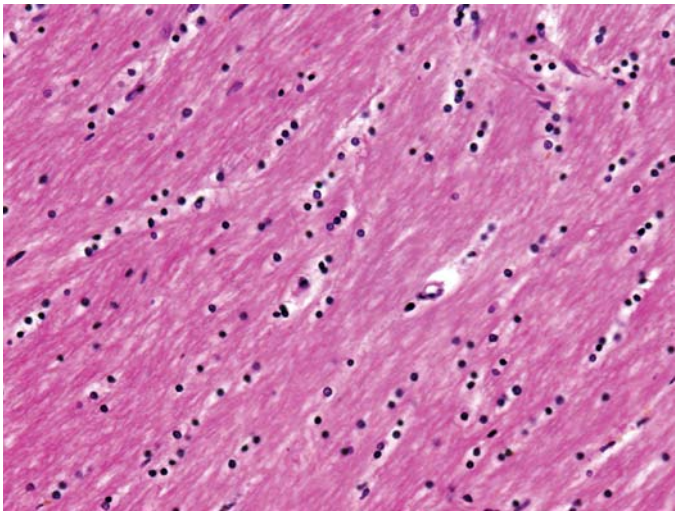

FIGURE 32-2. White matter. In contrast to gray matter, white matter is composed almost entirely of myelinated axons and the cells that produce and maintain their myelin sheaths, the oligodendroglia, whose small round nuclei are seen in between the fiber bundles.

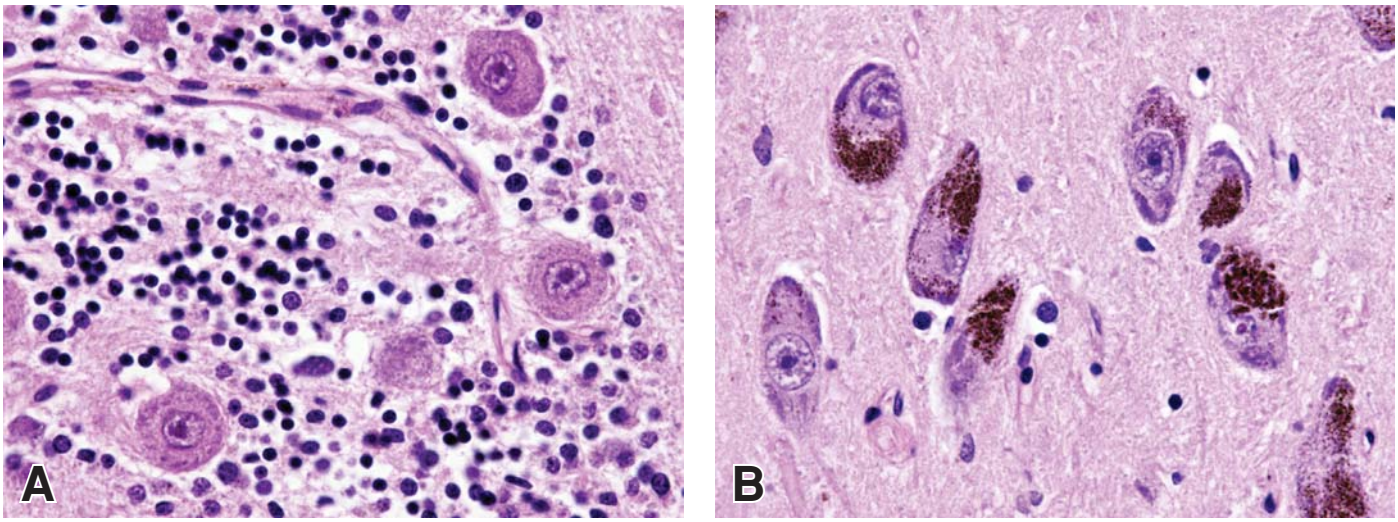

FIGURE 32-3. Neurons. A. The different neuronal populations of the central nervous system (CNS) subserve different functions, and this diversity is reflected in their morphology. Illustrative of the extremes are the large cell bodies of Purkinje cell neurons juxtaposed next to the diminutive granular cell neurons of the cerebellar cortex; the entire granular neuron cell body is not much bigger than the nucleolus of a Purkinje cell neuron! **B.** The pigmented catecholaminergic neurons with their prominent neuromelanin content serve as an additional, striking example of diversity in form and function among CNS neuronal populations.

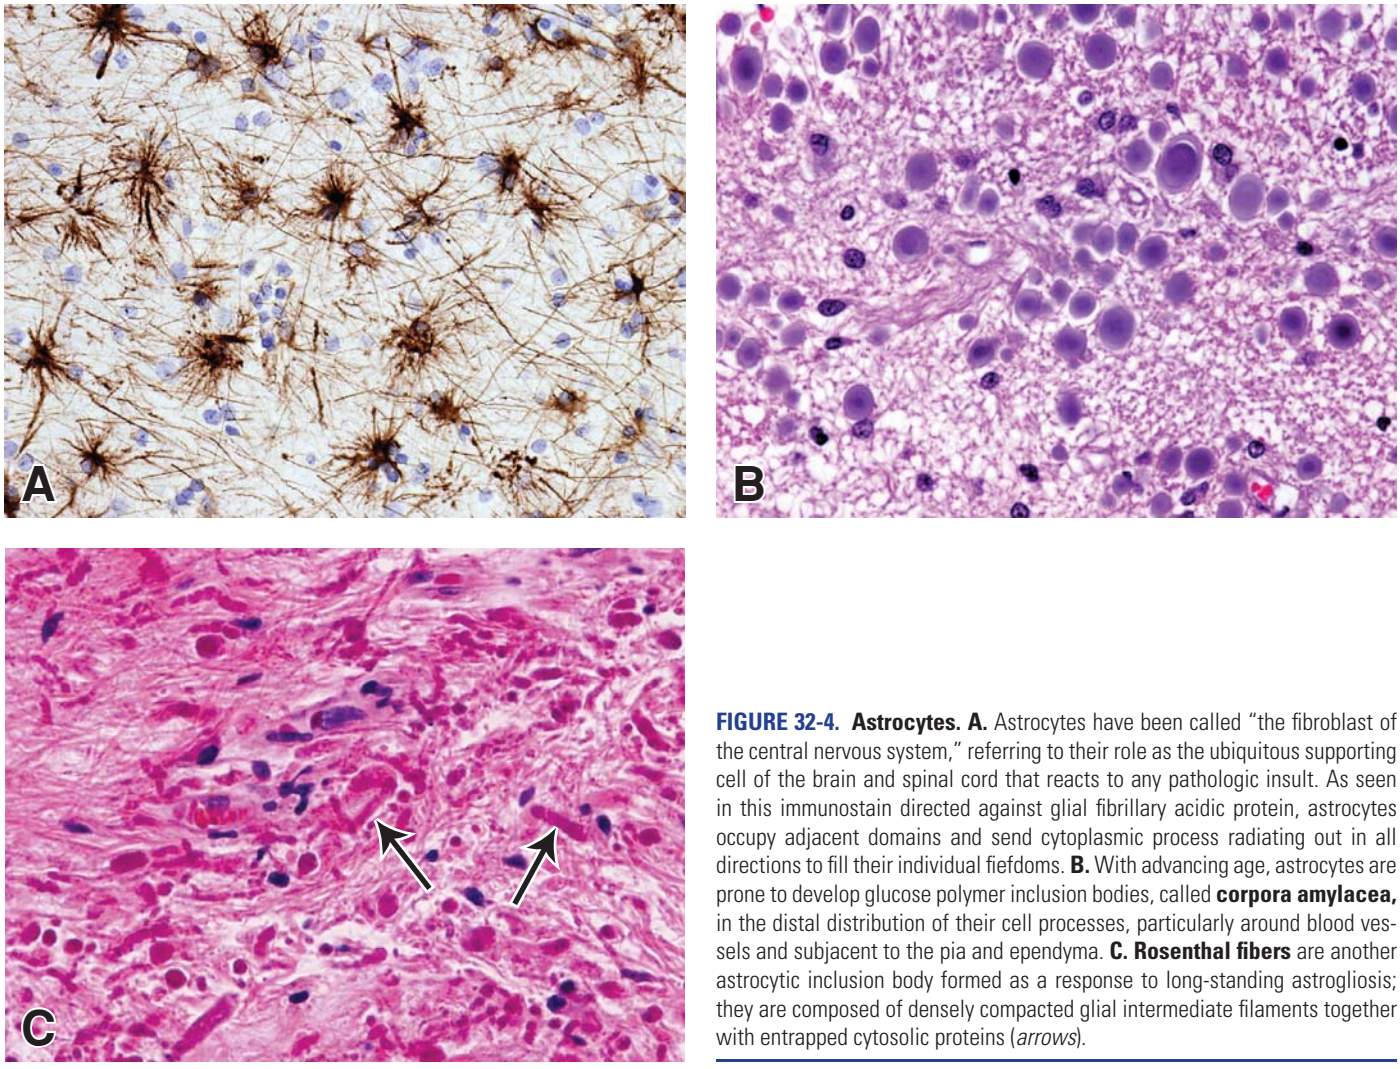

FIGURE 32-4. Astrocytes. A. Astrocytes have been called "the fibroblast of the central nervous system," referring to their role as the ubiquitous supporting cell of the brain and spinal cord that reacts to any pathologic insult. As seen in this immunostain directed against glial fibrillary acidic protein, astrocytes occupy adjacent domains and send cytoplasmic process radiating out in all directions to fill their individual fiefdoms. **B.** With advancing age, astrocytes are prone to develop glucose polymer inclusion bodies, called **corpora amylacea,** in the distal distribution of their cell processes, particularly around blood vessels and subjacent to the pia and ependyma. **C. Rosenthal fibers** are another astrocytic inclusion body formed as a response to long-standing astrogliosis; they are composed of densely compacted glial intermediate filaments together with entrapped cytosolic proteins (*arrows*).

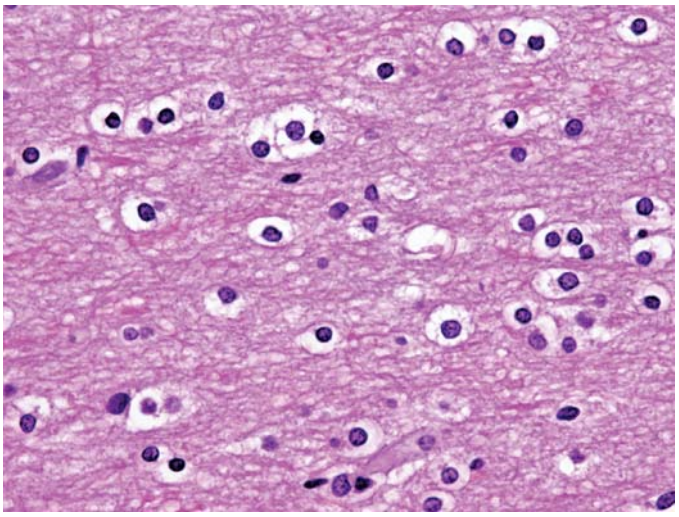

FIGURE 32-5. Oligodendroglia. Oligodendroglia are the myelin-forming glia of the central nervous system (CNS; including the optic "nerves," which are actually CNS tracts). On routine histologic imaging, oligodendroglia are easily recognized by their monotonous small dark round nuclei surrounded by a halo of vacuolated cytoplasm ("fried egg" appearance). This characteristic appearance is recapitulated in neoplastic oligodendrogliomas.

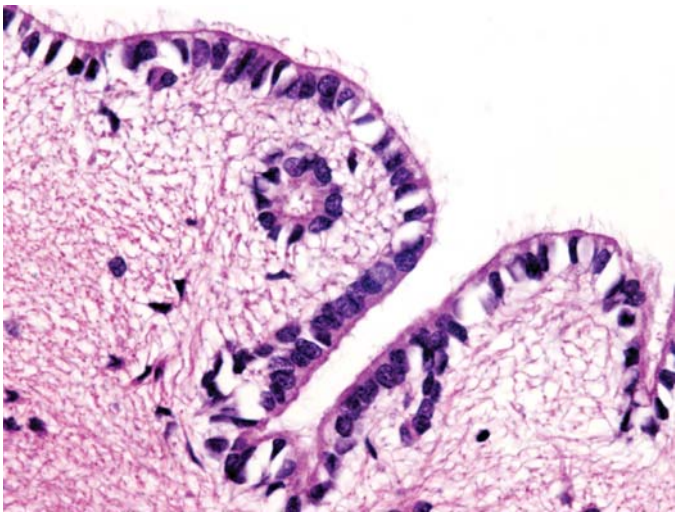

FIGURE 32-7. Ependyma. Ependymal cells form a ciliated cuboidal-to-columnar epithelium that lines the cerebral ventricles and spinal cord central canal. Ependymal cell clusters and true rosettes, as seen here, commonly are scattered beneath the ependymal lining.

Oligodendroglia cell bodies are dominated by uniform round nuclei that, in formalin-fixed paraffin-embedded tissue sections, are characteristically surrounded by only a small clear rim of vacuolated cytoplasm ("perinuclear halo") (Fig. 32-5).

MICROGLIA: Microglia are bone marrow–derived mononuclear phagocytes of the CNS. In health, they are inconspicuously distributed throughout the brain and spinal cord. But they respond quickly to CNS insults such as ischemia, trauma or viral infection by developing thin, elongated nuclei, migrating through the CNS and localizing to the site of injury (Fig. 32-6A,B).

EPENDYMA: The ependymal lining of the ventricular system forms a barrier between cerebrospinal fluid (CSF) and brain parenchyma and regulates fluid transfer between these two compartments. The normal ependyma is lined by ciliated cuboidal-to-columnar simple epithelium (Fig. 32-7).

SPECIALIZED REGIONS OF THE CENTRAL NERVOUS SYSTEM

CHOROID PLEXUS: The choroid plexus produces CSF. It is in the cerebral ventricles, including the temporal horns bilaterally, interventricular foramen of Monro, the roof of the third ventricle and the roof and lateral recesses of the fourth ventricle. The choroid plexus is composed of cuboidal epithelium (derived from embryologic ependyma) that covers a fibrovascular core (Fig. 32-8A). The highly vascular core

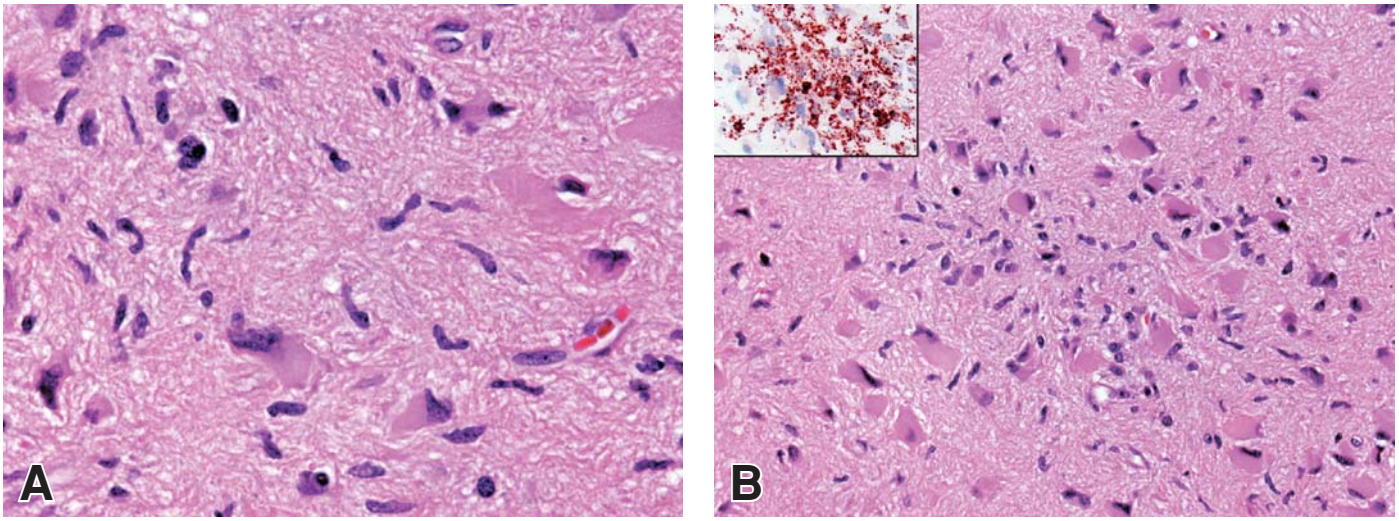

FIGURE 32-6. Microglia. A. Microglia are the resident representatives of the monocyte–macrophage system in the brain and spinal cord. While inconspicuous in normal healthy brain ("resting microglial"), they become very prominent when responding to central nervous system (CNS) injury and are easily recognized by their elongated nuclei ("rod cells"), which reflect their infiltrative phenotype. **B.** Actively migrating through CNS parenchyma, they commonly cluster around foci of disease; such collections are known as "microglial nodules." Microglia demonstrate strong immunohistochemical reactivity for the macrophage marker CD68 (*inset*).

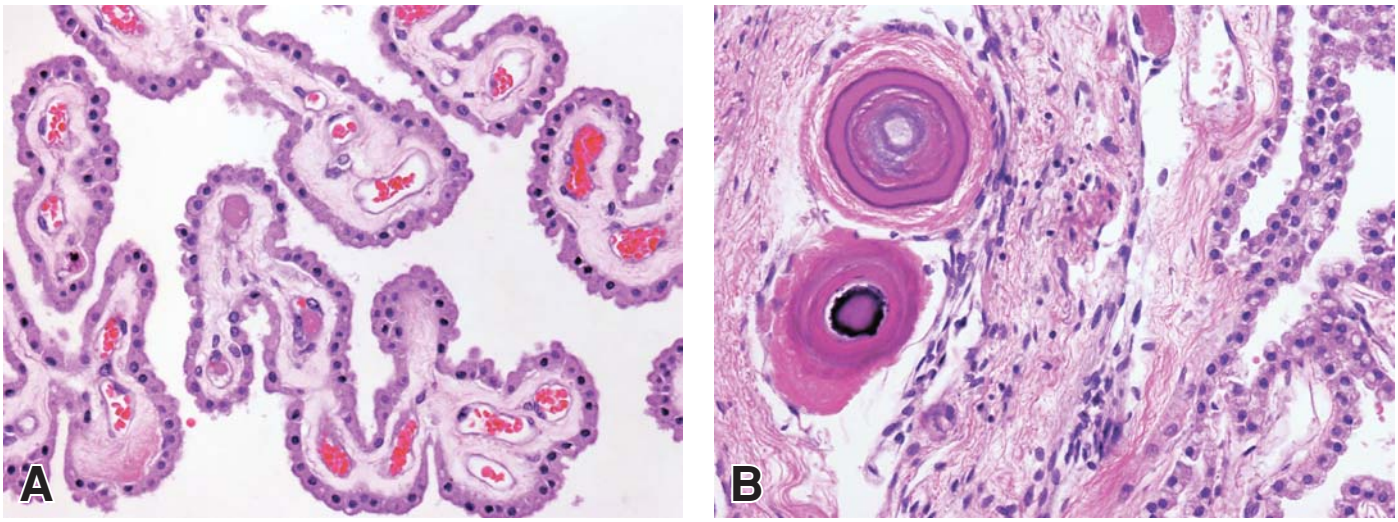

FIGURE 32-8. Choroid plexus. A. Choroid plexus is the central nervous system (CNS) organ responsible for producing cerebrospinal fluid and consists of innumerable papillae with a highly vascular core covered by cuboidal epithelium that is derived embryologically from the ependyma. **B.** The core also contains arachnoid (meningothelial) cell nests (by virtue of its embryologic derivation from the pia-arachnoid) that tend to mineralize with age, forming psammoma bodies (*B*).

is critical to CSF formation. It develops from leptomeninges (pia and arachnoid) and contains scattered nests of arachnoid (meningothelial) cells (Fig. 32-8B), hence the occasional "intraventricular" meningioma that is actually a choroid plexus meningioma.

MENINGES: Three layers of meninges cover and protect the CNS. The **dura** is the tough outer fibrous membrane. It is primarily collagen. Its outer surface is the inner periosteum of the cranial bones and its inner surface attaches weakly to the subjacent arachnoid via cell junctions. The two dural layers separate in several sites to form dural venous sinuses, the largest of which is the superior sagittal sinus. The underlying arachnoid is bound to the overlying dura by a loosely cohesive layer of cells, the **dural border cell (DBC) layer**. This layer is the path of least resistance to pathogenic fluids, which easily dissect the weak intercellular junctions to form so-called subdural hematomas, hygromas and empyemas. The meningeal layer just beneath the DBC layer, the **arachnoid barrier cell (ABC) layer,** in contrast, forms a cohesive outer limiting membrane of the subarachnoid space via abundant intercellular junctions (desmosomes) that weld together elongated, interlacing arachnoid (meningothelial) cell processes. Whorls of arachnoid cells are common in thicker areas of the arachnoid (Fig. 32-9); this feature is often recapitulated in arachnoid tumors (meningiomas).

PINEAL GLAND: The pineal gland (see Chapter 27) contains pineal parenchymal cells (pineocytes), plus supporting glial cells (pineal astrocytes), arranged in cell clusters separated by collagenous septa (Fig. 32-10). Inconspicuous autonomic peripheral nerve fibers coming from cell bodies in the superior cervical ganglia provide sympathetic nervous system (noradrenergic) innervation.

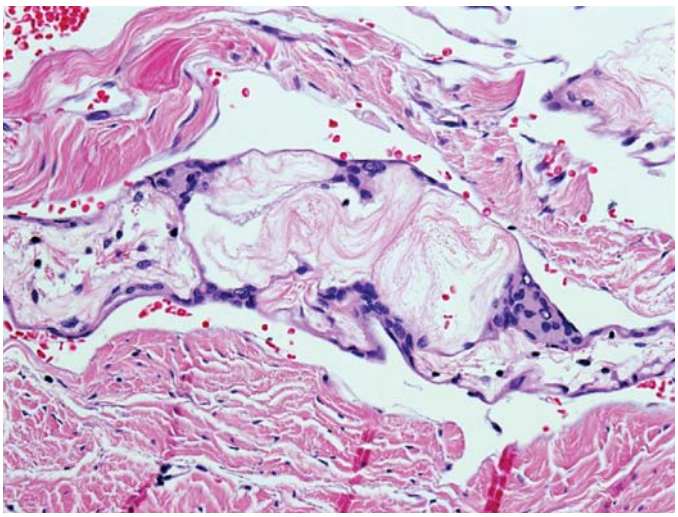

FIGURE 32-9. Arachnoid villi. The arachnoid membrane forms the outer boundary of the subarachnoid space and also protrudes into the dural venous sinuses, as seen here, to form arachnoid villi whose function is to return cerebrospinal fluid (CSF) into the venous circulatory system. The villi are covered by a layer of meningothelial cells, called arachnoid cap cells, that varies in thickness from a single cell to multilayered whorls.

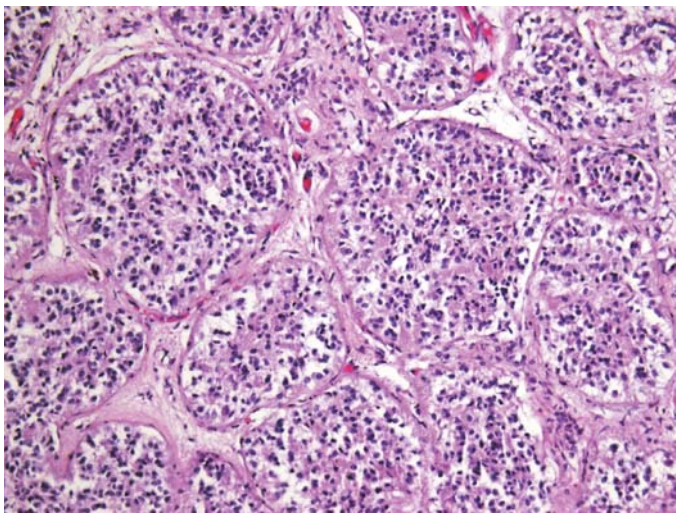

FIGURE 32-10. Pineal gland. The pineal is composed of pineal parenchymal cells (pineocytes) organized into lobules by fibrovascular septa.

INCREASED INTRACRANIAL PRESSURE AND HERNIATION

ETIOLOGIC FACTORS: Pathophysiologically, the most important aspect of the brain is that it ***lives in a closed box***! The brain, CSF and blood going to and from the brain occupy the intracranial space. In the adult, this is a rigidly fixed cavity. Any disease that takes up space does so at the expense of brain, CSF or blood. This is a verbal expression of the Monro-Kellie hypothesis that states:

$$\text{Intracranial volume} = \text{Volume}_{CNS} + \text{Volume}_{CSF} + \text{Volume}_{blood} + \text{Volume}_{lesion}$$

Space-occupying lesions may occur with every major category of disease except for degenerative disorders. Examples include brain tumors, abscesses, swollen brain contusions following trauma and stroke with brain swelling.

The immediate result of trying to fit more volume into the fixed space of the intracranial vault is increased intracranial pressure (ICP). The normal mean ICP is less than 200 mm H_2O or 15 mm Hg for a patient in the lateral decubitus position. The pressure can be measured by lumbar puncture or by an intracranial pressure transducer. As ICP increases, patients have headaches, confusion and drowsiness and may develop papilledema. To compensate, CSF volume is reduced; hence, the ventricles are compressed to small slits and sulci are effaced.

If a lesion takes up more space than a reduction in CSF volume can accommodate, blood flow then decreases. Such lower cerebral blood flow may have an immediate adverse impact as the brain is critically dependent upon uninterrupted supply of oxygen and nutrients. If the lesion expands further, the only structure remaining to "give" is the brain itself. The intracranial compartment is subdivided by the dura—the tentorium cerebelli divides the vault into supra- and infratentorial compartments; and the falx divides the supratentorial compartment into right and left compartments. Depending on where the space-occupying lesion is, the brain may be forced out of one compartment into another. Such shifts are called brain herniations.

CLINICAL FEATURES:

CINGULATE HERNIATION: If a hemisphere is forced under the falx, the cingulate lobe is the first part of that hemisphere to be displaced. These situations are **subfalcine,** or **cingulate, herniations**. Someone experiencing such a herniation becomes confused and drowsy. The anterior cerebral artery is also displaced beneath the falx, so that infarction within this vessel's territory may occur, leading to contralateral lower extremity weakness and urinary incontinence.

UNCAL HERNIATION: If one hemisphere is forced from the supratentorial compartment toward the infratentorial compartment, the medial temporal lobe (the uncus) is the first portion of the hemisphere displaced; thus, this is an **uncal,** or **transtentorial, herniation** (Fig. 32-11). The ipsilateral oculomotor nerve (cranial nerve III) is crushed by the displaced temporal lobe, leading to ipsilateral pupillary dilatation and paresis of all extraocular muscles except the lateral rectus (cranial nerve VI) and superior oblique (cranial nerve IV). The unopposed action of the lateral rectus leads to the eye "looking" laterally. A dilated unresponsive or minimally responsive pupil indicates extreme danger and necessitates immediate measures to arrest the herniation.

FIGURE 32-11. Transtentorial herniation. The uncus (*arrow*) of the parahippocampal gyrus is herniated downward to displace the midbrain, resulting in distortion of the midbrain with increased anterior-to-posterior and diminished left-to-right dimensions. The oculomotor nerve may be compromised, leading to an ipsilateral third nerve palsy.

As medial displacement continues, the midbrain shifts away from the displaced hemisphere, with the contralateral cerebral pedicle driven into the unyielding tentorium. This crushing injury of the cerebral pedicle **(Kernohan notch)** causes hemiparesis on the same side of the body as the offending mass. A hemispheric mass will normally cause hemiparesis on the opposite side of the body; ipsilateral hemiparesis, which may be clinically confusing, and this is called a "false localizing" sign.

Downward and medial displacement of a hemisphere through the tentorial opening may also lead to compression of one or both posterior cerebral arteries as they travel from the infratentorial compartment to the now crowded supratentorial compartment. This can impair blood flow to the occipital lobes, resulting in infarction with attendant visual field disturbances bearing no obvious relationship to the inciting mass. This occipital lobe infarction and its attendant signs are also "false localizing."

Uncal herniation syndrome is very ominous but is reversible with removal of the offending mass. Temporary measures to reduce intracranial pressure include intravenous mannitol to shrink the brain osmotically and hyperventilation to reduce PCO_2-inducing cerebral vasospasm and so decrease cerebral blood volume and thus pressure. These actions may gain enough time for definitive surgical treatment.

CENTRAL HERNIATION: If both hemispheres herniate transtentorially, **central herniation syndrome** results. Both

FIGURE 32-12. Duret hemorrhages (*arrow*) in a case of transtentorial herniation tend to be midline and to occupy the brainstem from the upper midbrain to midpons. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

pupils dilate; flaccidity and coma ensue. The downward displacement of the brainstem may wrench vessels from their parenchymal beds within the midbrain and pons and cause multiple linear hemorrhages known as **Duret hemorrhages** or secondary hemorrhages of herniation (Fig. 32-12).

CEREBELLAR TONSILLAR HERNIATION: If the infratentorial compartment becomes crowded either from migrating supratentorial contents or from a mass arising in the infratentorial compartment, the brainstem and cerebellum may be forced through the foramen magnum. The compressed cerebellar tonsils and medulla may compress vital medullary centers and cause death. This bleak situation is **tonsillar herniation**.

FUNGUS CEREBRI: If there is a traumatic or surgical defect in the skull, the brain is under increased pressure and may ooze from the opening. This process is known as fungus cerebri.

Cerebral Edema May Occur Whenever Intracranial Pressure Increases

Cerebral edema can set up a self-perpetuating cycle in which increasing edema begets increasing pressure, which in turn begets more edema.

ETIOLOGIC FACTORS: Cerebral edema is an absolute increase in brain water content. The amount of water in brain tissue is tightly controlled by the rates of CSF production, CSF outflow from the cranial vault and water flux across the blood-brain barrier. The blood-brain barrier (BBB) separates the brain from the blood so that only lipid-soluble molecules, or molecules that can access specialized transport systems, enter the brain. The structural basis of the BBB is endothelial cell tight junctions lining cerebral vessels. Water can enter the brain uncontrollably if the barrier is disrupted or if osmotic forces across it are sufficient to drive water into cerebral tissues. Three major forms of cerebral edema may occur:

- **Cytotoxic edema:** Water flows across an intact BBB by osmotic forces arising because cells within the brain fail to maintain osmotic homeostasis or because of systemic water overload. In either case, water is driven down its concentration gradient into cerebral tissues until osmotic equilibrium is reestablished.
- **Vasogenic edema:** The blood-brain barrier loosens, permitting uncontrolled entry of water into the tissues. ***This is the most common cause of edema*** and occurs with neoplasms, abscesses, meningitis, hemorrhage, contusions and lead poisoning. A combination of cytotoxic and vasogenic edema is common in infarcts. The above processes may disrupt endothelial barrier activity, or the vessels formed in neoplasms may be defective from their inception. Vasogenic edema often responds dramatically to administration of corticosteroids, which restore barrier integrity even in tumors.
- **Interstitial edema:** While cytotoxic and vasogenic edema involve water fluxes across the endothelium, interstitial edema involves CSF overproduction or its failure to leave the cranial cavity, so that the fluid seeps across the ependymal lining of the ventricles and accumulates within the white matter.

Hydrocephalus Can Be Noncommunicating or Communicating

Hydrocephalus is accumulation of CSF within the ventricles, causing them to dilate (Fig. 32-13). When ventricular distension is sufficiently advanced, fluid will leak trans-ependymally into the white matter, causing interstitial edema. CSF accumulation can arise from (1) ***overproduction of CSF, which is very rare,*** occurring only in the context of tumors of the choroid plexus; and (2) ***failure of CSF to leave the cranial vault, which is more common***. If the blockage occurs within the ventricular system itself, ventricles proximal to the block dilate, while those situated downstream from the block are spared. This is **obstructive,** or **noncommunicating, hydrocephalus**. The most frequent site of block is at the ventricular system's narrowest strait—the aqueduct of Sylvius connecting the third and fourth ventricles.

A block may occur after the CSF leaves the ventricular system and travels over the cerebral convexities to the arachnoid granulations that usher the fluid into the venous sinuses. Then, all the ventricles dilate. This is **communicating hydrocephalus,** meaning that ventricles are unobstructed in fluid flow. Communicating hydrocephalus may complicate subarachnoid hemorrhage or inflammation, resulting in arachnoid scarring, or may result from thrombosis of the dural venous sinuses themselves.

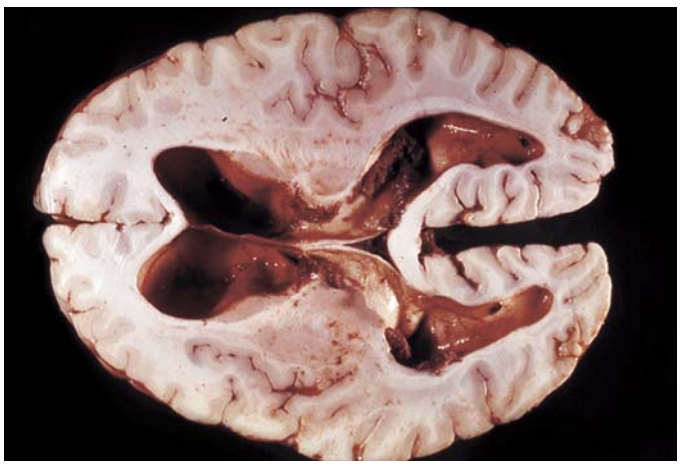

FIGURE 32-13. Hydrocephalus. Horizontal section of the brain from a patient who died of a brain tumor that obstructed the aqueduct of Sylvius shows marked dilation of the lateral ventricles.

CLINICAL FEATURES: The clinical features of hydrocephalus depend on the patient's age. In infants and children, before cranial sutures have fused, the head enlarges sometimes to grotesque proportions as the ventricles dilate. As hydrocephalus is common in infants and treatable by shunting, measurement of the head circumference is a fundamental part of the pediatric physical examination.

After sutures fuse, hydrocephalus cannot enlarge the head, but rather increases intracranial pressure. This causes headache, confusion, drowsiness, papilledema and vomiting. Ventricles enlarge at the expense of brain volume so that in advanced cases only a mantle of several millimeters' thickness remains. Remarkably, such individuals may retain substantial cognitive abilities, although spasticity may cloak the expression of this intelligence.

In older people, hydrocephalus may develop insidiously. Slow ventricular enlargement may appear clinically as progressive dementia, gait impairment and urinary incontinence as the long white matter fibers connecting portions of cortex to one another and lower motility centers are stretched apart by relentless expansion of the ventricles. This condition is usually accompanied by normal baseline intracranial pressure and so is called **normal-pressure hydrocephalus,** which may respond to shunting. If long-term CSF pressure is monitored, periodic waves of elevated intracranial pressure are seen.

All of the above forms of hydrocephalus result from disturbance of CSF dynamics and should be distinguished from **hydrocephalus ex vacuo,** which is compensatory ventricular enlargement due to loss of CNS tissue from other diseases. This occurs most often in diffuse cortical atrophy, but focal destruction such as occurs at the site of an old infarct may lead to focal compensatory ventricular enlargement.

TRAUMA

EPIDEMIOLOGY: Physical injury to the brain, spinal cord and peripheral nervous system is a major cause of loss of life and productivity. Populations at highest risk for such injuries include children, men in late adolescence and early adulthood and the elderly. Such injuries are a signature of modern warfare, are the leading cause of death in childhood and young adulthood and are a major concern for participants in contact sports.

ETIOLOGIC FACTORS: The brain and spinal cord are enclosed in protective bony cases that dissipate forces delivered to these delicate structures. However, evolutionary selection has not yet adequately responded to the need to survive motor vehicle crashes, personal assaults or dives into shallow pools. Injury to the nervous system results from the transfer of kinetic energy to the neural tissues—the degree of injury correlates with the quantity of energy delivered and the time over which it was delivered. This energy transfer may directly disrupt tissues in penetrating injuries, or the energy may be translated into movement and compression of neural structures within the skull or spinal canal in a closed injury. Extreme injury of the brain and cord is possible with minimal disruption of overlying tissues. Conversely, superficial tissues can sustain dramatic injury while the nervous system underneath remains unaltered.

Epidural Hematomas Are Often Fatal

Epidural hematomas usually result from blows to the head with skull fracture. Unless treated promptly, they can be fatal. The intracranial dura is securely bound to the inner aspect of the calvaria and so is analogous to the intracranial periosteum. The middle meningeal arteries reside in grooves in the inner table of the bone between the dura and the calvaria, and their branches splay across the temporal–parietal area. The temporal bone, being one of the thinnest bones of the skull, is particularly vulnerable to fracture. Seemingly minor trauma may fracture it, which may in turn lacerate branches of the middle meningeal artery, causing life-threatening epidural hemorrhage (Fig. 32-14).

PATHOLOGY: Transection of the middle meningeal artery allows blood under arterial pressure to escape into the epidural space that separates the dura from the calvaria. The dura is tightly bound to the calvarium at the coronal sutures. Thus, epidural bleeding will not extend beyond the suture lines. This leads to a lens-shaped accumulation of fresh blood that stops at the coronal suture lines (Fig. 32-15).

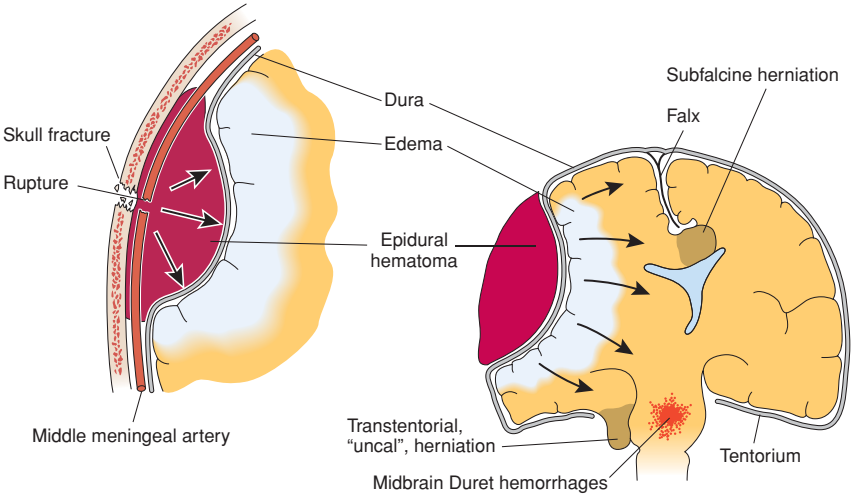

FIGURE 32-14. Development of an epidural hematoma. Laceration of a branch of the middle meningeal artery by the sharp bony edges of a skull fracture initiates bleeding under arterial pressure that dissects the dura from the calvaria and produces an expanding hematoma. After an asymptomatic interval of several hours, subfalcine and transtentorial herniation occur, and if the hematoma is not evacuated, lethal Duret hemorrhages will occur.

FIGURE 32-15. Epidural hematoma. A discoid mass of fresh hemorrhage overlies the dura covering frontal–parietal cortex but does not transgress the coronal sutures.

CLINICAL FEATURES: Up to 1/3 of patients do not lose consciousness at the time of the precipitating injury and may have a "lucid interval" of unimpaired consciousness for several hours while epidural blood accumulates under arterial pressure. When the hematoma reaches 30–50 mL, symptoms of a space-occupying lesion appear. Epidural hematomas are invariably progressive and, when not recognized and evacuated, may be fatal in 24–48 hours.

Subdural Hematomas Develop More Slowly Than Epidural Hematomas

Subdural hematomas are a significant cause of death after head injuries from falls, assaults, vehicular accidents and sporting accidents. The hematomas expand more slowly than epidural hematomas, so their clinical tempo is slower, but once critical increased intracranial pressure is attained, clinical deterioration and death can occur with horrific rapidity.

PATHOLOGY: The cerebral hemispheres float in the CSF, tethered loosely by blood vessels and cranial nerves. Blood drains from cerebral hemispheres through veins that cross the subarachnoid space and arachnoid to breach the dura and enter the dural sinus. There is no true subdural space per se, but the inner layer of meningothelial cells of the dura has fewer tight junctions than those in the outer layers of the dura. Shearing forces will separate these cells, allowing blood to seep between them. Since bleeding in this situation is under low venous pressure, it is slow and may stop spontaneously from a local tamponade effect. The bleeding is within the dura itself and readily extends beyond the coronal sutures, causing a hematoma that can extend along the entire anterior to posterior dimensions of the calvarium (Fig. 32-16). Granulation tissue forms in reaction to the blood, and the delicate capillaries of this tissue may themselves leak. This leads to gradual accumulation of an ever enlarging subacute, and ultimately chronic, subdural hematoma.

The blood and granulation tissue are surrounded by a sheet of fibrous connective tissue—the "membranes" of a chronic subdural hematoma. Fibroblasts first create a membrane on the calvarial side of the hematoma, the **outer membrane**. Then they invade the subjacent hematoma to form a fibrous membrane subjacent to the blood clot. This **inner membrane** is visible in about 2 weeks (Fig. 32-17). A subdural hematoma may evolve in three ways. It may (1) be reabsorbed and leave only a small amount of telltale hemosiderin; (2) remain static, and perhaps calcify; or (3) enlarge as a result of recurrent microhemorrhages in the granulation tissue.

Expansion of the hematoma, and onset of symptoms, commonly results from rebleeding, usually within 6 months. Granulation tissue is fragile and so vulnerable to minor trauma, even that caused by shaking the head. Thus, subdural hematomas can rebleed and create a new hematoma subjacent to the outer membrane. Episodes of sporadic rebleeding expand these lesions periodically and at unpredictable intervals. Since the bleeding occurs in the inner dural border cell zone rather than an imaginary subdural space, no blood is seen in the CSF. In addition to granulation tissue and blood, other cellular constituents include plasma cells, lymphocytes and extramedullary hematopoiesis. These may contribute to the cellular dynamics of the subdural hematoma by releasing cytokines and causing cerebral edema in the underlying brain.

CLINICAL FEATURES: Symptoms and signs of subdural hematomas are diverse. Stretching of meninges leads to headaches; pressure on the motor cortex produces contralateral weakness; and focal cortical irritation can initiate seizures. Subdural hematomas are bilateral in 15%–20% of cases, and these may impair cognitive function and lead to a mistaken diagnosis of dementia. Rebleeding with expansion may cause lethal transtentorial herniation (Fig. 32-16A).

Parenchymal Injuries Produce Variable Symptomatology

Traumatic brain and spinal cord injuries range in severity from temporary loss of function with little or no discernible structural damage in concussion, to intermediate damage with hemorrhage and necrosis of the tissue in contusions, to profound disruption of structure and function in lacerations.

Concussion

Concussion is transient loss of consciousness due to biomechanical forces acting on the CNS. A blow that causes an epidural hematoma does not necessarily produce a concussion. Consciousness depends on a functional brainstem reticular formation interacting with the cerebral hemispheres and is lost if either the reticular formation or both hemispheres are damaged. A classic example of concussion occurs in boxing, from a blow that deflects the head upward and posteriorly, often with a rotatory component. These motions impart quick rotational acceleration to the brainstem and cause dysfunction of reticular formation neurons. By contrast, a blow to the temporal–parietal area may cause a skull fracture and lethal epidural hematoma but may not cause loss of consciousness because lateral movement of the cerebral hemispheres does not occur.

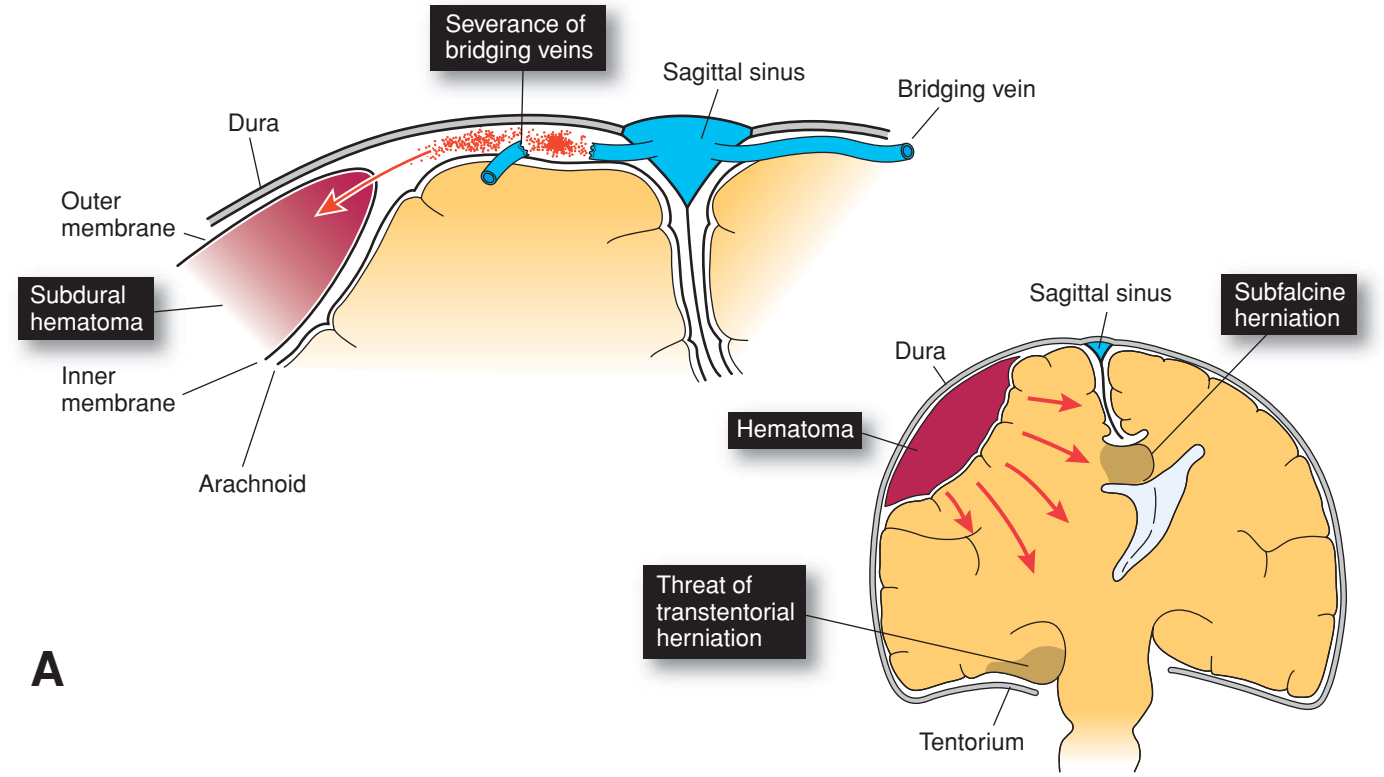

FIGURE 32-16. Development of a subdural hematoma. A. With head trauma, the dura moves with the skull, and the arachnoid moves with the cerebrum. As a result, the bridging veins are sheared as they cross between the dura and the arachnoid. Venous bleeding creates a hematoma in the expansile subdural space. Subsequent transtentorial herniation is life-threatening. **B.** The right hemisphere exhibits a large collection of blood in the "subdural space," owing to rupture of the bridging veins.

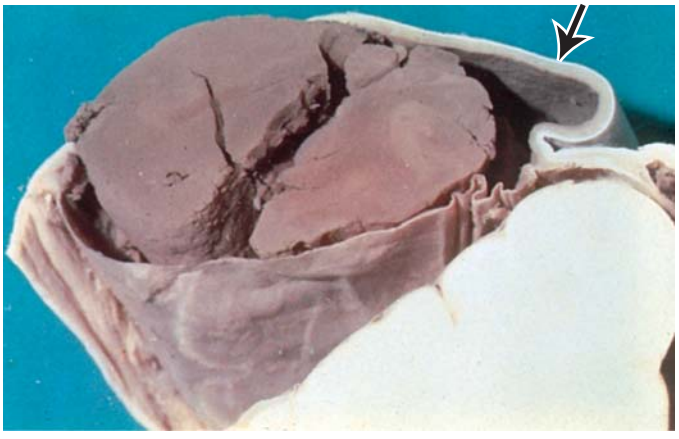

FIGURE 32-17. Chronic subdural hematoma with well-developed surrounding membranes. The thicker membrane (*arrow*) is the exterior membrane and the thinner membrane is adjacent to the brain. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Classically, concussion is not associated with gross neuropathology, and since the condition is not lethal, microscopic examination is not possible. Recent advances in diffusion tensor imaging suggest that axonal injury functionally disconnects the reticular activating system from the cerebral hemispheres. Axonal injury and disconnection may also account for cognitive and memory difficulties, vertigo and the feelings that "things are just not quite right" that bedevil people who have sustained "mild" traumatic brain injury.

Cerebral Contusion

ETIOLOGIC FACTORS: A cerebral contusion is a brain bruise—an area of tissue disruption and blood seepage—usually when the brain strikes the irregular bony contours of the skull because of abrupt acceleration or deceleration. If a moving object strikes the head, acceleration will be imparted to the skull and its delicate cargo, the brain. In contrast, a fall results in an abrupt deceleration.

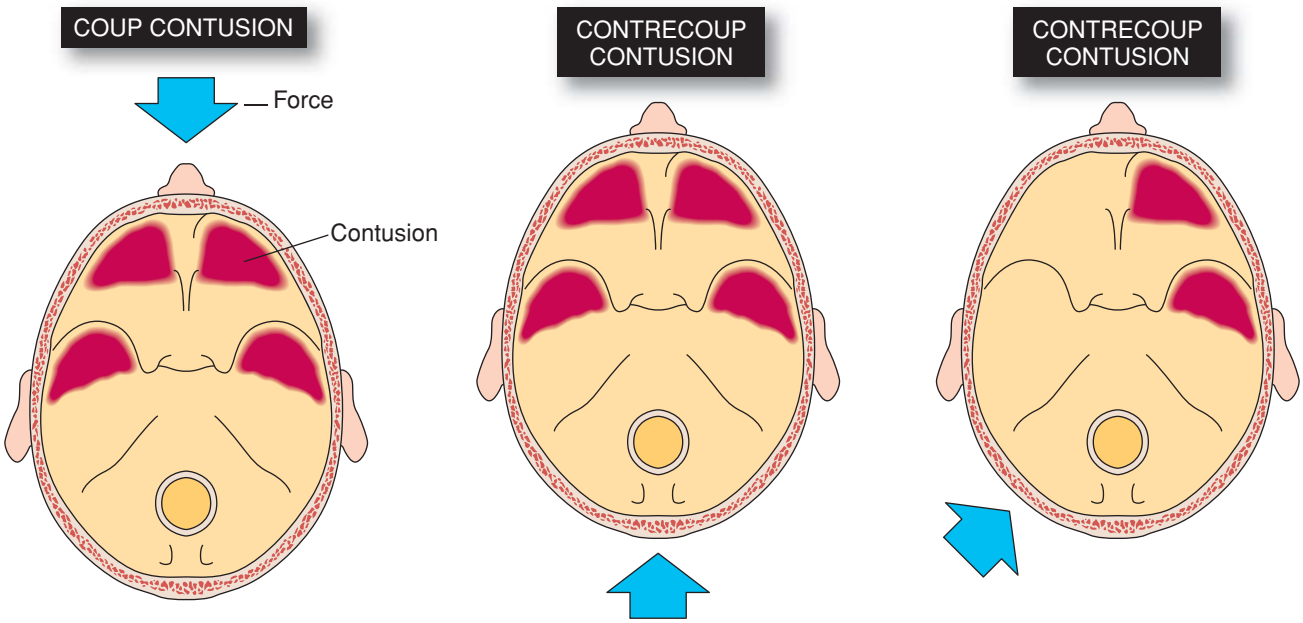

FIGURE 32-18. Biomechanics of cerebral contusion. The cerebral hemispheres float in the cerebrospinal fluid. Rapid deceleration or acceleration of the skull causes the cortex to impact forcefully into the anterior and middle fossae. The position of a contusion is determined by the direction of the force and the intracranial anatomy.

When a contusion occurs at a point of impact, the lesion is a **coup** injury (French, *coup* = "blow") (Fig. 32-18). If the side of the brain opposite the impact site strikes the skull, resulting contusions are contralateral to the point of initial contact **(contrecoup)**. Coup injuries are maximal when the head is stationary and struck by an object, while contrecoup contusions are more severe when the head is in motion and abruptly stops. If an individual is struck by an assailant with a baseball bat, a large coup contusion will be present. In contrast, if a person falls off of a ladder, a large contrecoup contusion results.

PATHOLOGY: If the force of impact is mild, cerebral contusion is limited to the cortex and the crowns of gyri (Fig. 32-19A). Greater force destroys larger expanses of cortex, creating cavitary lesions that may extend into the white matter or lacerate the cortex, causing intraparenchymal hemorrhage (Fig. 32-19B). Together, edema and hemorrhage in a contusion may cause the contusion to expand over several days, which can become life-threatening as a result of increased intracranial pressure.

Contusions leave permanent marks on the brain. Bruised, necrotic tissue is phagocytosed by macrophages and eliminated in large part via the bloodstream. Astrocytosis then leads to local scar formation, which persists as telltale evidence of a prior contusion. Usually some residual hemosiderin imparts an orange brown hue to the old contusion (Fig. 32-20).

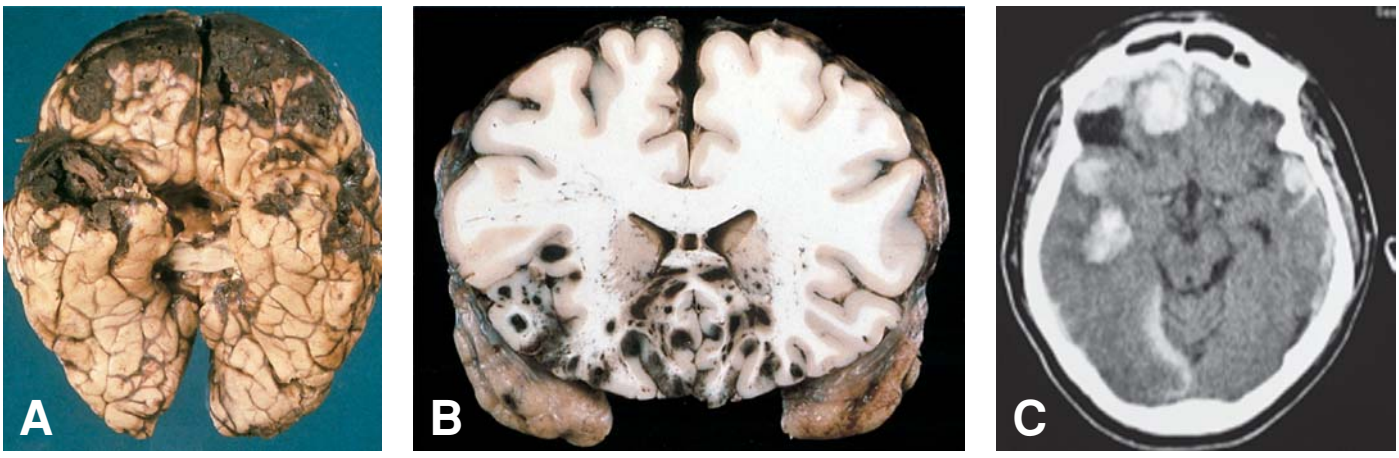

FIGURE 32-19. Acute contusions of the brain. A. After an automobile accident, the brain exhibits necrosis and hemorrhage involving the frontal and temporal lobes. **B.** In addition, there are some underlying white matter hemorrhages. **C.** Axial noncontrast computed tomography showing acute contusions in the basal frontal and temporal tips regions. The hemorrhage is the white signal in the frontal and temporal regions. (A and B Courtesy of Dr. F. Stephen Vogel, Duke University.)

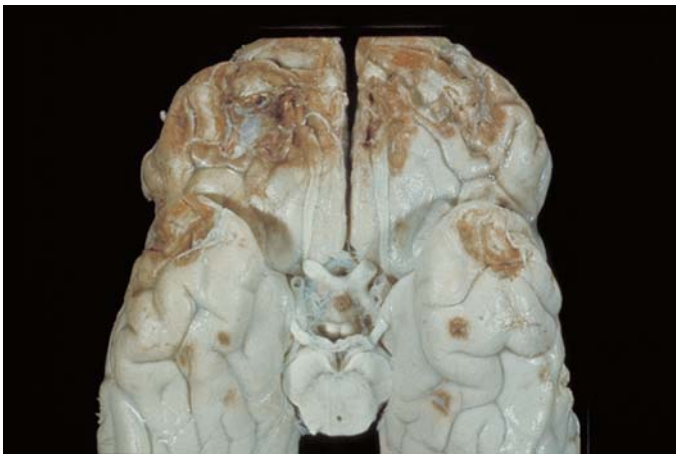

FIGURE 32-20. Remote contusions of the brain. Bilateral large frontal and smaller temporal tip contusions were cleared out by macrophages, leaving residual hemosiderin-stained divots. Also, note the involvement of the olfactory bulbs—anosmia (loss of sense of smell) is the most common cranial neuropathy following traumatic brain injury.

Diffuse Axonal Injury

Diffuse axonal injury (DAI) is a very common result of traumatic brain injury and may lead to severe neurologic deficits and coma in patients without gross hematomas, contusions or lacerations. Advances in imaging techniques allow better detection and quantification of these injuries, which are major contributors to morbidity and mortality. There is also increased interest in DAI as part of blast injuries.

ETIOLOGIC FACTORS: The parasagittal cerebral hemispheres are anchored to arachnoid villi **(pacchionian granulations),** while the lateral aspects of the cerebrum move more freely. This anatomic feature, together with the differential density of gray and white matter, allows for shearing forces between different brain regions, leading to axonal shearing injuries. Shearing injuries can distort or disrupt axons, causing immediate loss of function. Experimental studies indicate that diffuse axonal injury evolves over hours to days, so axons may be injured at the time of primary injury, with impaired axonal transport and cytoskeletal disruption leading to accumulation of axoplasm at sites of injury. Then, physical separation leads axons to form axonal retraction spheroids. Since diffuse axonal injury evolves over time, rather than being a catastrophic event leading to immediately severed axons, it may be possible to arrest its progression and preserve axonal structural integrity. If an injury is severe, the functional loss of axonal activity may immediately render the patient comatose, but imaging may show only small hemorrhages and focal edema, particularly in the corpus callosum and midbrain. However, more widely distributed axonal swelling and retraction spheroids may be seen in cerebral white matter, corpus callosum and brainstem. These can be highlighted by immunostaining for amyloid precursor protein (APP), which is normally transported along axons and accumulates at sites of injury where transport is impaired. Diffusion tensor imaging (DTI), a specialized magnetic resonance imaging (MRI) technique, detects and quantifies DAI.

Chronic Traumatic Encephalopathy

Acute traumatic brain injury has long been the primary focus of neurotrauma research, but long-term effects are now receiving overdue attention as large numbers of military service members return from Iraq and Afghanistan. In addition, the possible long-term neurodegenerative effects of repetitive head injury in sports—specifically chronic traumatic encephalopathy—has raised major concern in professional and amateur athletics. In 1928, it was recognized that boxers with repetitive head injury developed dementia and their brains showed neuronal loss and neurofibrillary tangles.

This disorder, initially named "dementia pugilistica" but now called chronic traumatic encephalopathy (CTE), occurs in nonboxers experiencing varying degrees of repetitive head injury. Younger people (ages 20–40) tend to have a rapidly progressive course primarily involving behavioral and mood changes, while older people (ages 50–70) have slower disease progression involving primarily cognitive difficulties. There is a spectrum of abnormalities in individuals with CTE.

PATHOLOGY: The most distinctive finding is deposition of tau in neurons at the depths of sulci and around blood vessels. Abnormal tau accumulation occurs in many neurodegenerative diseases, including Alzheimer disease, frontotemporal lobar degeneration and progressive supranuclear palsy, among others, but it is the distribution of neurofibrillary tangles in CTE that is unique. CTE may represent a mechanistic bridge between acute injury and progressive neurodegenerative disease.

Penetrating Traumatic Brain Injury

PATHOPHYSIOLOGY: Penetrating objects like bullets and knives enter the cranium and traverse the brain with variable velocities. If there is no direct damage to vital brain centers, hemorrhage is the immediate threat to life (Fig. 32-21).

The damage a projectile does depends on how much kinetic energy is involved ($E = mv^2$, where m = mass and v = velocity). Thus, projectile velocity is the key determinant of injury. The kinetic energy of a high-velocity bullet directly disrupts tissues by its own mass as well as by a centrifugal blast zone whose diameter is determined by the projectile's original kinetic energy. Thus, a high-velocity bullet can cause an explosive increase in intracranial pressure, which forcefully herniates the cerebellar tonsils into the foramen magnum, causing immediate death.

Spinal Cord Injury

ETIOLOGIC FACTORS: Traumatic lesions of the spinal cord may result from direct injury by penetrating wounds (e.g., stab wounds, bullets) or indirect injury from vertebral fractures or displacement. The spinal cord may be contused not only at the site of injury but also above and below the point of trauma. Compromised arterial supply to the cord, with resulting infarction, may complicate traumatic injury.

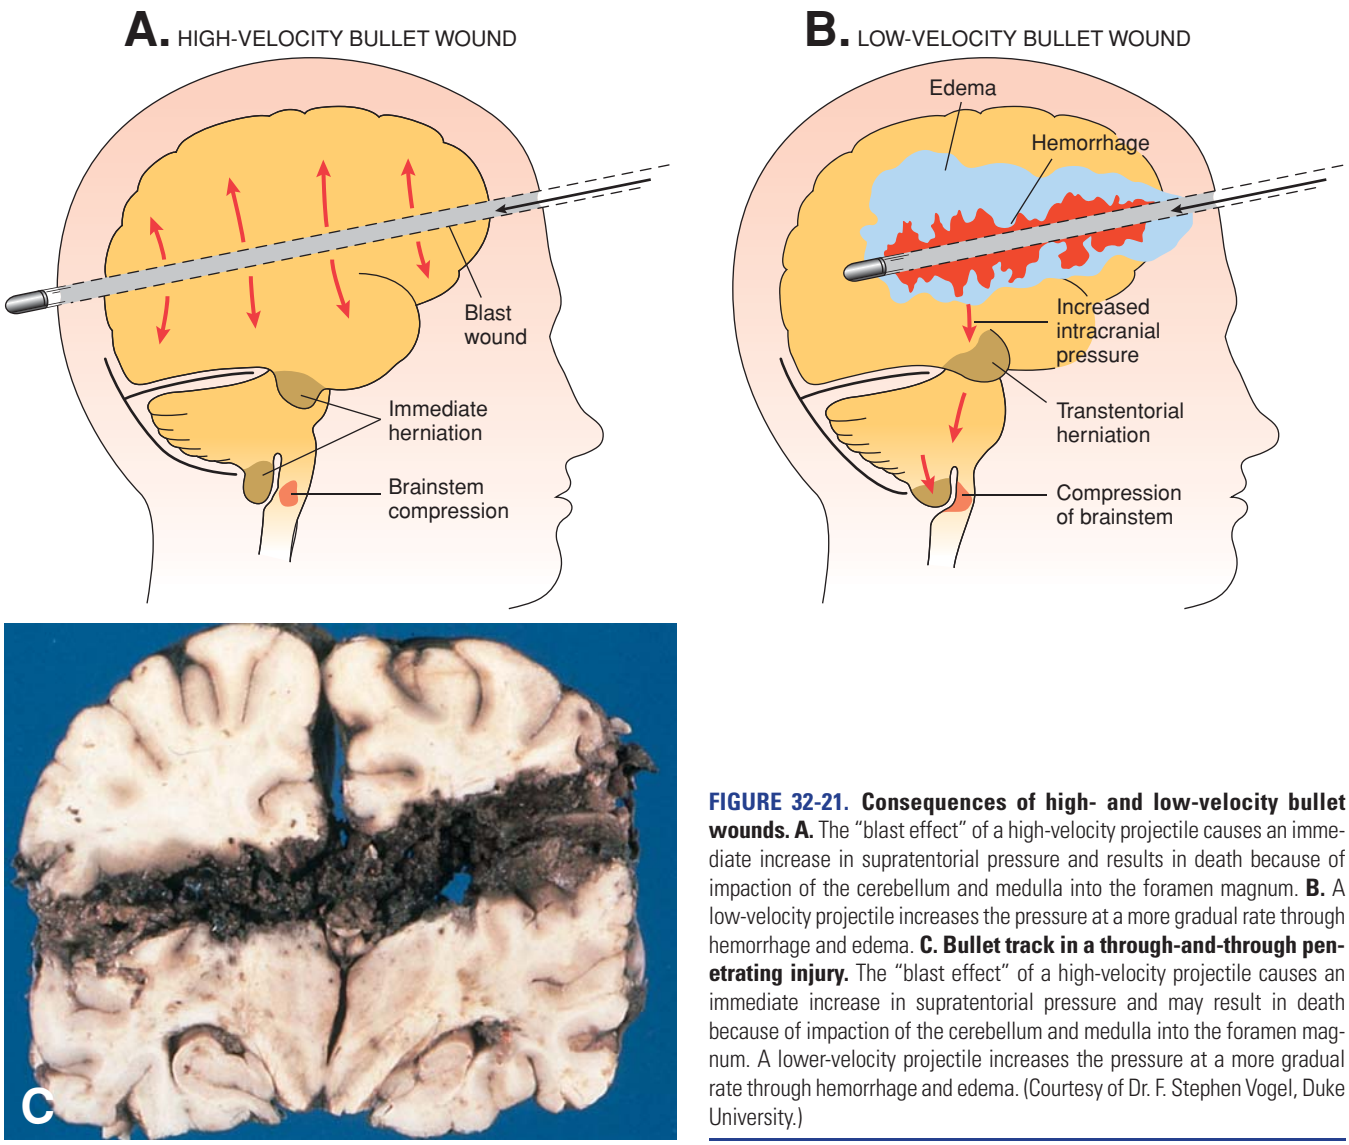

FIGURE 32-21. Consequences of high- and low-velocity bullet wounds. A. The "blast effect" of a high-velocity projectile causes an immediate increase in supratentorial pressure and results in death because of impaction of the cerebellum and medulla into the foramen magnum. **B.** A low-velocity projectile increases the pressure at a more gradual rate through hemorrhage and edema. **C. Bullet track in a through-and-through penetrating injury.** The "blast effect" of a high-velocity projectile causes an immediate increase in supratentorial pressure and may result in death because of impaction of the cerebellum and medulla into the foramen magnum. A lower-velocity projectile increases the pressure at a more gradual rate through hemorrhage and edema. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Vertebral bodies are separated by intravertebral disks and are stabilized in normal alignment by two longitudinal ligaments and the posterior bony processes. The anterior spinal ligament adheres to the ventral surface of the vertebral bodies, while the posterior spinal ligament is affixed to the dorsal vertebral column. After extreme flexion or extension, the angulation of the bony vertebral column brings the spinal cord forcefully into contact with bone or interferes with regional circulation.

The consequences of a spinal cord injury depend on the severity of the trauma. **Spinal cord concussion** is the mildest injury, with transient, reversible functional disturbance. **Contusion of the spinal cord** results from more severe trauma, varying from minor transient bruises to hemorrhagic spinal cord necrosis (Fig. 32-22). Spinal cord necrosis and edema due to severe contusion are **myelomalacia.** A hematoma within the cord is a **hematomyelia. Lacerations and transections of the spinal cord** are usually caused by penetrating wounds or severely displaced spinal fractures. They are irreversible and lead to complete loss of function below the spinal level of the injury. Whether paralysis affects only the legs **(paraplegia)** or all four extremities **(quadriplegia)** depends on the spinal level and extent of the injury. If even as little as 10%–15% of the cross-sectional diameter of the spinal cord is spared, functional recovery is much better than with complete transection.

Neurotrauma is a process, not an event. The initial transfer of kinetic injury sets into motion a cascade of secondary injury mechanisms. Mitigation of secondary injury and facilitation of recovery continue to be major thrusts in neurotrauma.

CEREBROVASCULAR DISORDERS

Stroke is the third leading cause of death in the United States, after myocardial infarction and cancer. As elsewhere, vascular disease can result from either vessel blockage, causing ischemia, or vascular leakage that results in hemorrhage. Vascular disorders of the nervous system lead to (1) globally or focally inadequate blood flow (ischemia), which, if sufficiently protracted, produces infarction; or (2) rupture of vascular structures that causes either intraparenchymal or subarachnoid hemorrhage.

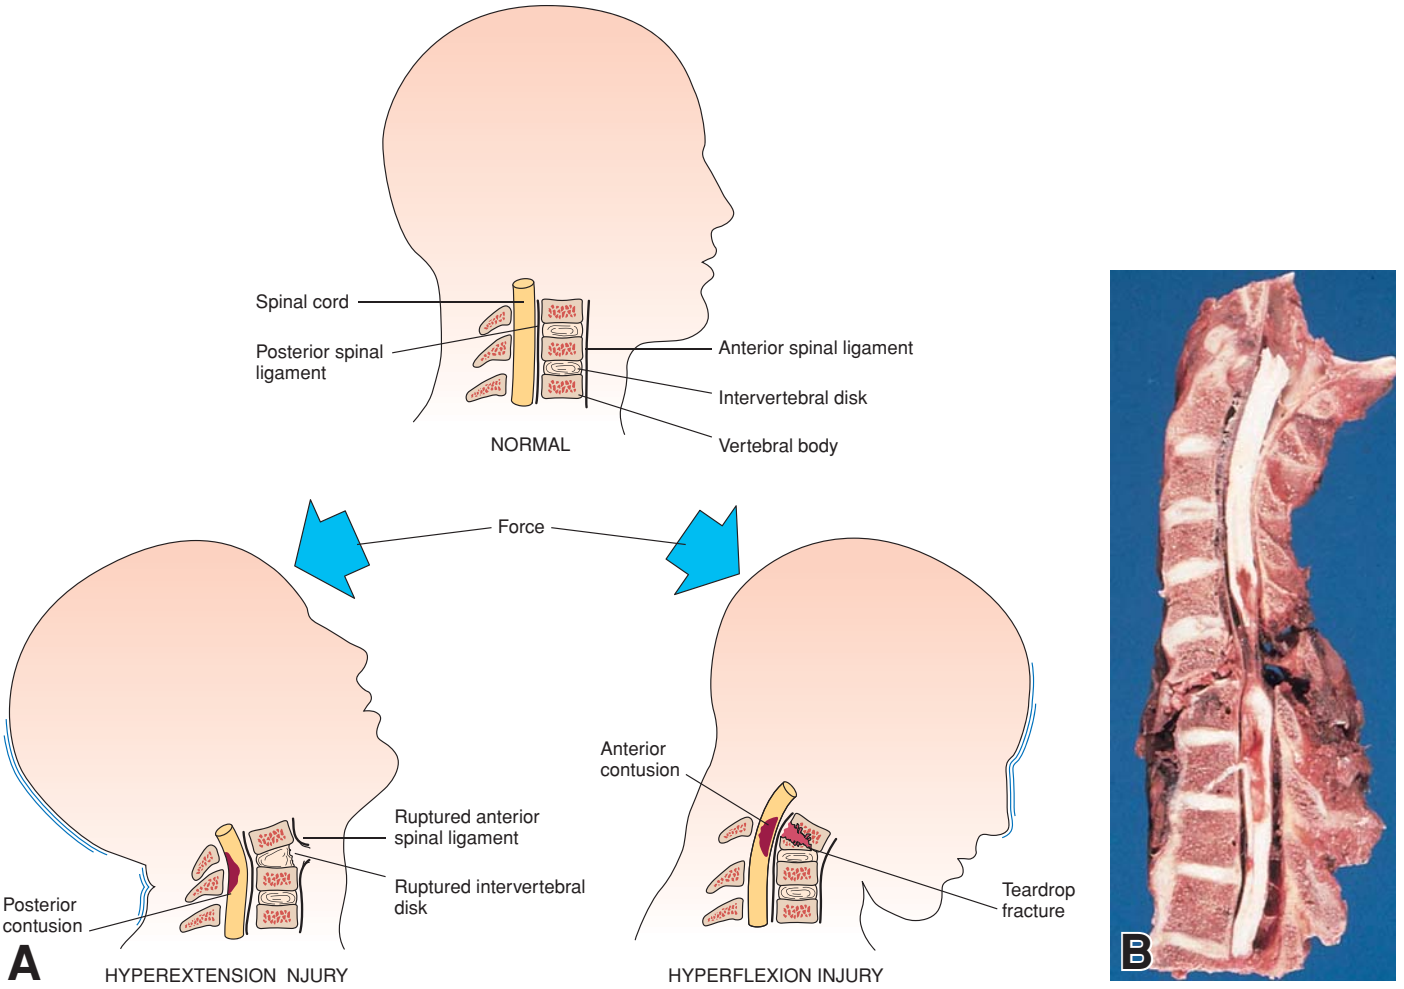

FIGURE 32-22. Spinal injury. A. Numerous different angles of force can be applied to the highly vulnerable cervical spine. Posterior (hyperextension) and anterior (hyperflexion) injuries are the most common. Hyperextension injury causes rupture of the anterior spinal ligament and excessive posterior angulation. Hyperflexion injury causes compression associated with a "teardrop" fracture of a vertebral body and produces excessive forward angulation of the cord. **B.** Fracture dislocation of the spinal column may result in spinal cord contusion, laceration, necrosis or frank transection. Preservation of a relatively small cross-sectional area of the spinal cord can have major beneficial effects on recovery. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Ischemic Stroke Often Follows Shock

ETIOLOGIC FACTORS: The brain receives about 20% of basal cardiac output. Aerobic glycolysis is virtually the sole source of energy of the mature brain. CNS glycogen reserves are meager and oxygen reserves are nil; hence, uninterrupted supply of oxygenated blood is essential for brain integrity. The brain's blood supply comes via paired internal carotid and vertebral arteries. The carotids, the "anterior circulation," supply most superficial and deep cerebral hemisphere structures; the vertebral arteries make up the "posterior circulation," feeding the brainstem, cerebellum and territory of the posterior cerebral arteries. The posterior and anterior circuits anastomose via the circle of Willis. This anastomotic network at the base of the brain is quite variable, but in some fortunate individuals, the blood supply of the brain is sufficiently redundant that complete blockage of two carotids and one vertebral can be asymptomatic. Despite these elaborate hemodynamic precautions, many people experience global or focal ischemia leading to cerebral infarction.

Global ischemia, which is usually due to cardiopulmonary arrest or extreme hypotension in severe shock, leads to widespread tissue injury, resulting in ischemic encephalopathy. If perfusion failure is brief (minutes), neurologic functions may quickly be restored with only transient postischemic confusion. Some patients may come back more slowly and suffer subtle higher intellectual function impairments, which may preclude complete resumption of societal activities. More severe injury may lead to dementia and spasticity. If the ischemic period is protracted, the patient may not regain consciousness and may show decorticate posturing and seizures and be in a coma indefinitely.

Although the entire brain is inadequately perfused, there is surprising focality to the pathologic alterations. Certain cell populations are most vulnerable to ischemic injury: the large neurons in the Sommer sector of the hippocampus, Purkinje cells of the cerebellum and neurons of layers 3 and 5 of the cerebral cortex (Fig. 32-23).

The basis of this selective vulnerability is not clear. It may be related to local metabolic requirements, hemodynamic factors and local neurotransmitters. When ischemia leads to brain energy failure, membranes depolarize, permitting uncontrolled release of the amino acid neurotransmitters glutamate and aspartate. These bind ligand-gated cation

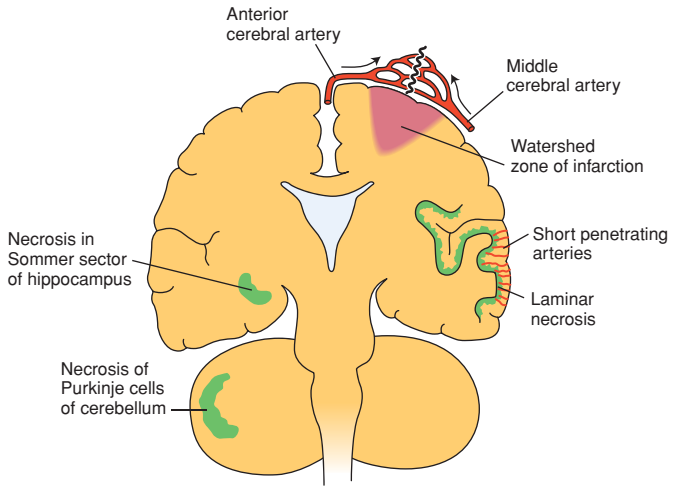

FIGURE 32-23. Mechanisms of injury in global ischemia. A global insult induces lesions that reflect the vascular architecture (watershed infarcts, laminar necrosis) and the selective vulnerability of individual neuronal systems (pyramidal cells of the Sommer sector, Purkinje cells, laminar necrosis). Both rheologic (blood flow) and neurochemical (excitotoxicity) factors may be operational in laminar necrosis.

channels on postsynaptic cells, opening the floodgates for calcium and sodium entry. The latter depolarizes the cell membrane.

Calcium may activate intracellular proteases and quench mitochondrial energy production, propagating the energy failure and magnifying cellular injury. Injury done by abnormally released neurotransmitters is **excitotoxicity,** which may play a role in neurodegenerative disorders, epilepsy and stroke. In excitotoxicity, the areas of brain injury depend on the local use of toxic neurotransmitters. For example, high levels of amino acid neurotransmitters make the midcortex more vulnerable to ischemic injury, resulting in a midcortical band of necrosis with relatively preserved cortex in deep and superficial layers on either side of this band. As infarcted tissue is infiltrated by macrophages, it becomes grossly conspicuous as **laminar necrosis** (Fig. 32-24).

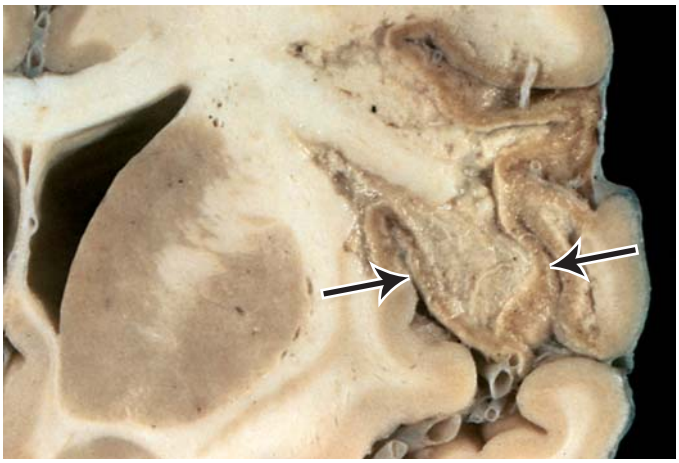

FIGURE 32-24. Laminar necrosis. A patient who suffered prolonged anoxia during a cardiac arrhythmia developed selective necrosis of layers in the cerebral cortex (*arrows*). (Courtesy of Dr. F. Stephen Vogel, Duke University.)

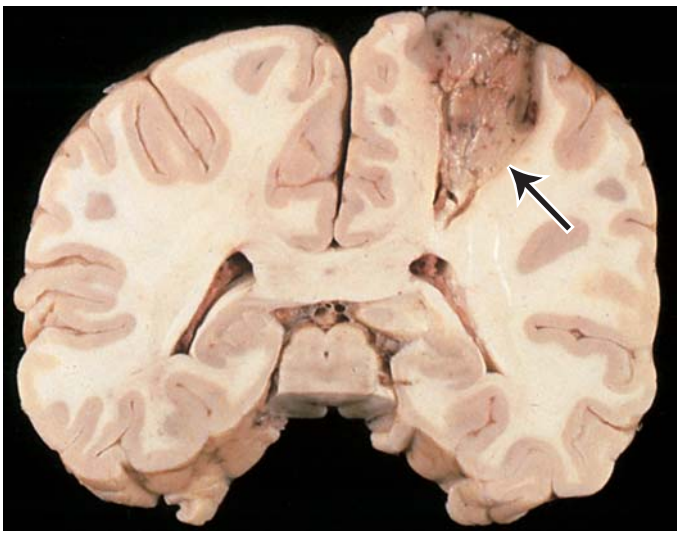

FIGURE 32-25. Watershed infarct. In global hypoperfusion, the most precarious perfusion zones are at the distal overlapping portions of the major cerebral vessels. Here an acute infarct is seen at the watershed of the anterior and middle cerebral arteries (*arrow*). (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Hemodynamic factors cause **watershed** or **border-zone infarcts,** which occur at junctions of major arterial supply zones (Fig. 32-25). These zones are at the precarious distal regions of arterial supply. If perfusion pressure drops, these are the first areas affected. The classic border zone lies between the anterior and middle cerebral arteries' distal territories (Fig. 32-25). With global ischemia, this area in both hemispheres may be infarcted, leading to symmetric wedge-shaped parasagittal high-convexity infarcts.

Regional Ischemia Causes Localized Cerebral Infarction

Cerebrovascular occlusive disease remains a major cause of morbidity and death because atherosclerosis is ubiquitous and progressive. ***Atherosclerosis predisposes to vascular thrombosis and embolism, both of which result in localized ischemia and subsequent cerebral infarction.***

ETIOLOGIC FACTORS: Cerebral infarcts are usually designated **hemorrhagic** or **bland**. ***In general, infarcts caused by emboli are hemorrhagic, while those due to local thrombosis are ischemic (i.e., bland).*** Emboli occlude vascular flow abruptly, after which the distal segments of affected blood vessels lose integrity and leak blood into the region during reperfusion (Fig. 32-26A). Atherosclerotic plaques in the common and internal carotid arteries may lead to emboli. But the heart is also a rich source of emboli. These may derive from infected or defective valves, hypokinetic thrombogenic endocardial walls after myocardial infarction or atrial thrombi in atrial fibrillation, especially if there is associated mitral insufficiency. Fat emboli and deep vein thrombi from the systemic venous circulation may embolize paradoxically through a patent foramen ovale. Emboli of amniotic fluid or tumors (e.g., from atrial myxomas) occur but are rare.

FIGURE 32-26. A. Distribution of cerebral infarcts. The normal distribution of the cerebral vasculature defines the pattern and size of infarcts and, consequently, their symptoms. Occlusion at the trifurcation causes cortical infarcts with motor and sensory loss and often aphasia. Occlusion of a striate branch transects the internal capsule and causes a motor deficit. **B. Acute middle cerebral artery distribution infarct.** An axial section of the brain of a patient who suffered thrombosis of the middle cerebral artery reveals a large infarct of the right hemisphere (*between arrows*) with swelling and focal dusky discoloration. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

PATHOLOGY: Most infarcts caused by thrombosis are anemic or bland and are difficult to see grossly for several hours, after which softening and discoloration are increasingly prominent (Fig. 32-26B). Swelling and liquefaction follow within 3–5 days, when the patient is in danger from the mass effect of the infarct. The infarct then matures over weeks to months into a cystic space (Fig. 32-27), sometimes accompanied by compensatory ventricular enlargement. If blood flow is restored to a bland infarct, as may occur in embolic or compressive vascular disease, blood may seep into the softened tissues. This may cause a hemorrhagic infarct, which is readily discernible grossly and radiologically (Fig. 32-28).

As in other tissues, an orderly procession of pathologic changes allows estimation of an infarct's age. If a patient survives for minutes to several hours, no changes are seen. If the patient survives for 6–24 hours, the infarct is slightly discolored and softened with blurring of the border between gray and white matter. Shrunken eosinophilic neurons ("red neurons") with nuclear pyknosis are present in the infarct (Fig. 32-29). These changes become more pronounced as the infarct ages. By 24–72 hours, neutrophils infiltrate the tissue and blood vessels are prominent. The tissue is soft and edematous and may be sufficiently swollen to cause lethal mass effect.

By 3–4 days, macrophages replace neutrophils and clear debris in the infarct at a rate of about 1 mL per month. The infarct is now frankly mushy. In the second week, proliferating astrocytes join the macrophages. Over weeks to months, these astrocytes form a dense fibrillary glial meshwork around the dead tissue. The macrophages dispose of debris in the infarct over weeks to months. Simultaneously, the infarct evolves into a glial lined cyst, crossed at points by delicate glial sheets and small vessels and invested with residual lipid and hemosiderin-laden macrophages.

CLINICAL FEATURES: The diversity of neurologic deficits caused by strokes reflects the functional eloquence of the brain. For example, the lengthy and slender striate arteries, which take origin from the proximal middle cerebral artery, are commonly occluded by atherosclerosis and thrombosis. Resultant infarcts often impact the internal capsule to produce hemiplegia (Fig. 32-26A). Similarly, the middle cerebral artery trifurcation is a favored site for lodgment of emboli and for thrombosis due to atherosclerosis. Middle cerebral artery occlusion at this site deprives much of the lateral hemispheric cortex of blood, producing motor and sensory deficits. If the dominant hemisphere is involved, aphasia may develop.

Localized ischemia may be associated with three distinct clinical syndromes:

- **Transient ischemic attack (TIA)** is focal cerebral dysfunction, lasting under 24 hours, and often only a few minutes. Although complete neurologic recovery follows, TIA heralds increased risk of cerebral infarction. TIAs, like angina, are warnings that all is not well with the cerebral blood supply. Their occurrence often triggers diagnostic and therapeutic activity. A patient with TIAs is at risk for later cerebral infarction; about 1/3 of patients with TIAs will have a stroke within 5 years. The period of highest risk is the first 30 days after TIAs begin; in 1/3 of patients,

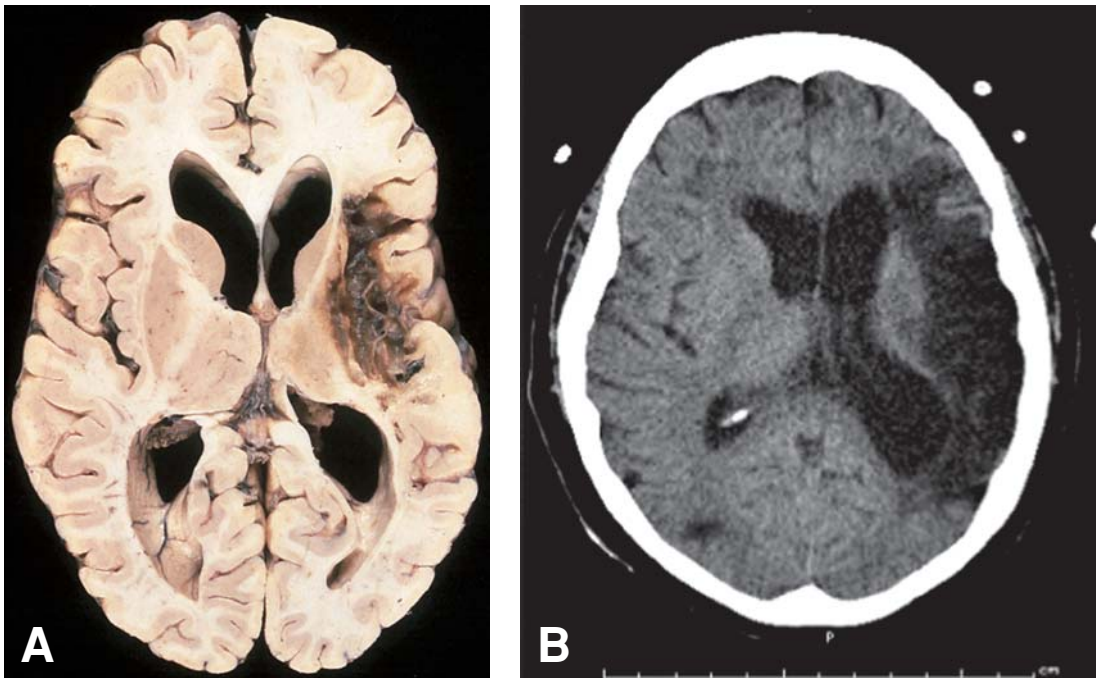

FIGURE 32-27. A. Remote middle cerebral artery distribution infarct. An axial section of the brain shows a remote middle cerebral artery distribution cystic infarct. The brain in Fig. 28-26B would transform to this state as a result of clearing out of the large infarct by macrophages. (Courtesy of Dr. F. Stephen Vogel, Duke University.) **B.** Axial noncontrast computed tomography showing a remote middle cerebral artery distribution infarct resulting from a cardiogenic embolus. Note the low signal in the middle cerebral artery territory and the compensatory enlargement of the ventricles.

the TIAs will simply continue; and about 1/3 of patients will have no more TIAs, nor will they suffer a stroke. ***TIAs often are harbingers of a stroke, but many people (50%–85%) who develop cerebral infarcts never have a preceding TIA.*** If a TIA lasts more than a few minutes, some tissue damage occurs as evidenced by MRI abnormalities on diffusion water inversion (DWI) sequences.

- **Stroke in evolution** describes the often stuttering progression of neurologic symptoms as a patient is being observed. This clinically unstable situation reflects propagation of a thrombus in the carotid or basilar arteries and necessitates urgent treatment.
- **Completed stroke** describes a stable or fixed neurologic deficit caused by a cerebral infarct. Two to three days after a completed stroke, there can be sufficient cerebral cytotoxic and vasogenic edema in the infarct that increased intracranial pressure and herniation become issues.

Our improved understanding of the basic pathophysiology of stroke has resulted in major advances in diagnosis and therapeutic intervention operating in a critical time window.

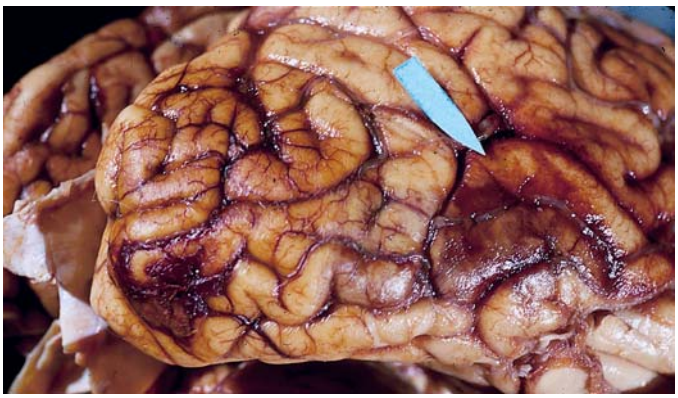

FIGURE 32-28. Hemorrhagic embolic infarct. Emboli from a carotid endarterectomy resulted in hemorrhagic infarcts in the territory of the middle cerebral artery (*arrow*). Such hemorrhagic infarcts may expand because of seepage of blood or frank hemorrhage and become life-threatening.

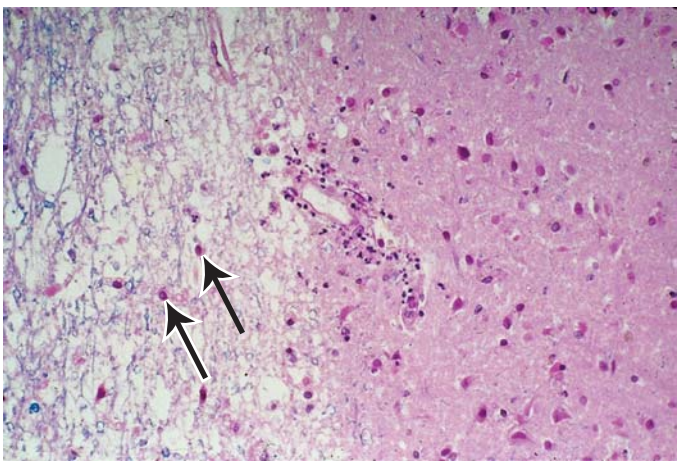

FIGURE 32-29. Acute cerebral infarct histopathology. An 18-hour-old cerebral infarct (*left*) shows edema, hypereosinophilic neurons and perivascular polymorphonuclear leukocytes. Pyknotic nuclei of dying neurons are shown (*arrows*).

Efforts directed at restoring circulation pharmacologically and through endovascular intervention are extremely promising, as are efforts to salvage vulnerable tissue through the use of neuroprotectant maneuvers.

Regional Occlusive Cerebrovascular Disease

PATHOLOGY: The various occlusive cerebrovascular diseases that lead to cerebral infarcts may be classified by the caliber and nature of the vessel involved.

LARGE EXTRACRANIAL AND INTRACRANIAL ARTERIES: These arteries are often sites of atherosclerosis. Most notably, atherosclerotic plaques occur frequently in the common carotid artery at its bifurcation into external and internal branches. Occlusion or stenosis of an internal carotid artery affects the ipsilateral hemisphere, but this can be offset by variable collateral circulation through the anterior and posterior communicating arteries. Usually, carotid artery occlusion produces infarcts limited to all or part of the distribution of the middle cerebral artery. The consequences of large vessel disease depend on the configuration of the circle of Willis. Thus, a large anterior communicating artery can furnish collateral circulation to a frontal lobe whose blood supply is compromised by internal carotid artery occlusion. The middle cerebral artery is most often occluded by thrombosis complicating atherosclerosis in the circle of Willis. As a major stepdown in vascular caliber occurs at the trifurcation of the middle cerebral artery, this is the main site occluded by emboli.

While atherosclerosis is the primary substrate of ischemic stroke, both arterial dissection and vasculitis may also lead to stroke.

PARENCHYMAL ARTERIES AND ARTERIOLES: These vessels are less often severely atherosclerotic, but they are damaged by hypertension and can be narrowed by atherosclerosis. This causes small infarcts in the territories of the deep penetrating vessels. These **lacunar infarcts** are usually less than 15 mm. Depending on the functions of the small region supplied, symptoms can range from none to profound—contralateral hemiparesis from an infarct in the internal capsule or pure hemisensory loss caused by a thalamic lacunar infarct. When multiple, these minute infarcts can lead to impaired cognition, called **multiple infarct dementia**.

Hypertensive encephalopathy describes the acute neurologic complications of malignant hypertension. As in other affected organs, malignant hypertension can cause fibrinoid necrosis of small arteries and arterioles, as well as minute hemorrhages **(petechiae)**. Cerebral edema may complicate the vascular pathology. Hypertensive encephalopathy usually presents as headache and vomiting that progress to coma and death. With modern antihypertensive therapy, malignant hypertension is uncommon.

MICROCIRCULATION: Small emboli, composed, for example, of fat or air, may occlude capillaries. **Fat emboli,** usually from fractured bones, travel through cerebral vessels until the size of the emboli exceeds that of the blood vessel, at which point they lodge and block blood flow. The distal capillary endothelium becomes hypoxic and permeable, and petechiae develop, mostly in the white matter (Fig. 32-30). **Air emboli** liberate many bubbles that further fragment as they encounter vascular bifurcations, until they impede vascular flow in small blood vessels. In this situation, petechiae are less restricted to white matter than those caused by fat emboli.

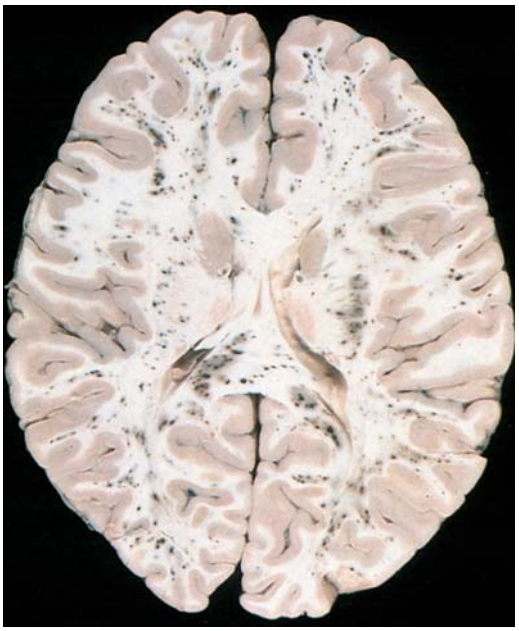

FIGURE 32-30. Fat emboli. An axial section of the brain in a patient with polytrauma with multiple bone fractures leading to cerebral fat emboli manifested by numerous small petechiae throughout the white matter where the small emboli lodge in the microcirculation. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

VENOUS CIRCULATION: The cerebral veins empty into large venous sinuses, the largest of which is the sagittal sinus, which accommodates venous drainage from the superior aspects of the cerebral hemispheres. Venous sinus thrombosis in the brain is a potentially lethal complication of systemic dehydration, phlebitis caused by adjacent infections like mastoiditis, obstruction by a neoplasm such as a meningioma or sickle cell disease. Since venous obstruction causes stagnation upstream, abrupt sagittal sinus thrombosis leads to bilateral frontal lobe region hemorrhagic infarction (Fig. 32-31). More protracted occlusion of the sinus (e.g., due to invasion by a meningioma) allows recruitment of collateral circulation through the inferior sagittal sinus, which lies at the lower edge of the falx and empties into the straight sinus.

Intracranial Hemorrhage Can Be Intraparenchymal or in the Subarachnoid Space

ETIOLOGIC FACTORS: Intraparenchymal hemorrhage is called intracerebral hemorrhage and usually results from rupture of small fragile vessels or vascular malformations. Subarachnoid hemorrhage is mostly caused by rupture of aneurysms or vascular malformations.

Intracerebral Hemorrhage

PATHOLOGY: Cerebral hemorrhages that occur without trauma are usually caused by vascular malformations or are due to long-standing hypertension. **Hypertensive intracerebral hemorrhage (ICH)** occurs at preferential sites, which in order of frequency are

FIGURE 32-31. Superior sagittal sinus thrombosis. Upon opening of the superior sagittal sinus, a thrombus filling the sinus is seen. The thrombus impeded venous drainage of the cerebral hemisphere, leading to bilateral hemorrhagic infarcts of the cerebral hemispheres. Venous thrombosis is seen in hypercoagulable states such as dehydration, pregnancy, hereditary defects of thrombolysis, sickle cell disease or extension of an infection or neoplasm into the sinus. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

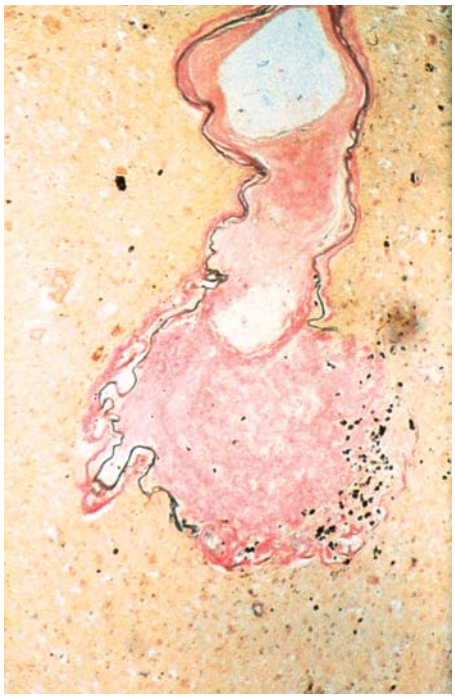

FIGURE 32-32. Charcot-Bouchard aneurysm. The combination of small penetrating cerebral vessels and high perfusion pressure leads to small microaneurysms that may rupture, leading to intracerebral hemorrhage. Effective treatment of hypertension reduces the formation of microaneurysms and the frequency of intracerebral hemorrhage. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

(1) basal ganglia–thalamus (65%), (2) pons (15%) and (3) cerebellum (8%). Hypertensive ICH can also occur in the white matter of cerebral hemispheres, where it is called **lobar ICH**. Lobar ICH should suggest possible amyloid angiopathy, vascular malformation, coagulopathy or bleeding into a tumor, as well as simple hypertensive hemorrhage.

Hypertension compromises the integrity of cerebral arterioles by causing lipid and hyaline material to deposit in their walls: **lipohyalinosis**. Weakening of the wall leads to formation of **Charcot-Bouchard aneurysms,** which occur mainly along the trunk of an arteriole rather than sites where it bifurcates (Fig. 32-32).

CLINICAL FEATURES: The onset of symptoms of a hypertensive cerebral hemorrhage is abrupt. A patient may clutch his head complaining of severe headache and lapse into coma. Basal ganglion hypertensive intracerebral hemorrhages may cause contralateral hemiparesis. If a hematoma progressively expands, as is common in the first day, death may occur when it reaches a critical volume of about 30 mL. An enlarging hematoma may cause death by transtentorial herniation. Rupture into a lateral ventricle may lead to massive intraventricular hemorrhage (Fig. 32-33).

INTRAVENTRICULAR HEMORRHAGE: Extension of the ICH into a ventricle rapidly distends the entire ventricular system with blood, including the fourth ventricle (Fig. 32-34). The blood may emerge from the foramina of Magendie and Luschka. Death may result from distention of the fourth ventricle and compression of vital centers in the

FIGURE 32-33. Intracerebral hemorrhage in the basal ganglia. A hypertensive patient bled into the basal ganglia, resulting in acute severe headache, contralateral hemiparesis and rapid decline in level of consciousness. The deep cerebral nuclei (basal ganglia) and thalamus are the most common locations of intracerebral hemorrhages. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

FIGURE 32-34. Intraventricular hemorrhage. A sagittal section of the brain shows ventricular chambers filled with blood that extended from a more anterior basal ganglionic intracerebral hemorrhage. The patient died rapidly from compression of the brainstem by blood in the fourth ventricle.

FIGURE 32-36. Cerebellar hemorrhage. Intracerebral hemorrhage in the cerebellum leads to acute-onset occipital headache, nausea, vomiting, vertigo and ataxia. If the hematoma expands rapidly, fatal compression of the medulla may ensue. Surgical evacuation of the cerebellar intracranial hemorrhage can be life saving and is a neurosurgical emergency. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

medulla. Ventricular drainage allows reduction of intracranial pressure and removal of intraventricular blood.

PONTINE HEMORRHAGE: In this catastrophic event, loss of consciousness reflects damage to the reticular formation, an injury that overshadows all other specific cranial nerve deficits. The hemorrhage generally starts in the midpons (Fig. 32-35). It encroaches upon vital medullary centers with minimal enlargement, commonly causing death or severe disability.

CEREBELLAR HEMORRHAGE: Bleeding into the cerebellum leads to abrupt ataxia with a severe occipital headache and vomiting (Fig. 32-36). The expanding hematoma threatens life acutely by compressing the medulla or via cerebellar herniation through the foramen magnum. Surgical evacuation of the hematoma is life saving and may leave few serious neurologic deficits, while surgical intervention for intracerebral hematomas in other locations has little or no demonstrated benefit.

Causes of spontaneous cerebral hemorrhages other than hypertension include leakage from an arteriovenous malformation, erosion of a blood vessel by a primary or secondary neoplasm, endothelial injury such as occurs in rickettsial infections, a bleeding diathesis or embolic infarction with consequent hemorrhage into the area of necrosis (hemorrhagic conversion).

AMYLOID ANGIOPATHY: This vascular change results from deposition of β-amyloid protein in vascular walls, rendering them weak and friable (Fig. 32-37). Small

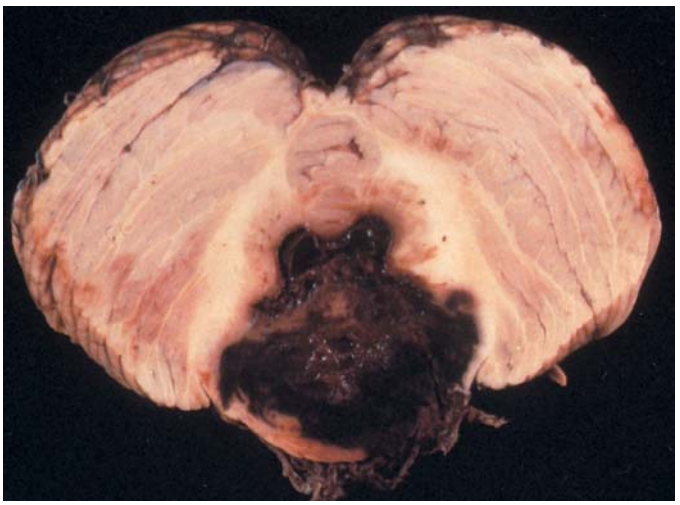

FIGURE 32-35. Pontine hemorrhage. Rupture of microaneurysms in the pons leads to rapid decline in level of consciousness as a result of disruption of the reticular activating system. Multiple cranial neuropathies, dysconjugate gaze, pupillary abnormalities, paralysis and dysregulation of respiration and cardiovascular systems are common. This is the second most common location of intracranial hemorrhage, and hemorrhage in the pons is often lethal. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

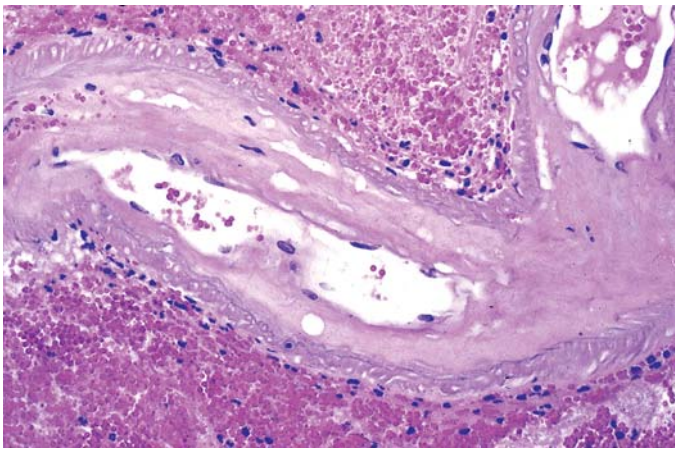

FIGURE 32-37. Amyloid angiopathy. While hypertension is the most common cause of intracerebral hemorrhage in the classic locations—basal ganglia and thalamus, pons and cerebellum—hemorrhage in the white matter of the cerebral hemispheres has a broader range of possible etiologies. These hemorrhages, called lobar hemorrhages, may be caused by amyloid angiopathy in which β-amyloid protein is deposited in the walls of vessels, rendering them weak and friable. This is the same protein as is involved in plaque formation in Alzheimer disease; amyloid angiopathy and Alzheimer disease frequently coexist.

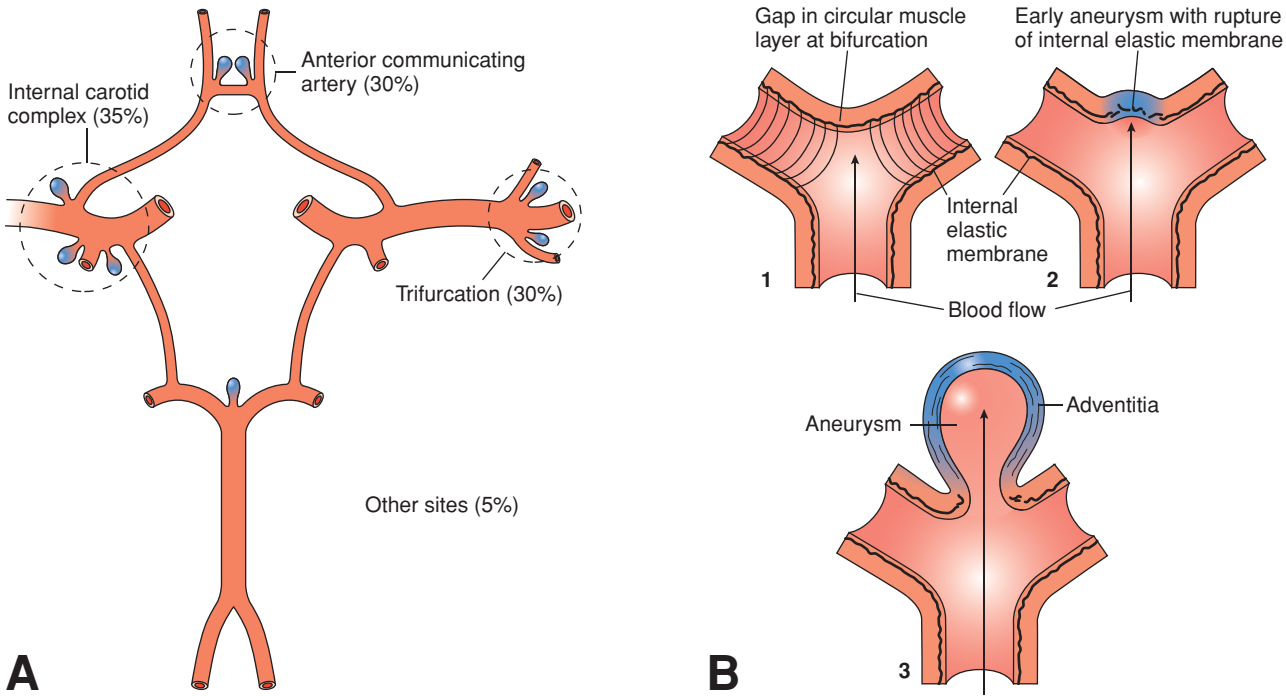

FIGURE 32-38. Pathophysiology of saccular aneurysm. A. The incidence of saccular aneurysms (berry aneurysms), which preferentially involve the proximal carotid tributaries, is shown. **B.** The lesion evolves as a result of blood under pressure acting on an early embryonic defect of the vascular wall at bifurcations.

intraparenchymal vessels in the lobar white matter are most affected, and their rupture may lead to lobar ICH. Amyloid angiopathy becomes more common with advancing age. It is an important cause of ICH in the elderly, in whom it may coexist with Alzheimer disease, in which β-amyloid protein processing is abnormal (see below).

Subarachnoid Hemorrhage

Intravascular pressure and weakness in arterial walls lead to formation of cerebral aneurysms that may rupture, leading to subarachnoid hemorrhage (SAH). Ruptured aneurysms cause about 85% of SAH, while vascular malformations account for 15%.

Saccular (Berry) Aneurysms

Saccular aneurysms are balloon-like outpouchings of cerebral arteries that may rupture to cause catastrophic subarachnoid hemorrhage. They tend to occur at branch points of the cerebral vasculature in or near the circle of Willis (Fig. 32-38).

PATHOLOGY: When a developing blood vessel bifurcates into two branches, the muscularis layer may not adequately span the branch point. This leaves an area of congenital muscularis thinning, covered only by endothelium, the internal elastic membrane and a thin adventitia. Over time, pressure from the pulsatile blood flow from the parent vessel enlarges the defect. The internal elastic membrane may degenerate or fragment, after which a saccular aneurysm evolves that is precariously covered only by a layer of adventitia. Active vascular wall remodeling may contribute to the aneurysm's evolution.

More than 90% of saccular aneurysms occur at proximal branch points in the anterior circulation fed by the carotid system; however, some may arise on branches of the posterior circulation, particularly on the posterior communicating and posterior cerebral arteries (Fig. 32-39). They are equally distributed at the junctions of the (1) anterior cerebral and anterior communicating arteries, (2) internal carotid–posterior communicating–anterior cerebral–anterior choroidal arteries and (3) trifurcation of the middle cerebral artery. In 15%–20% of cases, there are multiple aneurysms. The incidence of cerebral aneurysms is increased in polycystic kidney disease, coarctation of the aorta and Ehlers-Danlos syndrome.

CLINICAL FEATURES: Rupture of a saccular aneurysm leads to life-threatening SAH, with 35% mortality due to the initial hemorrhage. Blood may

FIGURE 32-39. Berry aneurysm. A saccular aneurysm (*arrow*) arises from the posterior cerebral artery. The dark color is a result of subarachnoid blood from this aneurysm that ruptured.

jet under arterial pressure to produce intracerebral or intraventricular hemorrhage in up to 1/3 of patients. The subarachnoid blood irritates pain-sensitive vessels and dura, leading to a sudden severe headache that the patient may describe as "the worst headache in my life," before then lapsing rapidly into coma. Those who survive 3–4 days may develop vasospasm, leading to fluctuating levels of consciousness and focal neurologic deficits. Survivors of the initial episode often rebleed within 21 days, and half of those who rebleed will perish. Therapy is directed at preventing rebleeding by isolating the aneurysm from the circulation by surgical occlusion of the vascular stalk or neck that connects the sac of the aneurysm to the parent vessel. A metallic clip across the neck of the aneurysm renders the aneurysm bloodless. An endovascular approach can also be taken: a catheter inserted through the femoral artery is guided to the cerebral circulation. Thin thrombogenic metallic coils are then threaded into the aneurysm sac, causing the blood in the aneurysm to clot. Aneurysmal coiling is less invasive than clipping and appears to be equally effective and durable.

At times, rather than rupturing, a saccular aneurysm enlarges to form a mass that may compress cranial nerves and produce palsies or impinge on parenchymal structures and induce neurologic symptoms. Classically, for example, a posterior communicating artery aneurysm may compress the third cranial nerve, leading to an isolated oculomotor nerve palsy with dilated pupil.

Mycotic (Infectious) Aneurysms

Bacterial or fungal infections of an arterial wall may cause a focal dilatation called a mycotic aneurysm. These usually result from septic emboli originating in an infected cardiac valve. The embolus usually flows through the carotid circulation and lodges in the vasa vasorum of a distal branch of the middle cerebral artery, where microbes proliferate, induce inflammation and destroy the affected arterial wall. This forms an aneurysm. Mycotic aneurysms occur in the distal cerebral circulation, unlike saccular aneurysms, which occur proximally. Rupture of the aneurysm can cause intracerebral or subarachnoid hemorrhage. Alternatively, microorganisms may be released and produce a cerebral abscess or meningitis.

Atherosclerotic Aneurysms

Aneurysms caused by atherosclerosis occur mainly in major cerebral arteries (vertebral, basilar, internal carotid) that are favored sites of atherosclerosis. Fibrous replacement of the media and destruction of the internal elastic membrane weaken the arterial wall and cause aneurysmal dilation. As they enlarge, atherosclerotic aneurysms tend to be fusiform and elongate. An enlarging atherosclerotic aneurysm may compress cranial nerves or parenchyma, leading to focal neurologic deficits. Thus, atherosclerotic aneurysms of the basilar artery may encroach upon the cerebellopontine angle, compressing the eighth cranial nerve, and causing deafness and vertigo. Basilar aneurysms may compress cranial nerve V, leading to trigeminal neuralgia, or cranial nerve VII, leading to hemifacial spasm. Atherosclerotic aneurysms rarely rupture leading to subarachnoid hemorrhage, but intraplaque hemorrhage may lead to vascular occlusion or a complicated plaque may lead to arterial thrombosis and ischemic stroke.

Vascular Malformations

Vascular malformations arise during embryogenesis but evolve during angiogenesis, vascular remodeling and recruitment of vessels from normal parenchyma. They are named according to the nature of vascular channels in the malformation and the intervening neuroglial parenchyma that may be normal, gliotic or absent. Vascular malformations may bleed to cause subarachnoid or intraparenchymal hemorrhage or both. They may also irritate normal cerebral cortex, resulting in seizures, or they may divert blood flow from adjacent structures, leading to focal neurologic deficits.

FIGURE 32-40. Arteriovenous malformation (AVM). A disorganized collection of arteries and veins is seen within the substance of the brain extending to the surface. AVMs may result in subarachnoid hemorrhage if they bleed on the surface or intraparenchymal hemorrhage if deeper vascular channels rupture. The hemorrhage is usually not as catastrophic as that seen in aneurysm subarachnoid hemorrhage or hypertensive intracerebral hemorrhage.

ARTERIOVENOUS MALFORMATION: An arteriovenous malformation (AVM) is a tangle of arteries and veins of varying caliber and wall thickness separated by abnormal gliotic parenchyma (Fig. 32-40). The abnormal vessels form in embryogenesis from focal communications between cerebral arteries and veins without intervening capillaries. Resulting congeries of abnormal vessels are typically located in the cerebral cortex and the contiguous underlying white matter. AVMs enlarge with time and recruit vessels from adjacent tissue.

CLINICAL FEATURES: Seizure disorders result from irritation of neural tissue; focal neurologic deficits caused by vascular steal; and intracranial hemorrhages, usually subarachnoid or intracerebral, which commonly arise in the second or third decades. The hemorrhage is not usually catastrophic but may be recurring.

CAVERNOUS ANGIOMA: Cavernous angiomas are wide, irregular, thin-walled vascular channels with no intervening neural parenchyma. They are less common than AVMs. Although most are asymptomatic, they may cause intracranial bleeding, seizures or focal neurologic disturbances. Cavernous angiomata may be multiple in 15%–20% of cases. Many patients have autosomal dominant cerebral cavernous malformations (CCMs), the most common form of which, CCM1, results from *krit* mutations.

TELANGIECTASIA: These are focal aggregates of uniformly dilated, thin-walled, small capillary-sized vessels with normal intervening neural parenchyma. They may very rarely initiate seizures but rupture only infrequently. Telangiectasias are usually discovered incidentally during imaging for other conditions or at autopsy.

VENOUS ANGIOMA: This malformation consists of a solitary or a few enlarged veins residing in normal parenchyma. They are distributed randomly in the spinal cord or brain and are generally asymptomatic.

There have been significant improvements in our understanding of molecular genetic mechanisms underlying vascular remodeling in aneurysm formation and growth, vascular malformations and small vessels exposed to chronic hypertension, so that major advances in the prevention and treatment of hemorrhagic stroke can be expected. Consequently, management of cerebrovascular disorders has moved from pessimistic nihilism toward a scientifically driven, clinically meaningful outlook.

CNS INFECTIONS

Many of the infections of the central nervous system are devastating or lethal if untreated. Their clinical course may be swift and ferocious or indolent and progressive, and can mimic many other disorders. Clinical vigilance, thorough diagnostic evaluation and emphatic therapeutic response, is essential for effective management. The clinical context of nervous system infections is crucial. Patients' age, socioeconomic situation, risky behaviors, immune status and travel history are critical in assessing infections of the CNS. AIDS, chemotherapy, economics, environmental change, bioterrorism, transglobal travel and immigration continue to change the face of infectious diseases.

Evaluation of CNS infections should include the location and extent of the infection, the nature of the host response and the inciting organism.

Empyema in the epidural or subdural space is usually related to trauma or spread from contiguous infection—usually bacterial—in the sinuses or ear.

In leptomeningitis **(meningitis),** the inflammatory response and most of the inciting organisms are in the subarachnoid space, floating in the CSF. The vigor of the inflammatory response may lead to parenchymal involvement including cerebral edema and vasculitis with thrombosis, hemorrhage or infarction. The war between host and organisms may involve the parenchyma, resulting in **cerebritis**. Long-term complications include effusions, obstruction of CSF flow with hydrocephalus and cranial neuropathies, particularly deafness from VIII nerve involvement.

Cerebritis is a purulent parenchymal infection that is usually bacterial or fungal. Brain tissue is soft and soupy and the borders of the infection cannot be easily discerned. If a host can contain the process, the cerebritis is walled off to form a brain abscess. Abscesses have many neutrophils within a necrotic core, surrounded by granulation tissue, a dense fibrovascular capsule and a gliotic rind.

Encephalitis, like cerebritis, is a parenchymal infection, but the term is usually reserved for viral infections with necrosis, perivascular lymphocytic cuffing and microglial nodules. Intranuclear or cytoplasmic viral inclusions may be seen, as may gliosis, demyelination and status spongiosus.

Different classes of infectious organisms produce distinctive host inflammatory responses. While not absolute, the inflammatory reaction provides clues about the inciting organism. Bacteria tend to induce vigorous polymorphonuclear (purulent) responses, while fungi and mycobacteria may elicit more indolent granulomatous reactions. In viral infections, lymphocytic responses predominate, while protozoa tend to incite lymphoplasmacytic infiltrates. Metazoan parasites generate eosinophilic and lymphocytic inflammation. Prions cause no inflammation but rather vigorous gliosis.

Bacterial Infections Produce Inflammation in the Subarachnoid Space

This response, called **leptomeningitis,** occurs between the pia and arachnoid layers of the meninges. The CSF filling this compartment is an excellent culture medium for most bacteria. The inflammatory response in the CSF to infections varies with the virulence of the organism and the tempo of the infection. Changes are detectable in CSF cellular constituents as well as glucose and protein concentrations. Organisms are sometimes visible microscopically in the CSF and can be definitively characterized by culture, antigenicity and in some cases polymerase chain reaction (PCR).

CLINICAL FEATURES: The signs and symptoms of meningitis include headache, vomiting, fever, altered mental status and seizures. Classic signs of meningeal inflammation include neck rigidity, knee pain with hip flexion (Kernig sign) and knee/hip flexion when the neck is flexed (Brudzinski sign). At the extremes of age—newborn and senescence—clinical manifestations vary more widely. A newborn may have autonomic instability and fragmentary seizures, while the elderly may have altered mental status without fever or headache.

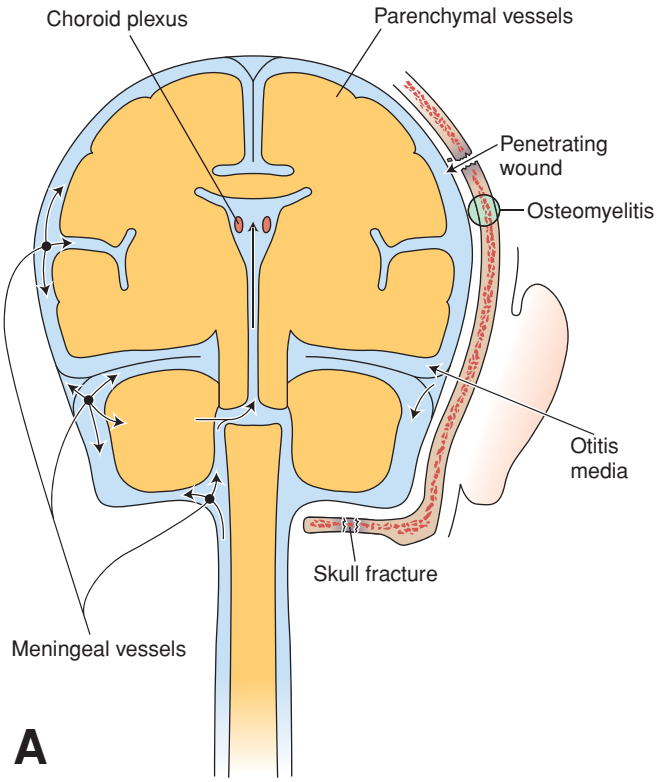
Bacterial Meningitis

ETIOLOGIC FACTORS: Since most bacteria initiate purulent responses, the presence of neutrophils in the CSF is strong evidence of meningitis. CSF glucose will often be decreased and CSF protein elevated. The causes of bacterial meningitis depend on the age of the patient. Gram-negative *Escherichia coli* and β-hemolytic *Streptococcus* sp. predominate in neonates. In unvaccinated young children, *Haemophilus influenza* dominates, but vaccination programs against *H. influenzae* group B have changed the epidemiology, so that *Streptococcus pneumoniae* and *Neisseria meningitidis* are becoming more prevalent. *N. meningitidis* is most common in adolescence and early adult life. *S. pneumoniae* is most common thereafter. Routes of entry to the intracranial vault are shown in Fig. 32-41A.

ESCHERICHIA COLI: In newborns, whose resistance to gram-negative bacteria has not yet fully developed, *E. coli* is a major cause of meningitis. Transplacental transfer of maternal immunoglobulin (Ig) G protects newborns from many bacteria, but *E. coli* and similar gram-negative organisms require IgM for neutralization, and IgM does not cross the placenta. Thus, in infancy, gram-negative organisms quickly produce purulent meningitis with a high mortality.

HAEMOPHILUS INFLUENZAE: Environmental exposure to the gram-negative *H. influenzae* is somewhat delayed. Thus, the incidence of meningitis peaks from 3 months to 3 years. *H. influenza* meningitis has decreased in recent years (see above).

STREPTOCOCCUS PNEUMONIAE: Later in life, *Pneumococcus* is the main cause of meningitis. Patients with a history of basilar skull fracture with CSF leak have a high incidence of pneumococcal meningitis, which often recurs



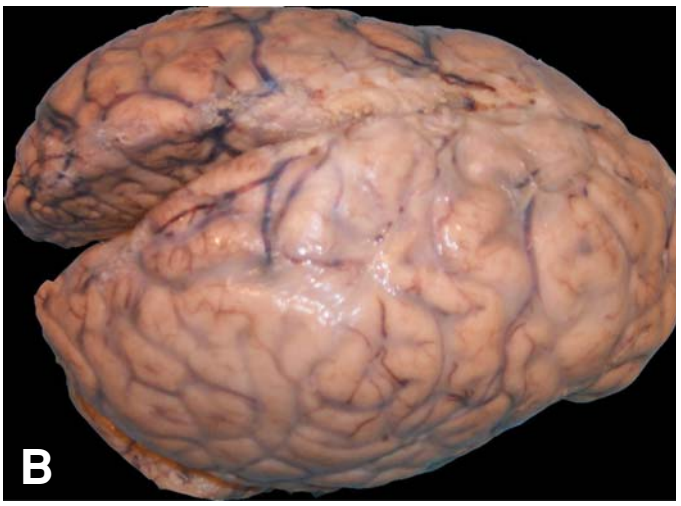


FIGURE 32-41. Purulent meningitis. A. Routes of entry of infectious organisms into the cranial cavity. B. A creamy exudate opacifies the leptomeninges in bacterial meningitis. The superficial veins are engorged and may develop thrombosis, and the arteries on the surface of the brain may also develop thrombosis, leading to infarcts.

after treatment. Alcoholics and patients who are asplenic are highly susceptible.

NEISSERIA MENINGITIDIS: The meningococcus resides in the nasopharynx, and airborne transmission in crowded places (e.g., schools or barracks) causes "epidemic meningitis." Initially, bacteremia causes fever, malaise and petechial rash, but intravascular coagulopathy may cause lethal adrenal hemorrhage **(Waterhouse-Friderichsen syndrome)**. Untreated meningococcal bacteremia can trigger acute fulminant meningitis. An available polyvalent vaccine is recommended for all young people and is extremely effective. There are, however, strains of *N. meningitidis* that are not covered by the vaccine. Unfortunately, vaccines are not widely available in many parts of the world. In 1996, sub-Saharan Africa experienced the largest epidemic of meningococcal meningitis in history, with over 250,000 cases and 25,000 deaths.

LISTERIA MONOCYTOGENES: Listerial meningitis is increasing in all ages and may account for up to 10% of bacterial meningitis. Its course is less fulminant than other bacterial meningitides and CSF cellular responses may be lymphocyte predominant.

BACILLUS ANTHRACIS: Anthrax produces a fulminant hemorrhagic meningitis in up to 50% of cases. During the bioterrorism attacks in 2001, the index case was diagnosed as a result of the presence of large gram-positive rods in the CSF. Anthrax is a readily weaponizable biological warfare agent.

PATHOLOGY: In bacterial meningitis, an exudate of leukocytes and fibrin opacifies the arachnoid. This exudate varies from mild and equivocal to the naked eye to prominent enough to obscure blood vessels. Purulent exudates are most conspicuous over the cerebral hemispheres (Fig. 32-41B) but may extend to the base

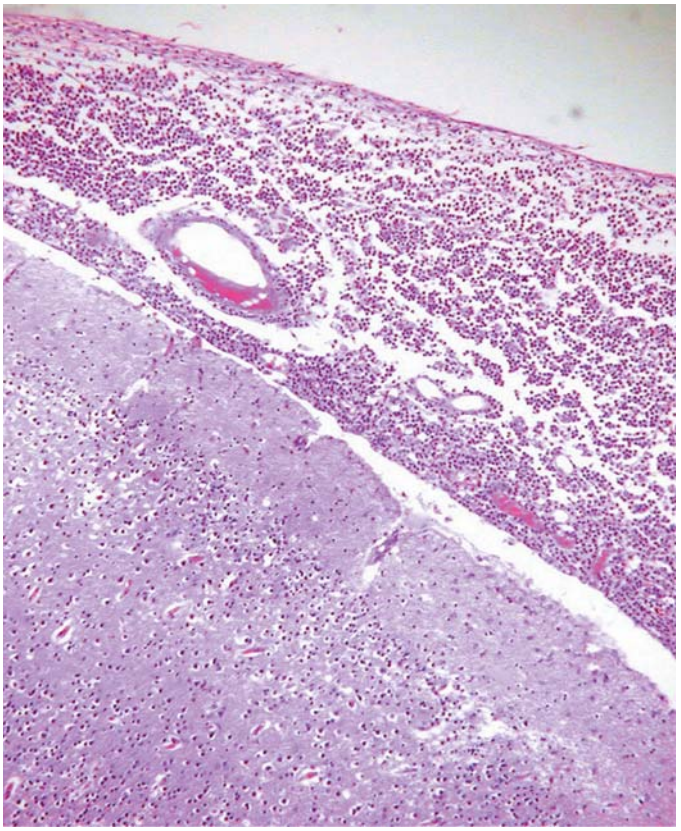

FIGURE 32-42. Bacterial meningitis. A microscopic section shows the accumulation of numerous neutrophils in the subarachnoid space.

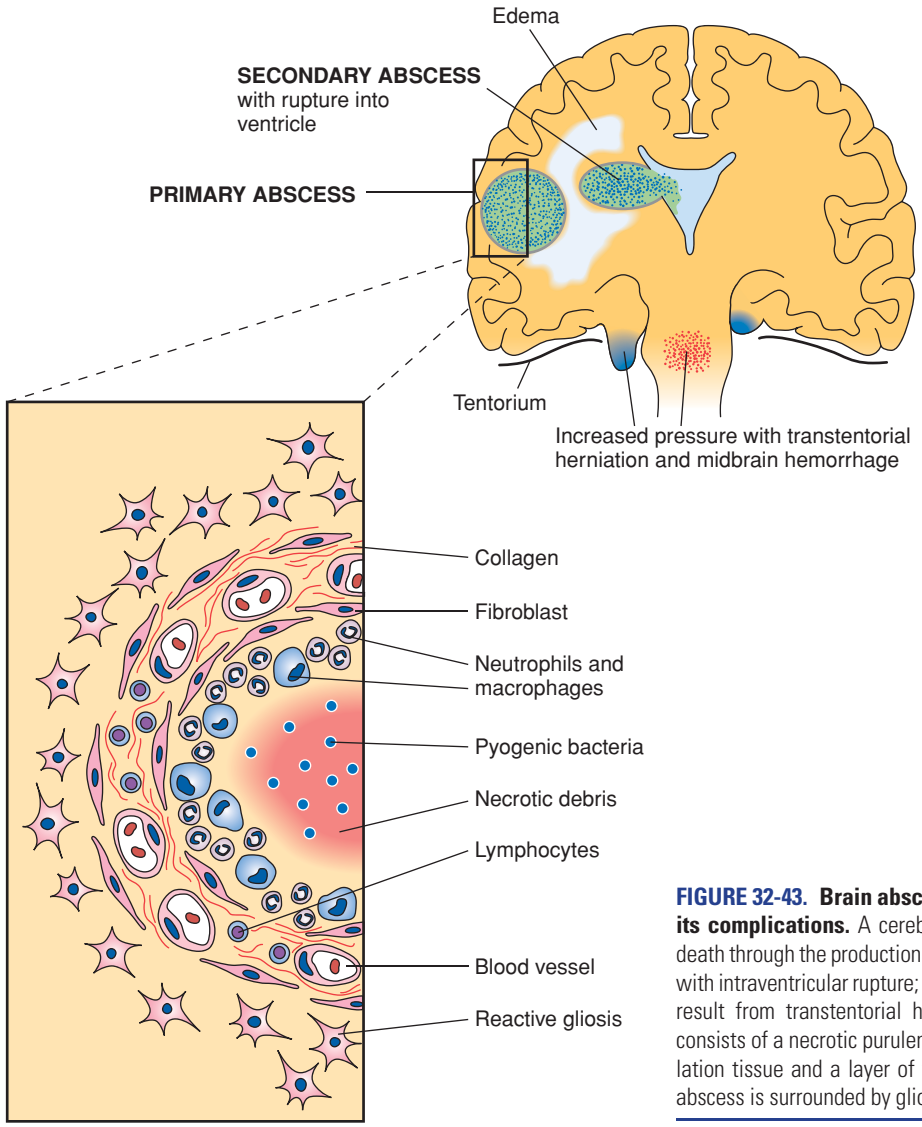

FIGURE 32-43. Brain abscess development and its complications. A cerebral abscess may cause death through the production of secondary abscesses with intraventricular rupture; alternatively, death may result from transtentorial herniation. The abscess consists of a necrotic purulent core, a layer of granulation tissue and a layer of fibrosis, and finally, the abscess is surrounded by gliosis.

of the brain and from intracranial to intraspinal and subarachnoid spaces. Cerebral abscesses rarely complicate meningitis. The pia forms sleeves around blood vessels that penetrate the brain **(Virchow-Robin spaces)** in continuity with the subarachnoid space. The subarachnoid space including the Virchow-Robin domain is usually packed with neutrophils and organisms (Fig. 32-42). A vigorous host response is essential to clear the infection, but significant vascular and neuropil damage results from cytotoxic substances such as free radicals and cytokines released by inflammatory cells. Those cells may compete with the brain for glucose; low CSF glucose in bacterial meningitis mostly reflects glucose consumption by inflammatory cells. Corticosteroids may be given with antibiotics to mitigate this host response–induced damage.

Cerebral Abscess

PATHOLOGY: A localized intraparenchymal abscess begins when bacteria or fungi lodge in the neuropil and incite an acute inflammatory and edematous reaction called **cerebritis**. The tissue is soft and soupy, and within days, liquefactive necrosis causes an expanding mass that may threaten life by herniation or rupture into a ventricle (Fig. 32-43). Vigorous reactive astrogliosis is triggered, and fibroblasts make a rare appearance in the brain by invading from cerebral microvasculature to encapsulate the nascent abscess.

As the abscess matures over days to weeks, three layers surround a central core of purulent debris: (1) an inner layer of vigorous granulation tissue where host and microbes engage in open warfare; (2) a second layer of a dense meshwork of fibroblasts and collagen that forms a tough rind around the core and granulation tissue; and (3) finally a zone of intense astrogliosis, microglial activation and edema (Fig. 32-44). The granulation tissue layer lacks a blood-brain barrier and leaks contrast, to cause a smooth ring of enhancement.

If the abscess is not drained or treated with antibiotics, pressure builds within it that may extrude microbes into adjacent parenchyma to spawn "daughter" abscesses. Or, the abscess may rupture catastrophically into the ventricles. The bacteria that cause brain abscesses are often anaerobic or microaerophilic, and so may be difficult to culture. They often spread to the brain hematogenously from the heart or lungs; as showers of organisms repeatedly enter the circulation, abscesses are multiple in 15%–20% of cases.

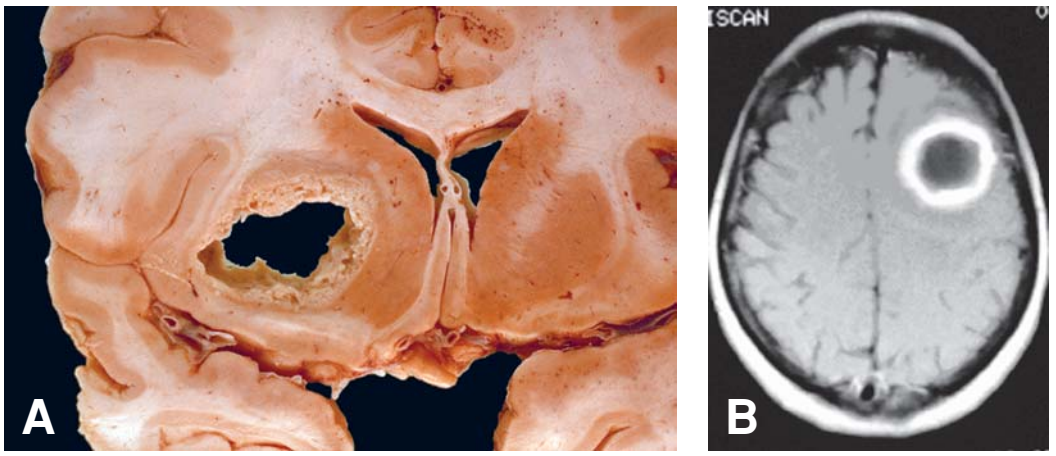

FIGURE 32-44. Cerebral abscess. **A.** A young man with bacterial endocarditis developed an abscess in the left basal ganglia. **B.** Axial contrast-enhanced computed tomography showing a smooth uniform ring of enhancement around a necrotic core of a brain abscess. A smooth ring-enhancing lesion is very suggestive of a brain abscess but may be seen with primary or secondary neoplasms of the brain.

Brain invasion may also be a result of contiguous spread from infected frontal or mastoid sinuses or neurosurgical wound infections.

Neurosyphilis

Syphilis is caused by a spirochete, *Treponema pallidum*. By aligning its transmission with host carnal impulses, *T. pallidum* has assured its status as a centuries-old scourge of mankind. The organism enters the bloodstream from the primary lesion, the chancre (see Chapter 9). Secondary syphilis is heralded by a maculopapular rash on the skin and mucous membranes. A few lymphocytes and plasma cells and increased protein in the CSF reflect entry of bloodborne spirochetes into the meninges, leading to a transient and often asymptomatic meningitis. The organisms usually do not survive for long and the CSF reverts to normal. However, sometimes the errant spirochete initiates a meningeal

Dura

FIGURE 32-45. Involvement of the central nervous system in syphilis. Hallmarks of neurosyphilis are meningovascular inflammation leading to pachymeningitis and strokes caused by obliterative endarteritis, tabes dorsalis caused by inflammation of posterior roots and meninges, and intraparenchymal involvement leading to dementia.

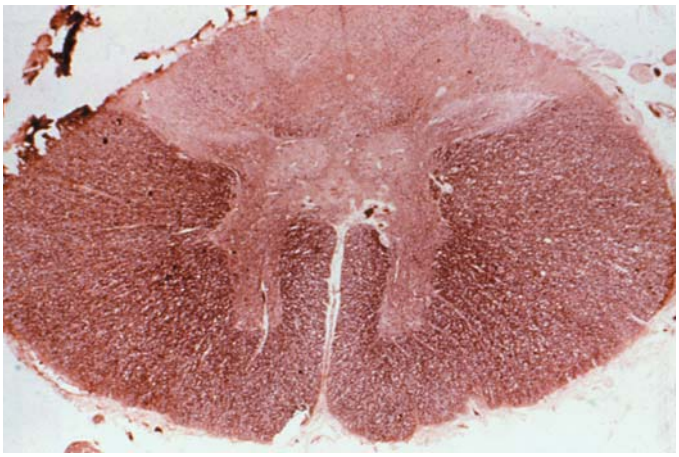

FIGURE 32-46. Tabes dorsalis. The spinal cord of a patient with tertiary syphilis displays posterior column degeneration (sliver impregnation stain). The patient would be unable to walk without visual cues because he has lost proprioception.

fibroblastic response, accompanied by obliterative endarteritis that induces multiple small cerebral cortex or brainstem infarcts. The classical eponymic brainstem strokes described in the 18th and 19th centuries were largely due to an obliterative syphilitic endarteritis. Plasma cells, the inflammatory hallmark of syphilis, surround arterioles of the cerebral cortex in meningovascular syphilis (Fig. 32-45).

Tabes Dorsalis

Tabes dorsalis is impairment of spinal dorsal column function, as manifested by loss of joint position sense and fine touch (Fig. 32-46). The dorsal nerve roots proximal to dorsal root ganglia are met by a conical sleeve of arachnoid filled with CSF, which can be the site of syphilitic inflammation. Fibrous tissue triggered by the inflammation constricts nerve roots, causing axonal (wallerian) degeneration. Since axons that course cephalad in the posterior columns do not synapse with intramedullary neurons, unlike spinothalamic afferents, wallerian degeneration initiated in the dorsal spinal nerves extends the length of the posterior fasciculi. The patient loses position sense in the legs and comes to rely on visual cues for the position of his or her feet and legs in space. In darkness or with his or her eyes closed, the patient becomes unsteady and may even fall. This inability to remain standing with eyes closed is called a positive Romberg sign and reflects severe posterior column dysfunction.

Luetic Dementia

T. pallidum may remain latent in the brain for decades. The spirochetes replicate sluggishly and escape eradication, resulting in dementia and psychosis years after the initial infection. The morphologic features include focal loss of cortical neurons, disfigurement of residual nerve cells ("wind-blown appearance"), marked gliosis and conversion of microglia into elongated forms encrusted with iron ("rod cells") associated with nodular ependymitis.

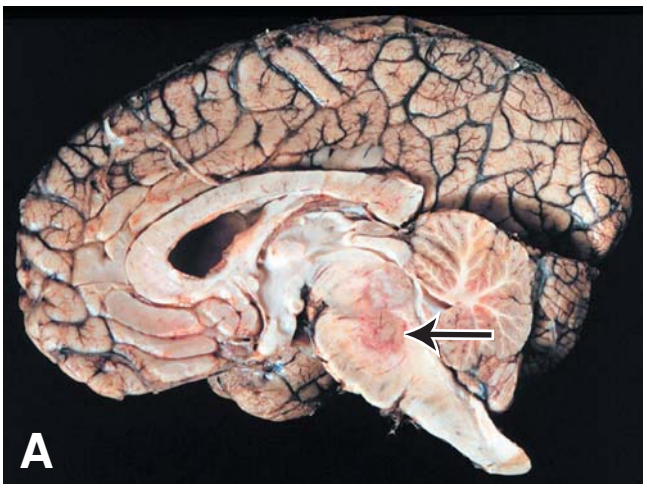
Mycobacterial and Fungal Infections Elicit Granulomatous Responses

PATHOLOGY: Mycobacterial and fungal infections progress more slowly than bacterial infections. Multinucleate giant cells are admixed with lymphocytes and plasma cells. Exudate tends to accumulate at the base of the brain, around the brainstem, rather than over the convexities as in bacterial meningitis.

CLINICAL FEATURES: This chronic basilar meningitis may block CSF flow through the foramina of Magendie and Luschka, leading to hydrocephalus, headache, nausea and vomiting. Cranial nerve palsies can occur as these nerves traverse the exudate where they emerge from the brainstem.

Tuberculous Meningitis and Tuberculomas

PATHOLOGY: Tuberculous meningitis is a chronic infection inciting a granulomatous host response with multinucleated giant cells and lymphocytes surrounding areas of caseous necrosis (Fig. 32-47).



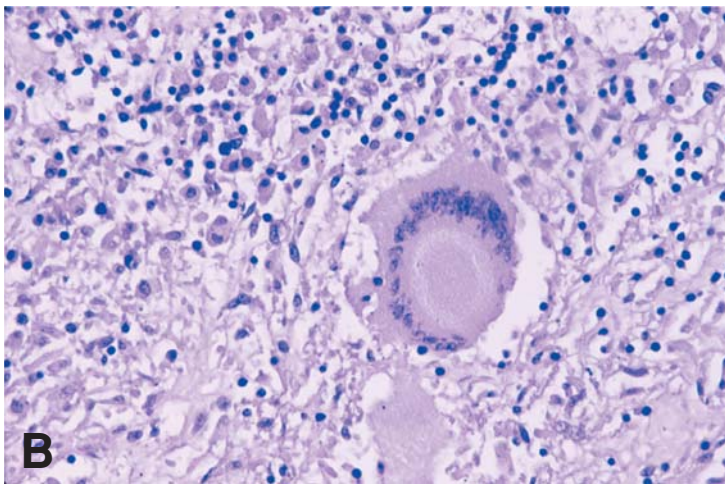


FIGURE 32-47. Tuberculoma. A. A focus of caseous necrosis is present in the pons and midbrain (*arrow*). **B.** A photomicrograph shows caseous necrosis, macrophages and Langhans giant cells in a tuberculoma. If the tuberculoma ruptures into the cerebrospinal fluid, tuberculous meningitis will ensue.

FIGURE 32-48. Tuberculoma. A focus of caseous necrosis is present in the pons and midbrain. In parts of the world where tuberculosis is endemic, tuberculomas are among the most common brain masses seen. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

FIGURE 32-49. Pott disease. Tuberculosis involving the spinal column leads to slow vertebral collapse and acute angulation of the spine ("gibbus" deformity). Spinal cord compression may result, with myelopathic findings. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Like neurosyphilis, mycobacterial meningitis may lead to meningeal fibrosis, communicating hydrocephalus and arteritis that may cause infarcts. As tuberculous meningitis preferentially affects the base of the brain, these infarcts are usually in the distribution of the penetrating striate and brainstem arteries. Untreated tuberculous meningitis is usually fatal in 4–6 weeks but may progress faster in immunocompromised patients. Parenchymal tuberculosis produces **tuberculomas,** individual masses with central caseous necrosis surrounded by granulomatous inflammation (Fig. 32-48). In parts of the world where tuberculosis is endemic, mycobacterial granulomas are the most common brain masses. In childhood, these granulomas congregate in the posterior fossa, which is also the most common site of childhood brain tumors. Confluent tuberculomas occur in miliary tuberculosis. Tuberculous meningitis usually reflects hematogenous dissemination from an initial pulmonary focus, as intraparenchymal granulomas rupture into the CSF to produce meningitis. **Pott disease** is tuberculosis of the spine, in which epidural granulomatous inflammation destroys the bony spine, leading to spinal cord compression (Fig. 32-49).

Fungal Infections

Fungal infections of the CNS are often opportunistic, reflecting the indolent saprophytic lifestyle of these organisms, but a few fungi are sufficiently virulent to cause disease in immunocompetent people. Fungi invading tissue may be round to oval, often budding, yeast forms or branching hyphae. In some infections, yeast and hyphae both appear in infected tissues, facilitating tentative identification of fungi in tissue sections. However, ultimate speciation requires antigenic, PCR or culture confirmation.

Cryptococcus

EPIDEMIOLOGY: Cryptococci are the most common fungal causes of meningitis. *Cryptococcus* often acts opportunistically in immunocompromised patients, but it can also establish meningitis in an immunologically competent host. *Cryptococcus neoformans* enters the host by inhalation. Birds are the major reservoir, and their inhaled fungus-laden excreta initiate a lung infection that may remain confined to the lungs or may disseminate to involve other organs including the brain.

PATHOLOGY: *C. neoformans* typically elicits granulomatous responses, with infectious foci appearing as discrete white meningeal nodules, about 1 mm. The organism may remain confined to the subarachnoid space, but infection sometimes spreads to the brain parenchyma. The gelatinous fungal capsule appears clear and glistening, so that microabscesses resemble soap bubbles (Fig. 32-50).

C. neoformans may be abundant, particularly in the Virchow-Robin spaces. An occasional multinucleated giant cell, sometimes with phagocytosed organisms, accompanies scant epithelioid cells and a few lymphocytes. The organisms are encapsulated, budding yeast forms that are large by fungal standards (5–15 μ) and have an external gelatinous capsule that looks like a clear halo. The organism can be highlighted by mixing contaminated CSF with India ink (Fig. 32-51). Its capsule shields the organism from host immune responses and accounts for the usually feeble inflammatory reaction. The capsule sheds specific antigens that can be detected in the CSF by the latex cryptococcal antigen test.

Coccidioidomycosis

Coccidioides immitis is endemic in arid regions of the Southwest and San Joaquin Valley in California. Initial pulmonary infection is usually asymptomatic and rarely spreads. It causes suppurative and granulomatous inflammation that

FIGURE 32-50. Cryptococcal "soap bubble" abscesses. The encapsulated organisms occur in great abundance in the Virchow-Robin space and in microabscesses within the parenchyma. The microbial capsule imparts a glistening clear appearance to these collections that has been likened to soap bubbles. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

sometimes includes an arteritis that may be complicated by infarction. The organism appears in tissue as an eye-catching refractile endosporulating spherule.

Histoplasmosis

Histoplasma capsulatum is endemic in the Mississippi basin and usually causes asymptomatic pulmonary infections. Rare CNS dissemination of this tiny, intracytoplasmic yeast form residing in macrophages may occur. A chronic meningitis ensues in which the surface of the brain may be studded by small granulomata.

Blastomycosis

Blastomyces dermatitidis is an uncommon cause of mycotic meningitis. The organisms are broad-based budding yeasts.

Mucormycosis (Zygomycosis)

Fungi of the order *Mucorales* are angioinvasive, nonseptate, hyphal forms that mostly cause disease in immunocompromised people or those with poorly controlled diabetes. The large vessels at the skull base, orbit and neck are subject to invasion with occlusion and distal infarction. Black nasal mucosa indicating mucosal infarction is sometimes seen and can be used for diagnosis.

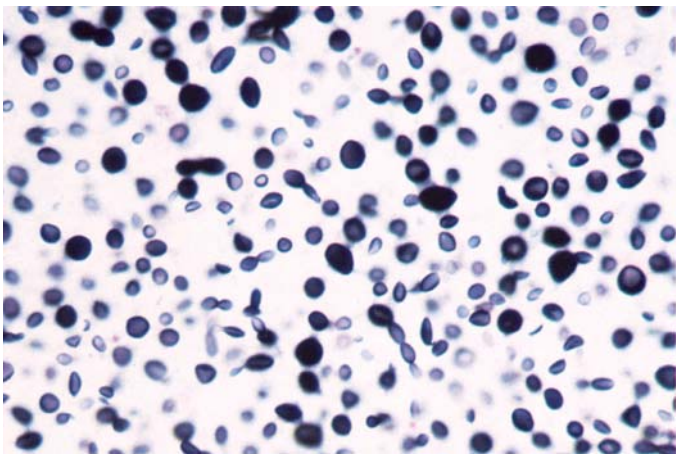

FIGURE 32-51. Cryptococcal meningitis. The cryptococcal organisms vary in size (5–15 microns in diameter), placing them among the largest of the yeast-form fungi (Gomori methenamine silver stain). They reproduce by budding. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Aspergillosis

Aspergillus is an angiocentric septate hyphal fungus (usually, *Aspergillus fumigatus*) that mainly causes disease in immunocompromised hosts. Vascular involvement produces multiple gray necrotic abscesses within the parenchyma. The lung is the primary site of infection, but the brain is the second most commonly involved organ.

Candidiasis

Candida albicans is a ubiquitous opportunistic fungus that shows both yeast and pseudohyphae morphology in infected tissues. *Candida* produces many microabscesses, most often in immunocompromised patients. Systemic involvement is the rule, and in large hospital-based autopsy series, this is the most common systemic fungal infection.

Exserohilum rostratum: Infection from Contaminated Corticosteroid Injections

In 2012 and 2013, a serious epidemic of localized spinal and skull base fungal infections was traced to inadequate quality control in manufacturing of corticosteroids used for local articular, paraspinal and epidural spinal injections for pain. *Exserohilum rostratum,* a pigmented environmental fungus that rarely infects humans, was the culprit in most cases. It produced soft tissue and bone destruction with potential involvement of vertebral and basilar arteries. Approximately 700 patients were affected, with almost 60 deaths. This serious epidemic drew attention to inadequate quality control and nationwide dissemination of contaminated injectable compounds.

CNS Viral Infections Vary in Severity, Time Course and Resolution

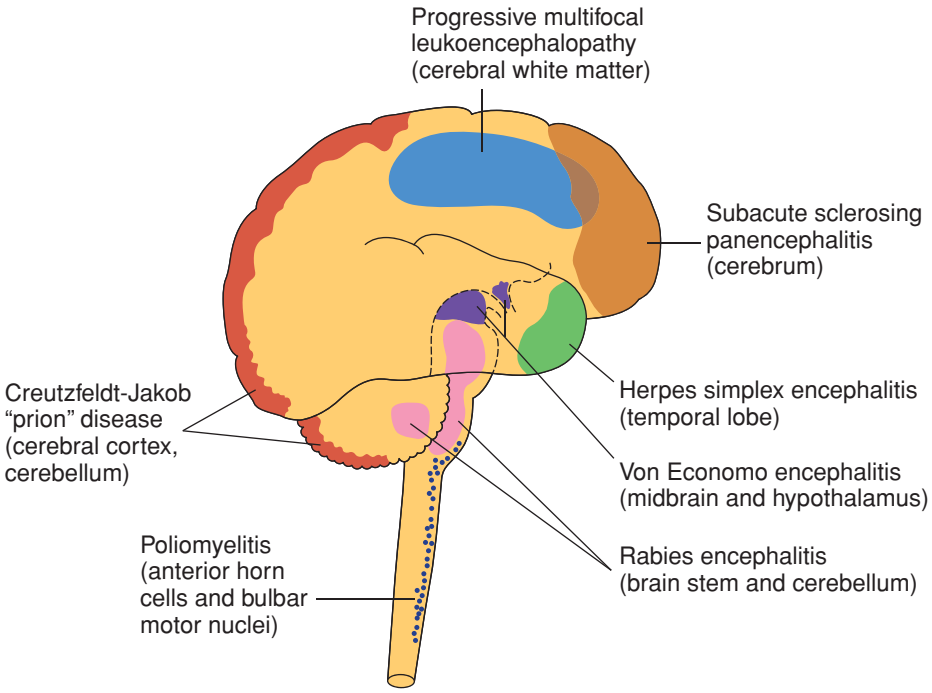
The manifestations of viral infections of the CNS are remarkably diverse, ranging from non–life-threatening viral meningitis to more ominous viral encephalitis affecting the parenchyma. These diseases may unfold over a period of hours or span decades. In addition to producing infections, viruses have been implicated in some autoimmune and neurodegenerative diseases.

Viral Meningitis

Unlike bacterial meningitis, viral meningitis is usually benign and resolves without sequelae. The most common causative agents are enteroviruses (e.g., coxsackievirus B, echovirus), but mumps, lymphocytic choriomeningitis, Epstein-Barr and herpes simplex viruses cause many sporadic cases. Viral meningitis (mainly a disease of children and young adults) begins as a sudden febrile illness with a severe headache. The CSF contains excess lymphocytes and a slight increase in protein but, unlike bacterial meningitis, no decrease in CSF glucose.

Viral Encephalitis

The manifestations of viral infections of CNS parenchyma are clinically and pathologically heterogeneous (Fig. 32-52). For



Progressive multifocal leukoencephalopathy (cerebral white matter)
Subacute sclerosing panencephalitis (cerebrum)
Herpes simplex encephalitis (temporal lobe)
Von Economo encephalitis (midbrain and hypothalamus)
Rabies encephalitis (brain stem and cerebellum)
Creutzfeldt-Jakob "prion" disease (cerebral cortex, cerebellum)
Poliomyelitis (anterior horn cells and bulbar motor nuclei)

FIGURE 32-52. Distribution of the lesions of viral encephalitides.

example, poliomyelitis affects spinal and brainstem motor neurons, while herpes simplex targets the temporal lobes. Subacute sclerosing panencephalitis involves the gray matter, while progressive multifocal leukoencephalopathy is a white matter disorder. The mechanisms of viral tropism may reflect binding of viruses to plasma membrane structure on specific CNS cells, the ability of viruses to remain latent or selective replication in specific intracellular microenvironments. Viruses may exploit axonal transport to travel to sites far distant from their point of entry, as exemplified by rabies and herpesviruses.

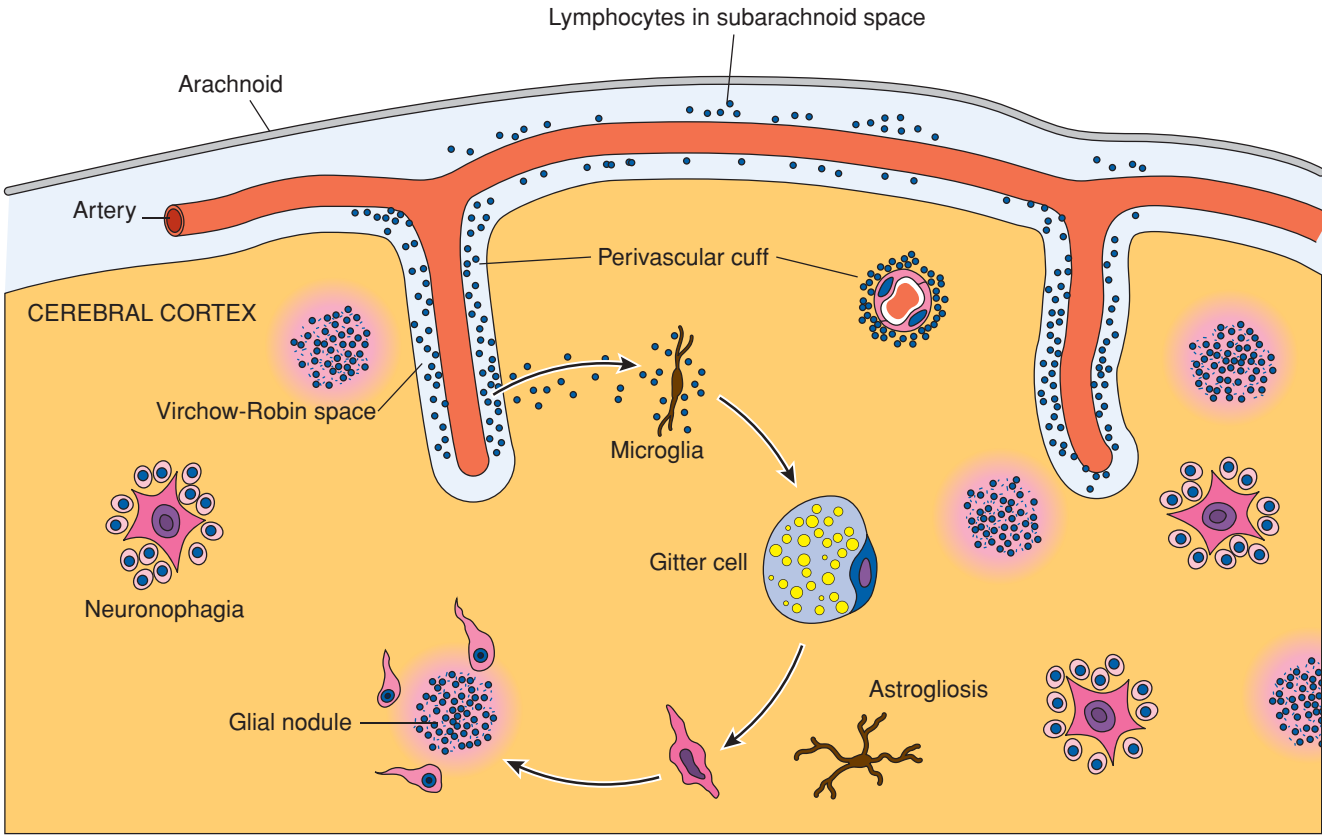


FIGURE 32-53. The lesions of viral encephalitis.

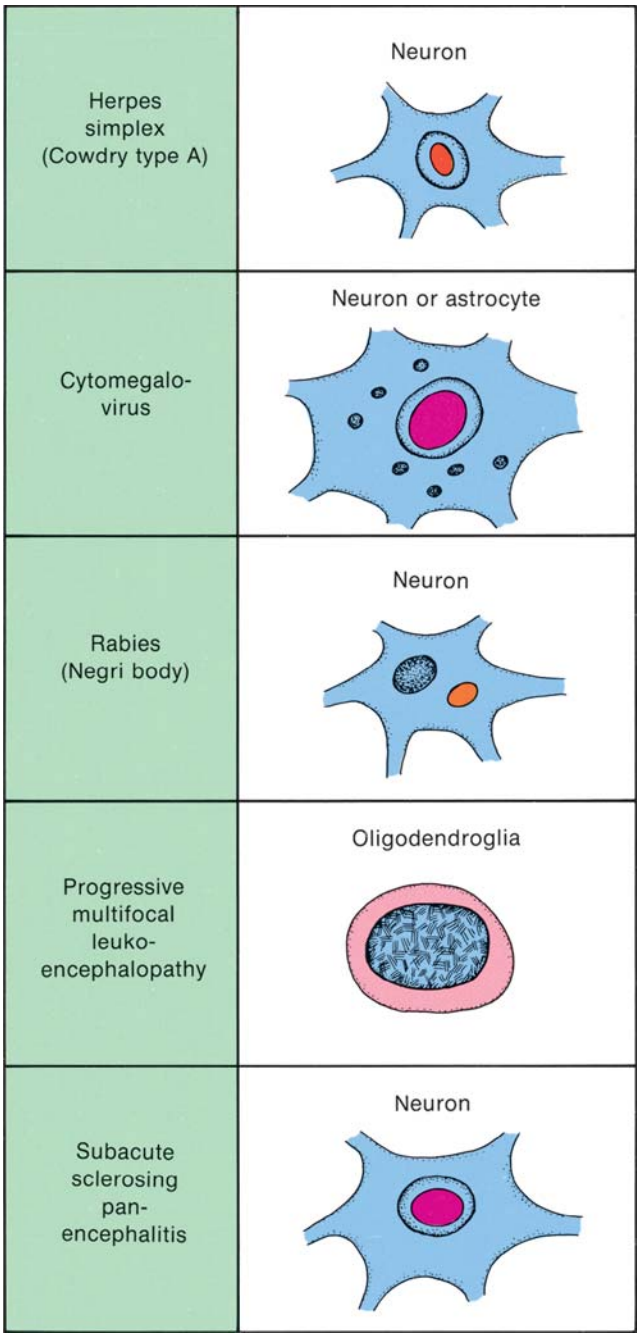

FIGURE 32-54. Inclusion bodies in viral encephalitides.

PATHOLOGY: Most CNS viral infections elicit perivascular lymphocytes, macrophage and microglial activation and gliosis (Fig. 32-53). These changes are not specific for viral infections, but the presence of viral inclusions strongly suggests a viral infection (Fig. 32-54). Such inclusion bodies do not occur with all viral infections. In situ hybridization, PCR and immunochemistry are most often used to establish a diagnosis.

CLINICAL FEATURES: Most viral encephalitides begin abruptly. Specific neurologic deficits (e.g., paralysis of poliomyelitis, difficulty in swallowing in rabies) reflect the localization of the infection. Most encephalitides run a rapid course, but the tempo can vary. For example, the clinical course of subacute sclerosing panencephalitis may last years. Herpes simplex and varicella-zoster viruses may be latent in sensory ganglia for years, only to be reactivated decades after initial infection.

Poliomyelitis

The term **poliomyelitis** describes any inflammation of the gray matter of the spinal cord. In common usage it implies an infection by poliovirus, which is one of the enteroviruses. These are small, nonenveloped, single-stranded RNA viruses.

Historical evidence suggests that poliomyelitis has occurred in epidemics since antiquity. Affected people shed large amounts of virus in their stools, and spread is by the fecal–oral route.

PATHOLOGY: Virus enters motor neurons via binding sites on their plasma membranes and replicates there. Infected cells may undergo chromatolysis, after which they are phagocytosed by macrophages (neuronophagia). Initial inflammatory responses briefly include neutrophils. Lymphocytes follow and surround blood vessels in the spinal cord and brainstem. The motor cortex usually shows no inflammation but may contain microglial nodules, which are focal collections of microglia and lymphocytes. Host immune responses to the virus, although limited, may halt progression of clinical disease. Sections of spinal cord in cases of healed poliomyelitis show loss of neurons, with secondary degeneration of corresponding ventral roots and peripheral nerves.

CLINICAL FEATURES: Nonspecific symptoms such as fever, malaise and headache are followed in several days by signs of meningitis, and then by paralysis. In severe cases, the muscles of the neck, trunk and all four limbs may be rendered powerless. Paralysis of the respiratory muscles may be life-threatening. Patients with milder disease may show asymmetric and patchy paralysis, most often in the legs.

Improvement begins in about a week, and only some of the muscles affected at the outset may remain permanently paralyzed. Mortality is 5%–25%, with death usually due to respiratory failure. Development of effective vaccines in the 1950s has largely eliminated polio in most of the world. However, in parts of Asia and Africa, political instability have jeopardized vaccination programs. Recently, wild-type poliomyelitis has recurred in the Congo, where many people have not been vaccinated and are immunologically naïve, resulting in high case fatality rates.

Rabies

EPIDEMIOLOGY: Rabies is an encephalitis caused by an enveloped, single-stranded RNA virus of the rhabdovirus group. Dogs, wolves, foxes and skunks are the main reservoirs, but bats and domestic animals, including cattle, goats and swine, also carry the disease. Rabies virus is transmitted to humans via contaminated saliva, introduced by a bite. In the United States, where dogs are routinely vaccinated against rabies, the few human rabies infections (1–5 per year) usually follow exposure to rabid bats. In areas of Asia, Africa and South America, however, rabies is endemic and most human

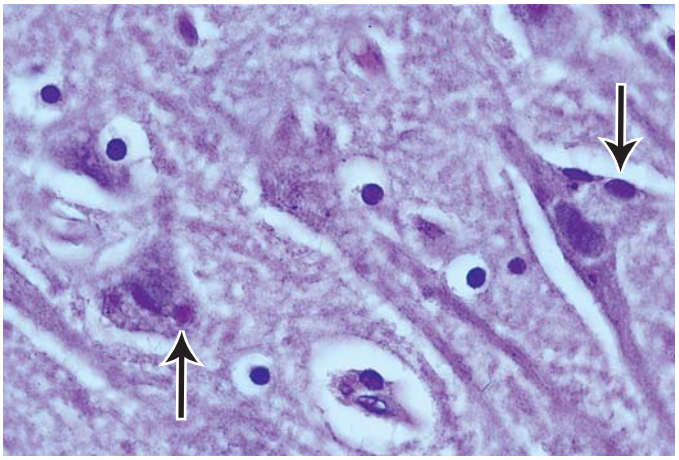

FIGURE 32-55. Negri body. Rabies encephalitis is characterized by round, eosinophilic cytoplasmic inclusions that resemble an erythrocyte (*arrows*).

infections come from dog bites. Rabies kills more than 50,000 people annually. Iatrogenic transmission has occurred, via corneal, solid organ and tendon transplants, and incubation periods may be extremely short or as mysteriously long as 18 months. Rabies is rare in industrialized countries, so the diagnosis may not be considered in potential organ donors. However, as the consequences of iatrogenic transmission of this uniformly fatal infection are so horrific, extreme caution is warranted in harvesting tissues from donors who die of strange or atypical neurologic disorders.

PATHOLOGY: The virus enters a peripheral nerve and is transported by retrograde axoplasmic flow to the spinal cord and brain. Latent intervals vary in proportion to the distance of transport, from 10 days to as long as 3 months.

Perivascular lymphocytes, scattered neurons with chromatolysis and neuronophagia and microglial nodules are seen. Inflammation is mainly in the brainstem and affects the cerebellum and hypothalamus. Eosinophilic cytoplasmic viral inclusion bodies in the hippocampus, brainstem and cerebellar Purkinje cells **(Negri bodies)** confirm the diagnosis (Fig. 32-55).

CLINICAL FEATURES: Destruction of brainstem neurons by rabies virus initiates painful spasms of the throat, difficulty swallowing and a tendency to aspirate fluids that prompted the original name, "hydrophobia." Clinical symptoms also reflect a general encephalopathy, with irritability, agitation, seizures and delirium. In up to 15% of cases, rabies may present in the paralytic form resembling Guillain-Barré syndrome rather than the encephalopathic form. The CSF displays a typical viral response, including (1) a modest increase in lymphocytes, (2) a moderate increase in protein and (3) unaltered glucose and CSF pressure. Once symptoms develop, the illness relentlessly progresses to death within 1 to several weeks. Urgent rabies vaccination and hyperimmune globulin are administered for postexposure prophylaxis.

Herpes Viruses

Herpes viruses include herpes simplex (types 1 and 2), varicella-zoster virus, cytomegalovirus (CMV), Epstein-Barr virus (EBV) and simian B virus.

HERPES SIMPLEX TYPE 1: Herpes simplex virus type 1 (HSV-1) is largely responsible for "cold sores." The region of the vesicular lesion on the lip is innervated by sensory axons from the trigeminal ganglion. HSV-1 may reside latently in the trigeminal ganglion, where it proliferates during periods of stress and is transmitted centrifugally through the nerve trunk to the lip. Reactivation and spread of HSV-1 to the CNS results in herpes encephalitis, which is the most common sporadic (i.e., nonepidemic) viral encephalitis.

PATHOLOGY: Herpes encephalitis is a fulminant infection that localizes mainly in one or both temporal lobes. The temporal lobes become swollen, hemorrhagic and necrotic (Fig. 32-56). Inflammation is mainly lymphocytic, with perivascular cuffing (Fig. 32-57). The small arteries and arterioles become hemorrhagic and edematous. Intranuclear eosinophilic inclusions, usually surrounded by a halo (Cowdry A), occur in neurons and glial cells (Fig. 32-58). Viral protein detection by immunohistochemistry is diagnostically reliable. The diagnosis is often made by PCR of CSF and viral culture.

HERPES SIMPLEX TYPE 2: In women, herpes simplex virus type 2 (HSV-2) initiates a vesicular lesion on the vulva **(genital herpes),** coupled with a latent infection in the pelvic ganglia. Newborns acquire HSV-2 from active lesions (primary or recurrent) as they pass through the birth canal. They thereafter may develop fulminant encephalitis with extensive liquefactive necrosis in the cerebrum and cerebellum.

VARICELLA-ZOSTER: Varicella-zoster virus (VZV) causes childhood exanthem "chicken pox" whereupon VZV may

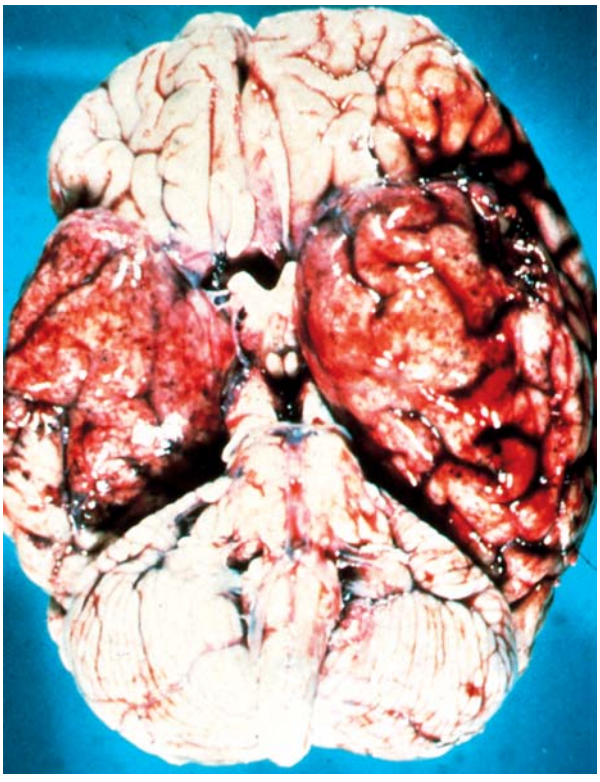

FIGURE 32-56. Herpes simplex encephalitis. Grossly, there are swollen hemorrhagic necrotic temporal lobes. The patient may experience memory disturbances and complex partial seizures as a result of this selective involvement of the temporal lobes. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

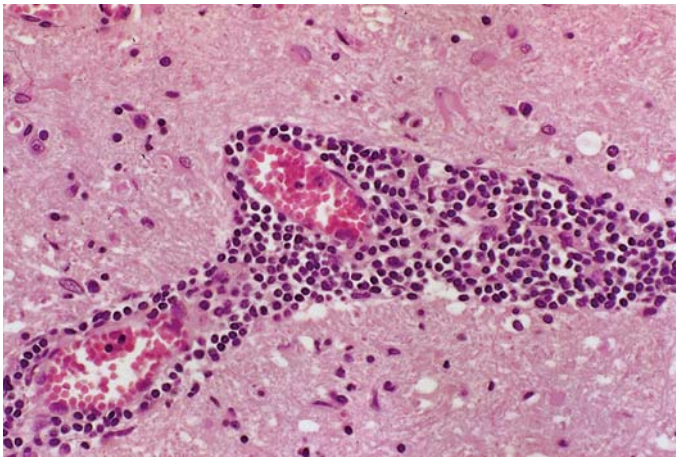

FIGURE 32-57. Herpes simplex encephalitis. Microscopically, the specimen exhibits pronounced perivascular lymphocytic inflammation. This finding indicates that active inflammation is present, but is not etiologically specific.

become latent in dorsal root ganglia. In later life, particularly after age 60, the virus may reactivate and be transported down the sensory axon to the skin, causing an exquisitely painful cutaneous vesicular eruption called "shingles" in the dermatome distribution of the dorsal root ganglion harboring the virus. The infection elicits only mild inflammation and rarely spreads to the CNS. Intranuclear Cowdry A inclusions like those of HSV are present.

Rarely, VZV may cause a fatal encephalitis, and the virus has been implicated in isolated giant cell arteritis of the CNS leading to stroke. "Shingles" reflects reemergence of latent infection by the VZV and may be the initial manifestation of immune dysfunction. The pain and vesicular eruption can be severe and disabling, but a VZV vaccine is now available and is recommended for individuals over 60 years of age.

CYTOMEGALOVIRUS: CMV crosses the placenta to induce encephalitis in utero. Lesions in the embryonic CNS are characterized by periventricular necrosis and calcification. Because of the proximity of these lesions to the

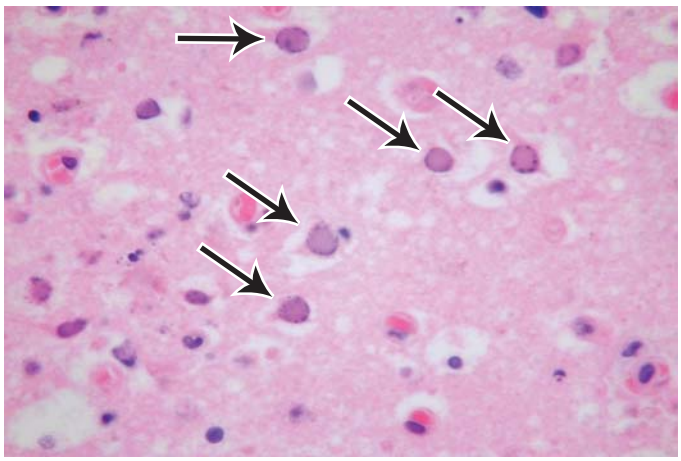

FIGURE 32-58. Herpes simplex encephalitis. The infected neurons display intranuclear, eosinophilic viral inclusions (Cowdry A inclusions) that fill the nuclei (*arrows*). The presence of these findings is extremely valuable in guiding diagnostic evaluation as a limited number of viruses produce Cowdry A inclusions.

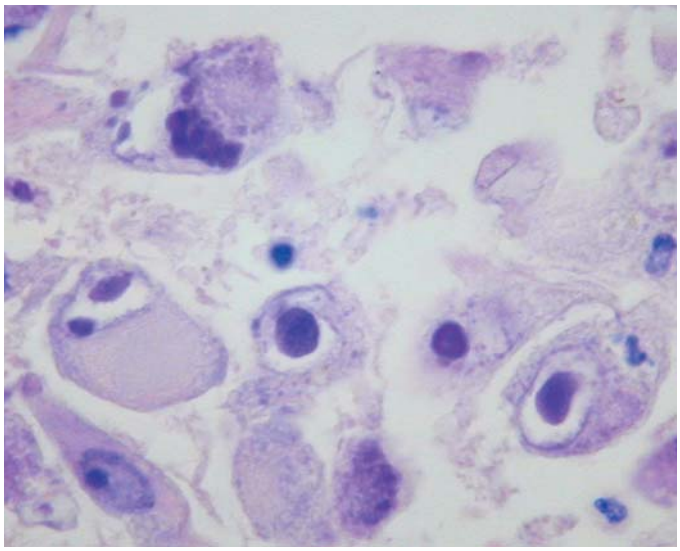

FIGURE 32-59. Cytomegalovirus ependymitis. Ependymal cells display large intranuclear inclusions in grotesquely enlarged infected cells.

third ventricle and the aqueduct, they may cause obstructive hydrocephalus. In adults, CMV encephalitis occurs in immunocompromised hosts. Eosinophilic nuclear and cytoplasmic viral inclusions are present in astrocytes and neurons, most conspicuously in enlarged nuclei, where they are sharply defined and surrounded by a halo (Fig. 32-59).

Arthropod-Borne Viral Encephalitis

EPIDEMIOLOGY: Arthropod-borne viruses, or **arboviruses,** are transmitted between vertebrates by blood-sucking vectors (e.g., mosquitoes, ticks). The Togaviridae, Bunyaviridae and Flaviviridae include most of the arboviruses that cause human encephalitis. Arbovirus infections are zoonoses of animals; humans are infected when bitten by virus-harboring arthropods. Humans are not generally reservoirs, nor do they continue viral propagation. The various encephalitides caused by arboviruses are named principally for the location where they were first noted (Table 32-1), for example, Eastern, Western and Venezuelan equine encephalitis; St. Louis encephalitis; Japanese B encephalitis; California encephalitis; and West Nile encephalitis. The latter has numerically eclipsed all other arbovirus encephalitides in the United States since it first appeared in 1999. West Nile encephalitis epidemics continue to occur, underscoring the importance of mosquito control. Most cases of West Nile infection are asymptomatic, so most infections are unrecognized. As infection can be transmitted by blood transfusion, it is now necessary to screen blood for West Nile virus. Immunocompromised patients may have a fulminant course with the arboviral infections.

PATHOLOGY: The lesions of the several arbovirus encephalitides resemble each other and vary from mild meningitis with scattered lymphocytes to severe inflammation of gray matter, thrombosis of small blood vessels and prominent necrosis. There are no inclusions in infected neurons. In necrotic foci, neuronophagia is evident, and if the patient survives, demyelination and

TABLE 32-1
INSECT-BORNE VIRAL ENCEPHALITIS

Virus	Insect Vector	Distribution
St. Louis encephalitis	Mosquito	North and South America
Western equine encephalitis	Mosquito	North and South America
Venezuelan equine encephalitis	Mosquito	North and South America
Eastern equine encephalitis	Mosquito	North America
California encephalitis	Mosquito	North America
Murray Valley encephalitis	Mosquito	Australia, New Papua
Japanese B encephalitis	Mosquito	Eastern and southeastern Asia
Tick-borne encephalitis	Tick	Eastern Europe, Scandinavia
West Nile encephalitis	Mosquito	Global

gliosis may develop. West Nile encephalitis has a tropism for the spinal cord and may produce a syndrome clinically indistinguishable from classical poliomyelitis.

CLINICAL FEATURES: Arthropod-borne encephalitides share many features, but each has a different course. For example, Eastern equine encephalitis is commonly a more fulminant potentially lethal disease, but Venezuelan equine encephalitis tends to pursue a more benign course. Mild cases of arbovirus encephalitis may entail only a mild flu-like syndrome and may not be diagnosed as encephalitis. In more severe cases, onset is abrupt, often with high fever, headache, vomiting and meningeal signs, followed by lethargy and coma. Death is more likely at the extremes of age, and those who survive may be left with cognitive impairment and seizures.

Subacute Sclerosing Panencephalitis

PATHOLOGY: Subacute sclerosing panencephalitis (SSPE) is a consequence of infection with the measles virus, and most patients have a history of measles. SSPE develops 6–8 years after the initial infection and is caused by a measles virus with defective expression of viral M (Matrix) protein. Nuclear inclusions occur in neurons and oligodendroglia, and marked gliosis affects gray and white matter, accompanied by patchy loss of myelin and ubiquitous perivascular lymphocytes and macrophages (Fig. 32-60). The intranuclear inclusions are basophilic, rimmed by a prominent halo. Affected neurons may have neurofibrillary tangles.

CLINICAL FEATURES: SSPE is a chronic, lethal, viral infection of the brain caused by measles virus. First recognized in 1933 as "subacute inclusion-body encephalitis," SSPE has an insidious onset, mainly in childhood, with cognitive and behavioral decline

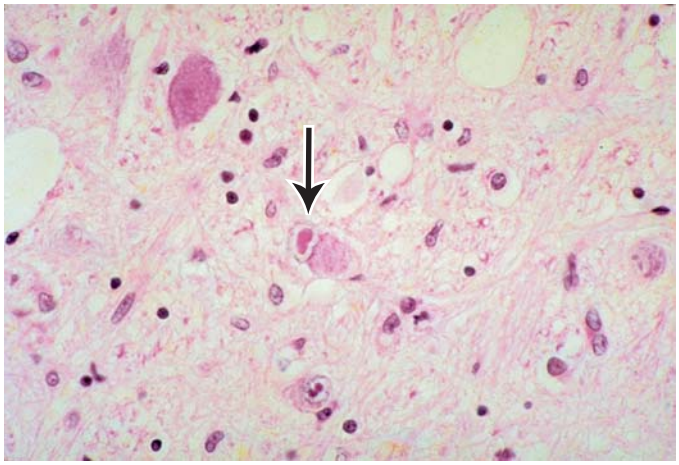

FIGURE 32-60. Subacute sclerosing panencephalitis. The brain shows loss of myelin and reactive gliosis. An intranuclear inclusion is present (*arrow*).

over months to years, ultimately leading to death. The CSF typically has increased antibody to measles virus. The course is protracted, and inflammation occurs mainly in cerebral gray matter. In adults, SSPE may follow a more rapid course.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is an increasingly common infectious demyelinating disease caused by a ubiquitous polyoma virus that infects oligodendrocytes and leads to cytolysis and patchy multifocal demyelination. Astrocytes are also infected, but instead of dying, they show extreme pleomorphism.

ETIOLOGIC FACTORS: JC virus is a polyoma virus, closely related to simian virus 40 (SV40). The "JC" derives from the initials of the first patient in whom the disease was described. Over 50% of people harbor JC virus, which resides in a latent state in the bone marrow after asymptomatic acquisition earlier in life. If the host becomes immunosuppressed, viremia ensues with specific neurovirulent viral strains.

CLINICAL FEATURES: PML occurs mostly in immunocompromised patients and manifests as dementia, weakness, visual loss and ataxia, usually leading to death within 6 months. It is a terminal complication in immunosuppressed patients, such as those treated for cancer or lupus erythematosus, organ transplant recipients and especially people with AIDS. PML may complicate the use of drugs that inhibit T-cell adherence to endothelial cells as a treatment of immunologic disorders. Natalizumab is such a drug and was temporarily withdrawn from the market after the appearance of PML in patients treated for multiple sclerosis or Crohn disease. The drug has been reintroduced to clinical use with stringent guidelines.

PATHOLOGY: Lesions typical of PML appear as widely scattered discrete foci of demyelination near the gray–white junction in the cerebral hemispheres and brainstem (Fig. 32-61). They are several millimeters and spherical, with a central area largely devoid of myelin. Axons are retained, a few oligodendrocytes are seen

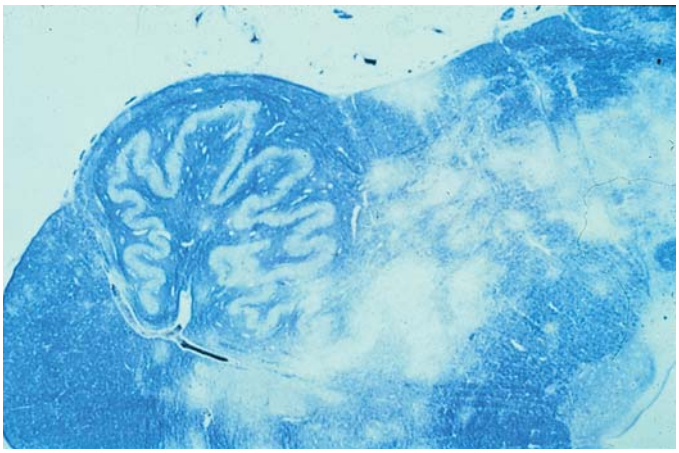

FIGURE 32-61. Progressive multifocal leukoencephalopathy. A Luxol fast blue stain of the medulla reveals severe patchy loss of myelin.

and the lesion is infiltrated by macrophages. At the edge of the demyelinated area, there are oligodendrocytes with enlarged nuclei occupied by homogeneously dense, hyperchromatic, "ground-glass" intranuclear inclusions lacking a halo. Electron microscopy discloses intranuclear, crystalline arrays of spherical 35–40-nm virions (Fig. 32-62). Infected astrocytes are highly pleomorphic, often with multiple irregular dark nuclei (Fig. 32-63). These astrocytes can be so pleomorphic as to suggest malignancy.

HIV

CNS disease is common in AIDS. Some patients have opportunistic CNS infections, such as toxoplasmosis, cytomegalovirus, herpes simplex or PML, or have EBV-driven primary CNS lymphoma (PCNSL). Cryptococcal meningitis is the most common fungal meningitis in AIDS patients, toxoplasmosis is the most common intracranial mass and PCNSL is the most common neoplasm. These are sentinels of AIDS; that is, any of these occurring in any patient should trigger diagnostic consideration of underlying AIDS. There are

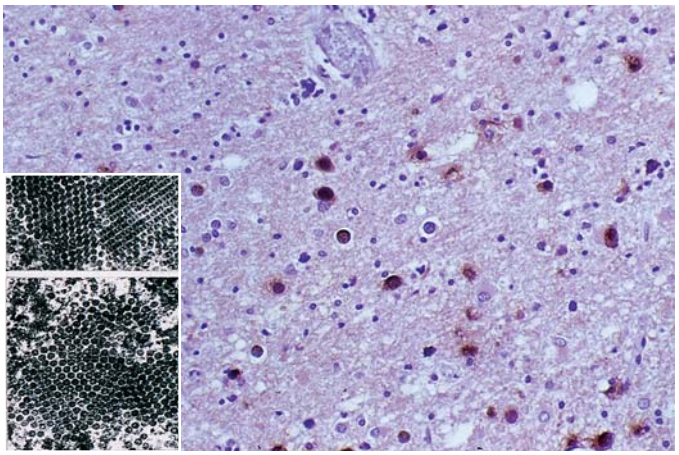

FIGURE 32-62. Progressive multifocal leukoencephalopathy. An immunohistochemical stain for JC virus demonstrates numerous infected oligodendroglia in the white matter. By electron microscopy, there are intranuclear paracrystalline arrays of viral particles (*insets*).

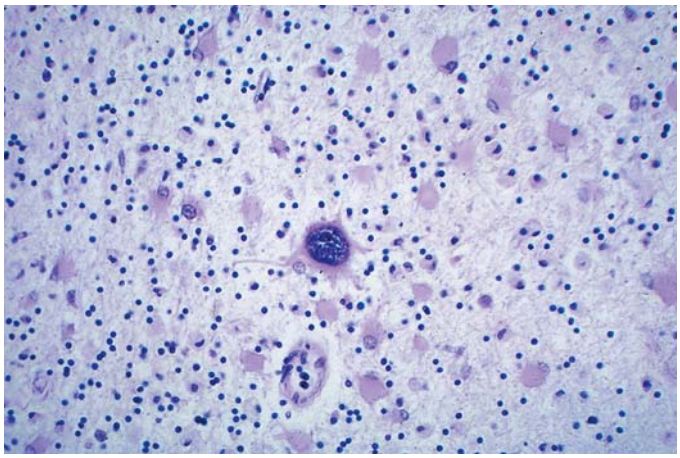

FIGURE 32-63. Progressive multifocal leukoencephalopathy (PML). A bizarre astrocyte is present (*center*) and may mimic neoplasia. The presence of macrophages and ground-glass inclusions should direct diagnostic consideration away from neoplasia and toward PML.

many other opportunistic nervous system infections that may complicate AIDS, and it is important to remember that the clinical presentation may be more fulminant or atypical than in immunocompetent individuals.

HIV Encephalopathy

Many AIDS patients have diffuse encephalopathy directly attributable to active CNS infection by HIV-1 retrovirus itself. This is variously called HIV encephalopathy (HIVE) or HIV-associated neurologic disease (HAND). Dementia was once the most common clinical manifestation of HIVE. It varies from mild to severe cognitive impairment with striking slowness of thought (bradyphrenia), often with marked bradykinesis mimicking Parkinson disease. CNS macrophages and microglial cells are productively infected by HIV-1. Infection of neurons and astrocytes is probably not clinically significant, but these cells are injured indirectly by neurotoxic viral proteins produced by infected cells or various cytokines, which cause oxidant-mediated cell injury.

The advent of highly active antiretroviral therapy (HAART) has dramatically extended the life span and quality of life of AIDS patients, including reducing opportunistic infections and primary CNS lymphoma. HAART drugs largely do not cross the blood-brain barrier, and since the virus enters the CNS via infected blood monocytes very soon after it enters the body, HAART has not altered the incidence of HAND. Rather, although frank dementia has become less common, a combination of sensory, motor and other defects causing minor cognitive motor disease (MCMD) affects as many as 30% of HIV-1–positive patients. As these people age, this prevalence increases by an additional approximately 5% of the HIV-1–positive population yearly. Initiation of HAART may also be complicated by immune reconstitution inflammatory syndrome (IRIS). In the brain, IRIS may lead to potentially lethal cerebral edema and exacerbation of focal symptoms and may contribute to fulminant HIVE.

PATHOLOGY: HAND is characterized by mild cerebral atrophy, dilation of the lateral ventricles and slight prominence of gyri and sulci. Histologic

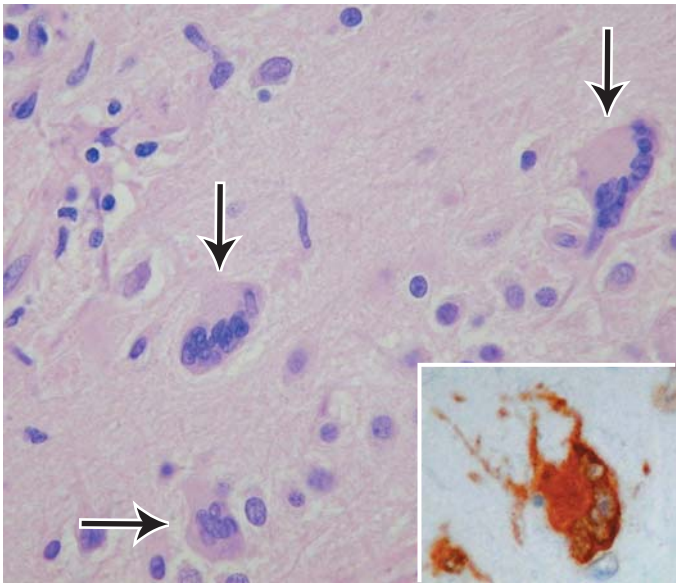

FIGURE 32-64. HIV encephalitis or encephalopathy (HIVE). Multinucleated giant cells (*arrows*) often in a perivascular location are characteristic of HIV encephalitis. *Inset.* Immunohistochemical stain for HIV anti-p24.

changes are usually in the subcortical gray and white matter. Multinucleated giant cells of monocyte/macrophage lineage are associated with microglial nodules (Fig. 32-64). In addition, myelin pallor, reflecting diffuse demyelination, intense astrogliosis and loss of neurons, is common (Fig. 32-65).

Vacuolar myelopathy is another disorder attributed to HIV infection, although it is less frequent than encephalopathy. It is characterized by marked vacuolation of the posterior and lateral columns, principally in the thoracic spinal cord. Ataxia and spastic paraparesis dominate the clinical presentation.

Both Protozoan and Metazoan Parasites May Infect the CNS

Protozoan Infections

- **Toxoplasmosis** is a ubiquitous protozoan to which most of us have protective immunity. Immunocompromised patients lose the ability to contain these organisms. Small comma-like tachyzoites and large polyorganismal cysts (bradyzoites) are seen in association with chronic inflammation, tissue necrosis and vasculitis. Toxoplasmosis is the most common cause of multiple intracranial masses in AIDS patients (Fig. 32-66).
- ***Naegleria* spp.,** especially *Naegleria fowleri,* cause primary amebic meningoencephalitis, a fulminant and rapidly fatal disease with diffuse brain swelling. The ameba infects the nasal cavities of people who swim in stagnant warm freshwater ponds or who irrigate their sinus passages with inadequately decontaminated water. They enter the brain by migrating up the olfactory bulb, through the cribriform plate. *Naegleria* trophozoites resemble macrophages (Fig. 32-67).
- ***Acanthamoeba*** produces granulomatous amoebic encephalitis, a subacute, usually fatal illness characterized by

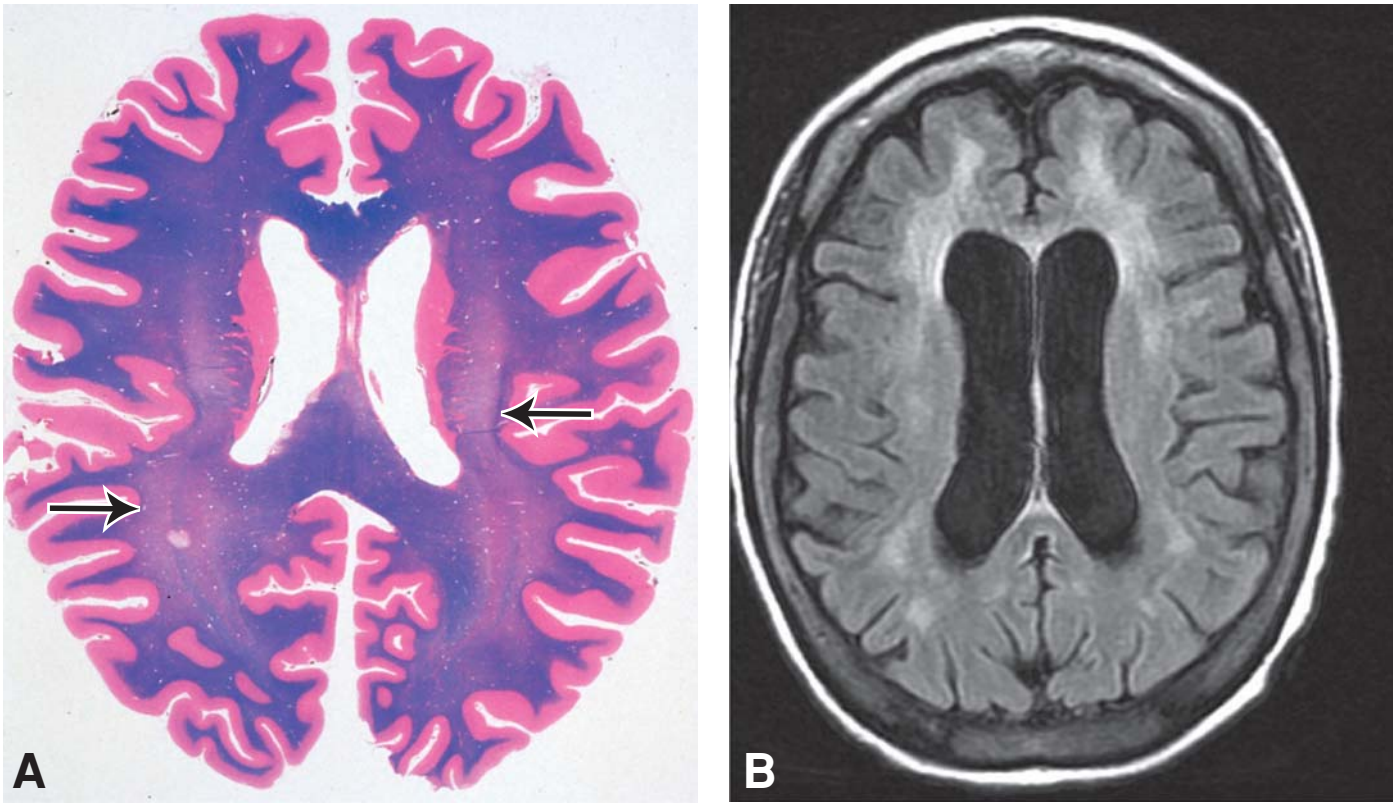

FIGURE 32-65. HIV encephalitis or encephalopathy (HIVE). A. An axial whole brain section in HIVE shows symmetric myelin pallor (*arrows*) caused by HIV-1. Demyelination caused by progressive multifocal leukoencephalopathy (PML) would be less symmetric and patchy. (Courtesy of Dr. F. Stephen Vogel, Duke University.) **B.** Axial magnetic resonance image showing bilateral white matter signal abnormalities in HIVE. The primary differential diagnosis is HIVE versus PML.

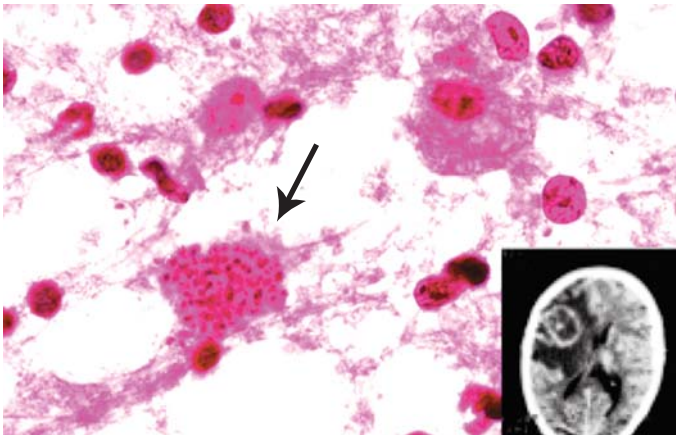

FIGURE 32-66. Toxoplasmosis in an HIV patient. This previously asymptomatic patient presented with an irregularly enhancing mass with surrounding edema that was initially thought to be a high-grade neoplasm. *Toxoplasma gondii* bradyzoites (*arrow*) are present in a necrotic inflammatory background. Toxoplasmosis is the most common mass lesion in patients with AIDS and is an indicator disease of HIV infection.

multiple granulomatous abscesses. This condition is usually seen in immunocompromised hosts.

- ***Entamoeba histolytica*** leads to amebic brain abscess by spread from a gastrointestinal or hepatic locus. Amebae in tissue sections can be difficult to distinguish from foamy macrophages.
- **CNS malaria** is most commonly caused by *Plasmodium falciparum*. During attacks of cerebral malaria, the CSF shows elevated protein and pressure but pleocytosis is uncommon. In fatal cases, the brain is diffusely swollen and may be otherwise unremarkable, but one may see microinfarcts with gliosis (Dürck granulomata) in white matter or many small hemorrhages. Infarcts and microhemorrhages may both arise from obstruction of blood flow in small vessels by parasitemia. Severity of cerebral malaria also reflects tumor necrosis factor-α release by host cells.

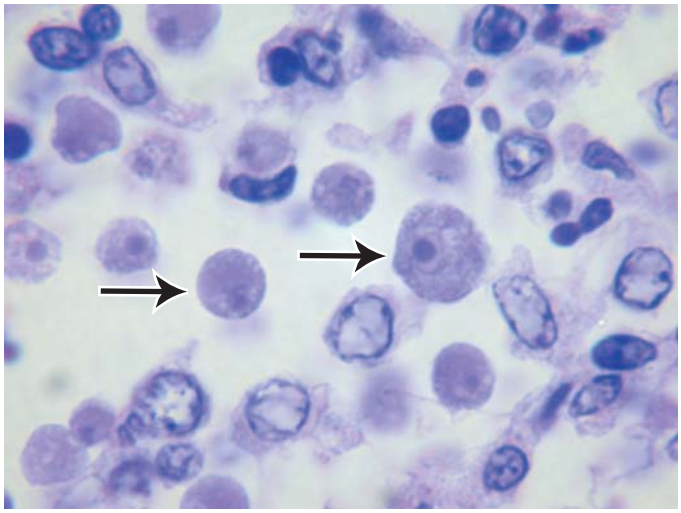

FIGURE 32-67. *Naegleria* meningoencephalitis. Amebic organisms (*arrows*) resemble macrophages but have much more prominent nucleoli.

- **Trypanosomal** infections include African sleeping sickness and American trypanosomiasis **(Chagas disease)**. Insect vectors transmit the disease. A meningoencephalitis may occur during the primary phase of infection. Reactivation of latent *Trypanosoma cruzi* produces multiple necrotic CNS lesions resembling toxoplasmosis and has been seen in people with AIDS and other forms of immunosuppression. Chagas disease is endemic in Central and South America, but 300,000–1,000,000 seropositive immigrants from those areas live in North America, and they are at risk for reactivation with immunosuppression.

Metazoan Infections of the Nervous System

- **Cysticercosis** caused by infection by *Taenia solium,* the pig tapeworm, may lead to multiple parasitic cysts up to 1 cm in the parenchyma, intraventricularly or in the basal cisterns. The intraparenchymal disease usually becomes symptomatic when the organism dies and is recognized immunologically by the host (Fig. 32-68). A peculiar form of this infection is racemose neurocysticercosis, in which grape-like clusters and sheets of worm tissues are made, without a fully formed worm. Racemose cysticercosis is essentially invertebrate tissue culture in the CSF and is resistant to therapy that is effective against intact parasites. Treatment of neurocysticercosis may lead to massive cerebral edema caused by massive host immune responses to the suddenly necrotic metazoan tissue. From a global health perspective, neurocysticercosis is one of the most common causes of epilepsy and intracranial mass lesions.
- **Echinococcosis** results from *Taenia echinococcus* or *Echinococcus granulosus,* the dog tapeworm, and produces cerebral cysts that are usually solitary and may be huge, in contrast to the smaller multiple cysts of cysticercosis. The brain lesion is frequently accompanied by hepatic cysts.
- **Trichinosis** is caused by *Trichinella spiralis* infection of skeletal and cardiac muscle, producing an acute eosinophilic myositis during the invasive phase. Larvae may then die and calcify, producing fibrosis and low-grade inflammation. The infection may rarely encroach on the CNS, producing lymphocytic-eosinophilic aseptic meningitis.

Prion Diseases (Spongiform Encephalopathies) Are Transmissible Neurodegenerative Diseases Caused by Modified Protein Particles

Prion diseases are characterized clinically by rapidly progressive ataxia and dementia and pathologically by accumulations of fibrillar or insoluble prion proteins, neuronal degeneration and vacuolization called **spongiform encephalopathy** (Fig. 32-69). The spongiform encephalopathies are biologically remarkable because the causative infectious agents, called **prions** (proteinaceous infectious particles), lack nucleic acids.

EPIDEMIOLOGY: The classic spongiform encephalopathies in humans include kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome (GSS) and fatal familial insomnia (Table 32-2). Similar diseases occur in animals, including scrapie in sheep and

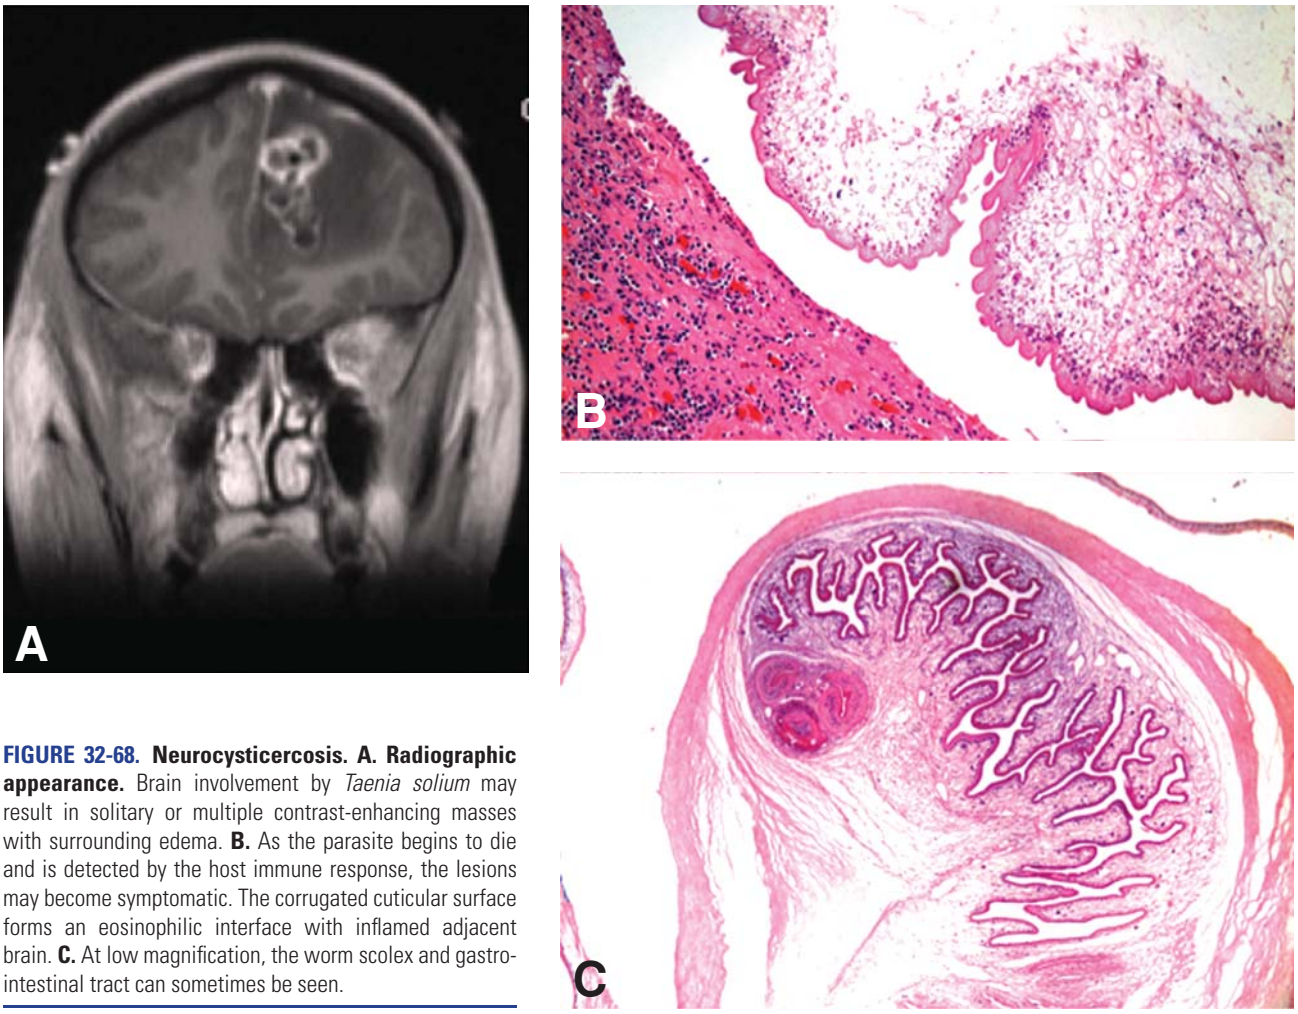

FIGURE 32-68. Neurocysticercosis. A. Radiographic appearance. Brain involvement by *Taenia solium* may result in solitary or multiple contrast-enhancing masses with surrounding edema. **B.** As the parasite begins to die and is detected by the host immune response, the lesions may become symptomatic. The corrugated cuticular surface forms an eosinophilic interface with inflamed adjacent brain. **C.** At low magnification, the worm scolex and gastrointestinal tract can sometimes be seen.

goats, bovine spongiform encephalopathy (BSE; mad cow disease), transmissible mink encephalopathy and chronic wasting disease in mule deer and elk. BSE is of particular interest because it resulted from inadvertent introduction of prion-contaminated feed to cattle, thus establishing that prions can be transmitted by the oral route. BSE is also more easily transmitted and does not show the species selectivity of other prions. It decimated the cattle industry in the United Kingdom and spread to other regions of the world and to other species including zoo animals, pets and humans.

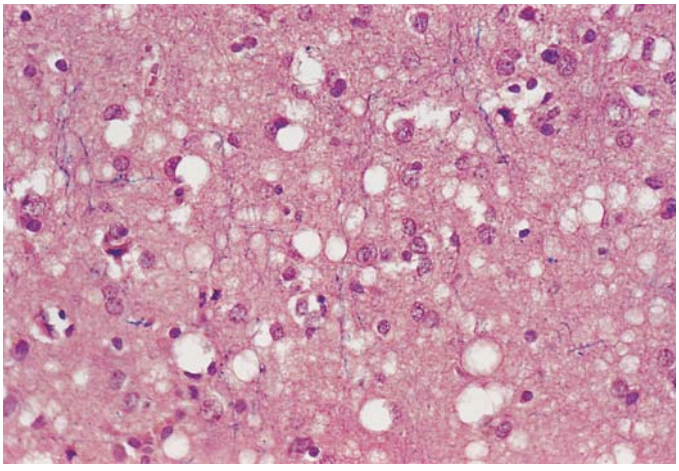

FIGURE 32-69. Creutzfeldt-Jakob disease. Spongiform degeneration of the gray matter is characterized by individual and clustered vacuoles, with no evidence of inflammation. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

MOLECULAR PATHOGENESIS: The signal molecular event in prion disorders is conversion of a native α-helix–rich protein into a pathogenic β-sheet–rich isoform that tends to polymerize with subsequent fibril formation (Figs. 32-70 and 32-71). Uniquely, conversion of the native protein to the pathogenic form is autocatalyzed by the pathogenic form itself. The pathogenic protein begets more pathogenic protein from the limitless supply of native protein! The native protein is coded by a human prion gene (*PRNP*) on the short arm of chromosome 20, which contains a single exon encoding 254 amino acid residues. The normal prion gene product, prion protein (PrP), is a constitutively expressed cell surface glycoprotein that binds neuronal plasmalemma via a glycolipid anchor. PrP is made widely throughout the body, but the highest levels of PrP messenger RNA (mRNA) are in CNS neurons. Its function is unknown. The normal cellular prion protein, cellular PrP or PrP^{C}, and the pathogenic (infectious) prion protein, known as scrapie PrP or PrP^{SC}, have the same primary amino acid sequence but different tertiary structures and patterns of glycosylation. Specifically, PrP^{C} is rich in α-helix configuration, but the β-pleated sheet configuration

TABLE 32-2
PRION DISEASES

I. Human

A. Creutzfeldt-Jakob disease (CJD)
   1. Sporadic (85% of all CJD cases; incidence 1 per million worldwide)
   2. Inherited mutation of the prion gene, autosomal dominant transmission (15% of all CJD cases)
   3. Iatrogenic
      a. Hormone injection: human growth hormone, human pituitary gonadotropin
      b. Tissue grafts: dura mater, cornea, pericardium
      c. Medical devices: depth electrodes, surgical instruments (none definitely proven)
   4. New variant CJD (vCJD)

B. Gerstmann-Sträussler-Scheinker disease (GSS; inherited prion gene mutation, autosomal dominant transmission)

C. Fatal familial insomnia (FFI; inherited prion gene mutation, autosomal dominant transmission)

D. Kuru (confined to the Fore people of Papua New Guinea, formerly transmitted by cannibalistic funeral ritual)

II. Animal

A. Scrapie (sheep and goats)

B. Bovine spongiform encephalopathy (BSE; "mad cow disease")

C. Transmissible mink encephalopathy

D. Feline spongiform encephalopathy

E. Captive exotic ungulate spongiform encephalopathy (nyala, gemsbok, eland, Arabian oryx, greater kudu)

F. Chronic wasting disease of deer and elk

G. Experimental transmission to many species, including primates and transgenic mice

predominates in PrP^{SC}. The pathogenic conformation is extremely stable so that PrP^{SC} strongly resists conventional microbial decontamination methods. If PrP^{SC} enters the brain either through infectious transmission or by spontaneous misfolding of native protein, it will change other PrP^{C} proteins into pathogenic PrP^{SC}, leading to autocatalytic, exponentially expanding accretion of abnormal PrP^{SC}. The masses of PrP^{SC} compromise cell function and cause neurodegeneration by mechanisms that remain to be elucidated but may be similar to those of other neurodegenerative diseases characterized by fibrillogenesis.

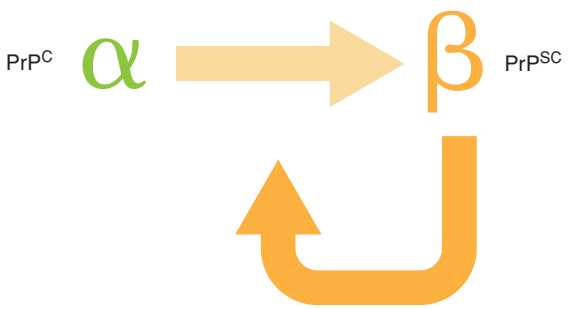

FIGURE 32-70. Creutzfeldt-Jakob disease. The unique mode of "reproduction" of the prion is the autocatalytic conversion of native α-helix–rich cellular prion protein into a β-sheet–rich pathogenic form that has a strong tendency toward aggregation.

All spongiform encephalopathies are transmissible, and inadvertent human transmission of CJD may follow administration of contaminated human pituitary growth hormone, corneal transplantation from a diseased donor, poorly sterilized neurosurgical instruments and surgical implantation of contaminated dura (Table 32-2).

PATHOLOGY: Prion diseases entail neuron degeneration, gliosis, spongiform degeneration and accumulations of insoluble prions forming extracellular plaques. There are many small, clear, often confluent microcysts in the neuropil (Fig. 32-71). Lesions occur mostly in cortical gray matter but also involve deeper nuclei of the basal ganglia, thalamus, hypothalamus and cerebellum.

CLINICAL FEATURES: The several human prion diseases are distinct.

KURU: In 1956, a medical officer in New Guinea provided an account of kuru, a progressive, fatal neurologic disorder, in members of the isolated Fore tribe. The disease takes its name from the word "trembling" in their language. Transmission of kuru was linked to ritualistic funereal cannibalism in which women and children ate brains of deceased relatives.

Kuru was the first human prion disease shown to be transmissible. It attained epidemic proportions in the Fore people but was eliminated when cannibalism ceased. The initial and most prominent clinical feature of kuru is ataxia of the limbs and trunk, due to severe cerebellar involvement. In 70% of cases, insoluble, fibrillar prion proteins accumulate extracellularly in plaques. Spongiform change is present in both the cerebral hemispheres and cerebellum.

CREUTZFELDT-JAKOB DISEASE: CJD is the most common form of spongiform encephalopathy. Symptoms begin insidiously, but usually within 6 months to 3 years, patients exhibit severe dementia leading to death. Cerebellar involvement produces ataxia, which helps to distinguish CJD from Alzheimer disease. Myoclonus often occurs for some weeks to months during the afflicted person's decline. CJD is classified based on etiology: sporadic, familial, iatrogenic and new variant:

- **Sporadic CJD:** The sporadic form occurs worldwide, with an incidence of 1 per million, and accounts for 75% of CJD cases. The mode of acquisition is unknown; patients do not have the mutations associated with inherited forms of CJD or other prion diseases, and there is no history of iatrogenic exposure. A polymorphism in PRNP codon 129 confers differential susceptibility to CJD: homozygosity for either methionine (M) or valine (V) at this codon leads to disproportionate susceptibility to prion disorders, while heterozygotes (M/V) are resistant. Codon frequencies for the white population are 51% M/V, 37% M/M and 12% V/V.
- **Inherited CJD: Familial CJD** accounts for 15% of prion diseases, with an incidence of 1 in 10 million. Several different PRNP mutations are documented in various kindreds. In those cases, the PrP^{C} has a greater tendency to

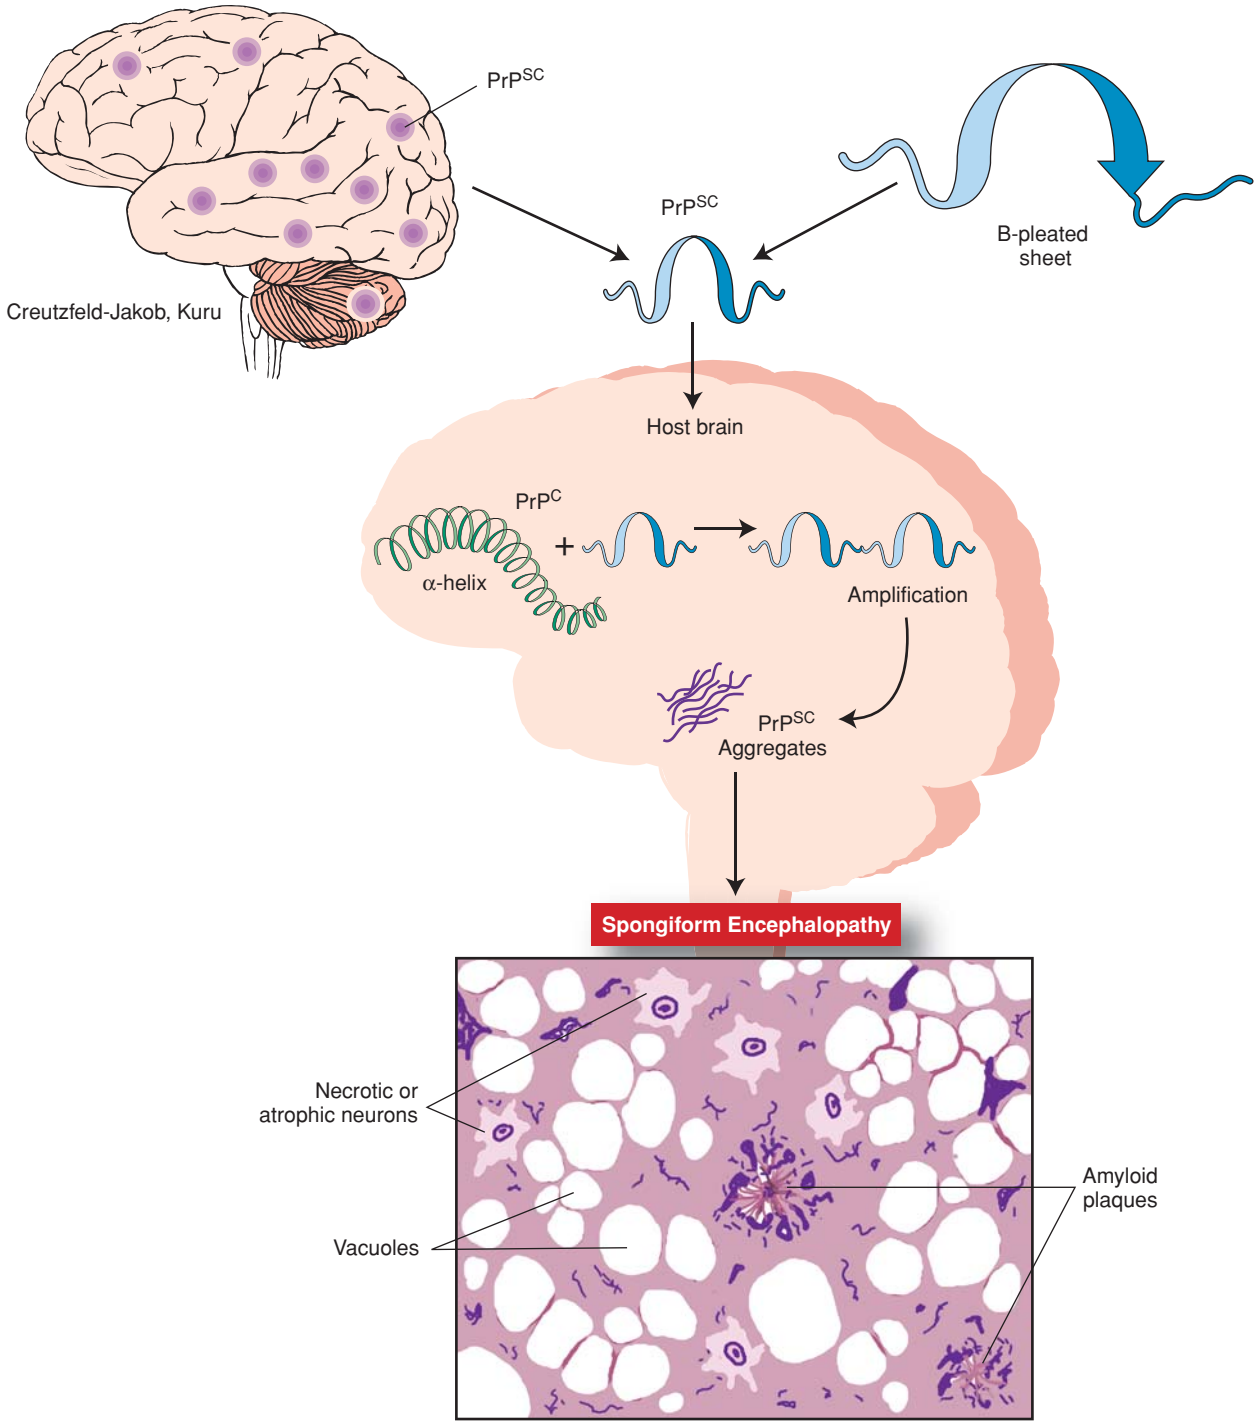

FIGURE 32-71. Molecular pathogenesis of prion disorders.

misfold into the pathogenic isoform. The mutated PRNP causes familial CJD, fatal familial insomnia and Gerstmann-Sträussler-Scheinker disease.

- **Iatrogenic CJD:** As listed in Table 32-2, several iatrogenic causes of CJD are known, but most causes for iatrogenic CJD now have been eliminated. Thus, recombinant human growth hormone has replaced human pituitary-derived preparations for therapy. When brain biopsies or autopsies are done in prion disease cases, special protocols are used to limit exposure of staff and patients to prions. Disposable instruments are used if possible, and surfaces and instruments are treated with 2 N NaOH. Conventional autoclaving and most standard disinfectants do not eradicate this hardy infectious agent.
- **New variant CJD (vCJD or nvCJD):** This form was identified by a surveillance program in the United Kingdom after the BSE epidemic (see above) between 1980 and 1996. A group of patients was identified that differed from other patients with sporadic CJD in several key characteristics, most importantly, age. The mean age at onset of symptoms for sporadic CJD is 65, but for vCJD it is 26. Also, vCJD patients had a longer duration of illness (median,

12 months vs. 4 months) and an atypical clinical presentation, including various behavioral changes or sensory disturbances (dysesthesias) and none of the usual electroencephalographic (EEG) findings of sporadic CJD. At autopsy, vCJD is characterized by prominent spongiform change in the basal ganglia and thalamus, and extensive PrP plaques in the cerebrum and cerebellum. The plaques are distinctive in that they resemble those of kuru. Finally, brains from vCJD patients contain much more PrP than brains of sporadic CJD patients. Physicochemical analysis showed different characteristics for vCJD PrP^{SC} from CJD PrP^{SC}, but similar to prions in BSE that were transmitted to mice and primates. Thus, BSE is considered to be the source of nvCJD. Current evidence suggests that vCJD cases have peaked and are declining. Essentially all vCJD cases were in codon 129 homozygotes (who are more susceptible), and a recent case in a heterozygote raises the unsettling specter of a longer incubation type of vCJD in this population. In addition, retrospective examination of surgical specimens of tonsils and appendices in the United Kingdom using PrP^{sc} has shown a significant number of asymptomatic individuals with pathogenic PrP that may become the nidus of a new epidemic of vCJD.

With globalization and diversification of economies, cultures and populations, a global perspective is essential in considering infectious diseases. New disorders can emerge and disseminate rapidly. Many of these infections have an impact on the nervous system, as we have seen with HIV and H1N1 influenza. Ease of movement leads to infections previously thought of as exotic or tropic occurring unexpectedly in industrialized countries. Larger populations rendered immunocompromised due to HIV, cancer or immunosuppressive therapies provide fertile grounds for clinically atypical neurologic infectious disease. Finally, there is the ever present danger of manmade biological agents being deployed.

DEMYELINATING DISEASES

Demyelinating diseases entail disruption of the myelin economy, including flawed manufacture **(dysmyelination),** destruction of myelin **(demyelination)** or disruption of myelin metabolism **(leukodystrophies)**. Central myelin is made by oligodendrocytes, while peripheral myelin is made by Schwann cells (see Chapter 31). These two types of myelin differ biochemically. Operationally, the border between the CNS and the peripheral nervous system can be considered to be the point of transition between myelin made by oligodendrocytes and that made by Schwann cells. This transition usually occurs about 2–3 mm after a cranial nerve or spinal root exits the brainstem or spinal cord. Myelin disorders affect central or peripheral myelin, or both.

Multiple Sclerosis Is the Most Common Demyelinating Disease

EPIDEMIOLOGY: Multiple sclerosis (MS) is a chronic demyelinating disease. With a prevalence of 1 per 1000, it is the most common chronic CNS disease of young adults in the United States. It is characterized by exacerbations and remissions over many years. It becomes symptomatic at a mean age of 30, and women are afflicted almost twice as often as men.

MOLECULAR PATHOGENESIS: The etiology of MS is obscure, but genetic predisposition and immune dysfunction are probably involved. MS is mainly a disease of temperate climates. People who emigrate before age 15 from areas with a low prevalence to more temperate endemic areas assume the increased risk associated with their destinations, suggesting that environmental factors are important.

There are familial aggregates of the disease, with increased risk in second- and third-degree relatives of MS patients and 25% concordance for MS in monozygotic twins. Susceptibility is also linked to certain major histocompatibility complex (MHC) alleles (e.g., human leukocyte antigen [HLA]-DR2), implying that immune mechanisms are involved in the pathogenesis.

The lesions' microscopic appearance also suggests immune involvement. For example, chronic MS lesions show perivascular lymphocytes, macrophages and many $CD4^+$ as well as $CD8^+$ T cells (see Chapters 4 and 11). Moreover, $CD4^+$ T cells in the CSF of MS patients tend to be oligoclonal. Although no target antigen is established, data suggest an immune response to a specific CNS protein. Further support for immune mechanisms comes from an experimental antigen-specific, T-cell–mediated, autoimmune disease, **experimental allergic encephalitis (EAE)**. Injecting myelin basic protein into animals, including nonhuman primates, elicits a demyelinating disorder similar to MS. However, unlike MS, EAE is a monophasic illness.

Although an assortment of viruses have been implicated in the etiology of MS, to date there is no compelling evidence for the involvement of any infectious agent.

PATHOLOGY: The demyelinated plaque is the hallmark of MS (Figs. 32-72 and 32-73). Plaques, rarely more than 2 cm, accumulate in great numbers in the brain and spinal cord (Fig. 32-74). They are discrete, with smoothly rounded contours, and are usually in white matter, although they may breach the gray matter. The lesions preferentially affect the optic nerves, chiasm, paraventricular white matter and spinal cord, but any part of the CNS may be involved.

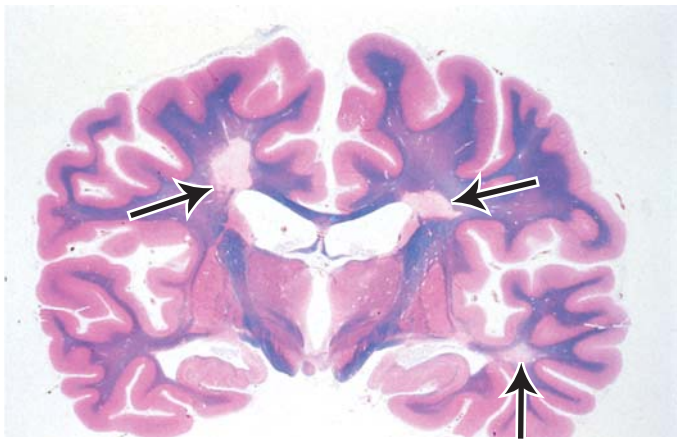

FIGURE 32-72. Multiple sclerosis. This myelin-stained coronal whole brain section of the brain of a patient with long-standing multiple sclerosis shows many areas of myelin loss—plaques (*arrows*)—with characteristic periventricular demyelination especially prominent at the superior angles of the lateral ventricles. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

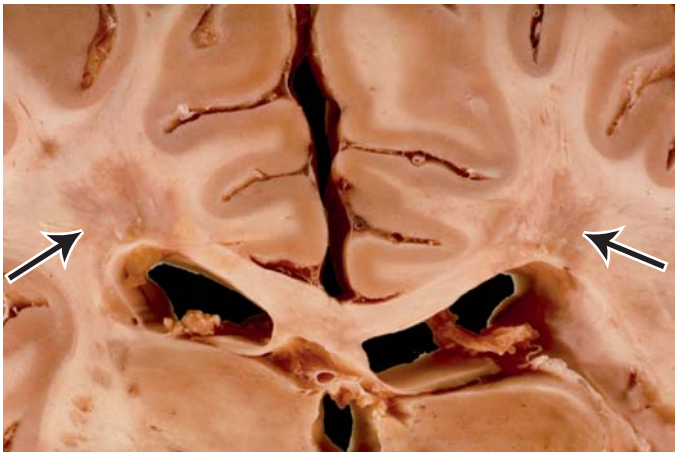

FIGURE 32-73. Multiple sclerosis. This fresh coronal section shows darker hues of the somewhat irregular periventricular plaques (*arrows*) reflecting the loss of myelin, which imparts the normal glistening white appearance of white matter.

Evolving plaques are marked by selective loss of myelin in regions of relative axonal preservation, lymphocytes clustering about small veins and arteries, influx of macrophages and considerable edema.

Neuronal bodies within plaques are remarkably spared, but axons may degenerate. Numbers of oligodendrocytes are moderately decreased. As plaques age, they become more discrete and less edematous. This sequence emphasizes the focal nature of the injury and its selectivity and severity, as demyelination is total within a plaque. Axons within plaques usually lose their myelin abruptly. Old MS plaques are dense and gliotic.

CLINICAL FEATURES: MS usually begins in the third or fourth decades, after which patients experience abrupt episodes of clinical progression, separated by periods of relative stability. The essential clinical criterion for MS is dissemination of lesions in space and time; that is, multiple separate areas of the CNS must be affected at differing times. Our understanding of disease activity in MS has been revolutionized by use of serial MRI studies, which show ongoing disease activity despite apparent clinical quiescence. New plaques emerge and regress, only occasionally causing clinical manifestations. Contemporary diagnostic criteria for MS strongly incorporate periodic imaging to visualize plaques scattered in space and time. Thus, MS is an ongoing active process even between clinical exacerbations. The therapeutic focus is now suppression of ongoing disease activity using a variety of immune system modulators such as β-interferon, and MRI efficacy is an endpoint in drug trials and clinical management. Neuropathologic studies have confirmed increased inflammatory activity in brains of MS patients between exacerbations.

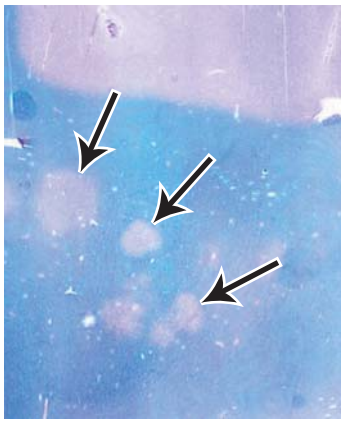

FIGURE 32-74. Multiple sclerosis. The subcortical white matter of a patient with multiple sclerosis showing multiple small irregular, partially confluent areas of demyelination (*arrows*). Normal intact myelin stains blue in this Luxol fast blue–stained section.

Many patients with MS pursue relapsing remitting clinical courses, but some suffer a relentless course without remissions. Each exacerbation reflects the formation of additional demyelinated MS plaques. MS typically begins with symptoms relating to lesions in the optic nerves, brainstem or spinal cord. Blurred vision or loss of vision in one eye as a result of optic neuritis is often the presenting complaint. When the initial lesion is in the brainstem, double vision and vertigo occur. In particular, internuclear ophthalmoplegia, caused by disruption of the medial longitudinal fasciculus, strongly suggests demyelinating disease when it occurs in a young person. Acute demyelination within the spinal cord is called **transverse myelitis** and produces weakness of one or both legs and sensory symptoms in the form of numbness in the lower extremities. Many of the initial symptoms are partially reversible within a few months.

Despite the fact that most patients have a chronic relapsing and remitting course, neurologic deficits accumulate gradually and relentlessly. Even in relatively quiescent plaques, there may be axonal attrition leading to irreversible lesions. In established cases, the degree of functional impairment is highly variable, ranging from minor disability to severe incapacity, with widespread paralysis, dysarthria, ataxia, severe visual defects, incontinence and dementia. Patients with severe disability usually die of respiratory paralysis or urinary tract infections. Most patients survive 20–30 years after the onset of symptoms.

Neuromyelitis Optica Is a Demyelinating Disease Common in Japan

Neuromyelitis optica (NMO) is a demyelinating disorder with a striking predilection for the optic nerves and spinal cord. Once regarded as a variant of MS, NMO is now recognized as resulting from autoantibodies against a water channel, aquaporin 4, and is thus pathophysiologically quite distinct from MS. It responds poorly to conventional MS therapy.

Postinfectious and Postvaccinal Encephalomyelitis Are Immune Responses to Viral Antigens

Some viral infections (e.g., measles, varicella, rubella) may rarely be followed in 3–21 days by an encephalomyelitis. The disease entails focal perivascular demyelination and conspicuous mononuclear cell infiltrates around small to medium-sized venules in brain and spinal cord white matter. It is suspected to be immune mediated, but its precise pathogenesis remains unclear. Onset of postinfectious encephalomyelitis is heralded by headache, vomiting, fever and meningismus that may be followed by paraplegia, incontinence and stupor. Up to 15%–20% of patients die.

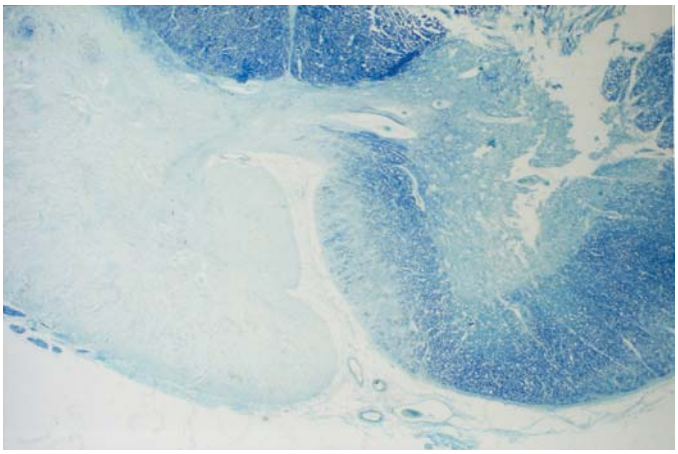

FIGURE 32-75. Postvaccinal encephalomyelitis involving the spinal cord with marked myelin loss in the lateral and anterior regions of the spinal cord on the left.

A similar syndrome, **postvaccinal encephalomyelitis,** may follow immunization against infectious agents (e.g., smallpox, rabies) (Fig. 32-75). Use of more-purified vaccines, free of cross-reacting antigenic contaminants, has dramatically reduced the frequency of this complication.

Chronic Lymphocytic Inflammation with Pontine Perivascular Enhancement Responsive to Steroids Affects the Brainstem

Chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids (CLIPPERS) is a rare, newly described disorder with brainstem and cerebellar T-cell–predominant inflammation and demyelination. Patients have symmetric curvilinear gadolinium enhancement scattered throughout the pons and extending variably into the medulla, cerebellum, midbrain and occasionally spinal cord. Radiologic and clinical improvement occurs with high-dose glucocorticosteroid therapy, but patients routinely worsen after glucocorticosteroids are tapered and often require chronic glucocorticosteroid or other immunosuppressive therapy.

Leukodystrophies Are Inherited Defects of Myelin Biochemistry

These disorders often impact both central and peripheral myelin and usually manifest in infancy or childhood, although milder adult phenotypes may occur. Disruption of central myelin leads to blindness, spasticity and loss of developmental milestones, while loss of peripheral myelin leads to weakness and loss of reflexes.

Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD), the most common leukodystrophy, is an autosomal recessive disorder characterized by accumulation of a cerebroside (galactosyl sulfatide) in the white matter of the brain and peripheral nerves. MLD predominates in infancy, but rare juvenile or adult cases are described. It is lethal within several years. A clinical trial using gene-corrected bone marrow transplantation has shown promise in preventing MLD progression.

PATHOPHYSIOLOGY: MLD is caused by deficiency in arylsulfatase A activity. This lysosomal enzyme is involved in the degradation of myelin sulfatides. Accordingly, there is progressive accumulation of sulfatides within the lysosomes of myelin-forming Schwann cells and oligodendrocytes.

PATHOLOGY: In MLD, the accumulated sulfatides form cytoplasmic spherical granules, 15–20 μ in diameter, which stain metachromatically with cresyl violet and toluidine blue. Normal staining is orthochromatic; that is, cresyl violet or toluidine blue stains tissue violet or blue. In metachromasia, the dye color shifts: tissue stained with cresyl violet or toluidine blue looks rusty brown to red. The brain shows diffuse myelin loss, accumulation of metachromatic material in white matter and astrogliosis. Demyelination of peripheral nerves is less severe.

Krabbe Disease

Krabbe disease is a rapidly progressive, fatal, autosomal recessive neurologic disorder caused by a deficiency of galactocerebroside β-galactosidase.

PATHOLOGY: The brain is small, with widespread loss of myelin and preservation of the cerebral cortex. Astrogliosis is severe. Multinucleated "globoid cells" develop in the white matter and cluster around blood vessels, leading to the alternative name, **globoid cell leukodystrophy**. The globoid cells are multinucleated macrophages full of undigested galactocerebroside (galactosylceramide). These cells are up to 50 μ, with up to 20 peripheral nuclei. In end-stage disease, numbers of globoid cells decline, and in areas of severe myelin loss, only scattered globoid cells remain. Marbled areas of partial and total demyelination are present. By electron microscopy, the globoid cells contain crystalloid-like inclusions with straight or tubular profiles.

CLINICAL FEATURES: Krabbe disease appears in infancy and progresses to death within 1–2 years. Severe motor, sensory and cognitive defects reflect diffuse involvement of the nervous system.

Adrenoleukodystrophy

MOLECULAR PATHOGENESIS: Adrenoleukodystrophy (ALD) is an X-linked (Xq28) inherited disorder in which dysfunction of the adrenal cortex and nervous system demyelination are associated with high levels of saturated very-long-chain fatty acids (VLCFAs) in tissue and body fluids. The enzyme mutation in ALD impairs degradation of VLCFAs by preventing normal activation of free VLCFAs by the addition of coenzyme A (CoA). Disease reflects accumulation of abnormal cholesterol esters and VLCFA toxicity.

PATHOLOGY: In the brain, there is confluent, bilaterally symmetric demyelination. The most severe lesions are in the subcortical white matter of the parieto-occipital region, which then extend rostrally

(while sparing cortex) to result in severe loss of myelinated axons and oligodendrocytes. Gliosis and perivascular infiltrates of mononuclear cells (mostly lymphocytes) are prominent in affected areas. Scattered macrophages contain periodic acid–Schiff (PAS)-positive and sudanophilic material. Peripheral nerves are affected, but to a lesser degree than the brain. The adrenal glands are atrophic. Electron microscopy of cortical cells shows pathognomonic cytoplasmic, membrane-bound, curvilinear inclusions or clefts (lamellae) containing VLCFAs. Similar inclusions occur in Schwann cells and CNS macrophages.

CLINICAL FEATURES: ALD occurs in children ages 3–10 years old, in whom neurologic symptoms precede signs of adrenal insufficiency. The disease progresses rapidly for 2–4 years, and the patient is quickly reduced to a vegetative state, which may persist for several years before death. Manipulation of dietary lipid composition and quantity using a 4:1 mixture of glycerol trioleate and glycerol trierucate ("Lorenzo's oil") reduces serum VLCFAs and slows progression of the disease in some cases. If the patient survives through childhood, the diet can be liberalized.

TOXIC AND METABOLIC DISORDERS

Given the enormous appetite of the brain for oxygen and amino acids and other metabolic morsels, it is not surprising that the brain is subject to malfunction as a result of lack or malutilization of essential substances, intoxication and hereditary metabolic diseases. These disorders are particularly important since correction of underlying metabolic derangements restores function. In most cases, these dysfunctions may be functionally profound but have no morphologic correlate; however, in some cases, pathologic changes occur.

Metabolic Storage Diseases Reflect Lack of Key Enzymes

Neuronal storage diseases are inherited enzyme defects in which normal metabolic products accumulate in lysosomes. Unlike leukodystrophies, which produce blindness and spasticity, these diseases affect neurons to cause seizures and cognitive decline.

Tay-Sachs Disease

Tay-Sachs disease is a lethal, autosomal recessive disorder caused by deficiency of hexosaminidase A. Thus, ganglioside accumulates in CNS neurons. The disease is fatal in infancy and early childhood. Retinal involvement increases macular transparency and causes a **cherry-red spot** in the macula.

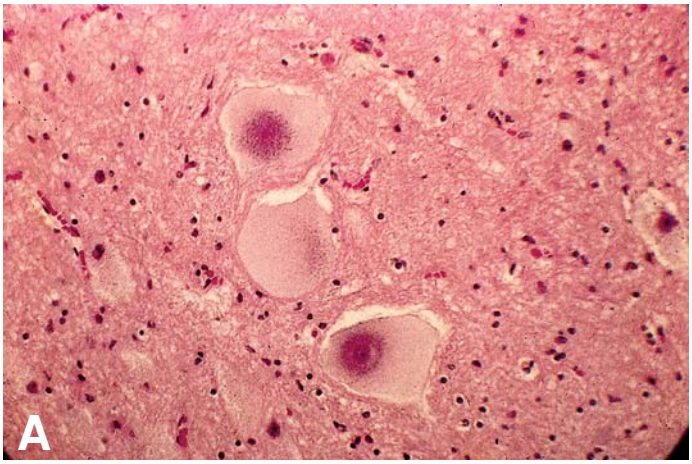
The brain is the major site of ganglioside storage, and it progressively enlarges in infancy. Lipid droplets in the cytoplasm distend CNS and peripheral neurons (Fig. 32-76A). Electron microscopy demonstrates the lipid within lysosomes as whorled "myelin figures" (Fig. 32-76B). The neural tissues develop diffuse astrogliosis. An affected infant appears normal at birth but by age 6 months shows delayed motor development. Thereafter, progressive deterioration leads to flaccid weakness, blindness and severe mental impairment. Death usually supervenes before the end of the second year.

Hurler Syndrome

Hurler syndrome is an autosomal recessive disturbance in glycosaminoglycan metabolism that results in intraneuronal accumulation of mucopolysaccharides. Clinical variants of this syndrome are distinguished by variable involvement of visceral organs and the nervous system. The disease is typically expressed in infancy or early childhood as reduced stature, corneal opacities, skeletal deformities and hepatosplenomegaly. The intraneuronal storage distends the cytoplasmic compartment and is accompanied by astrogliosis and progressive mental deterioration.

Gaucher Disease

Gaucher disease is an autosomal recessive genetic deficiency of glucocerebrosidase, leading to glucocerebroside accumulation, principally in macrophages. The CNS is most severely involved in infantile (type II) Gaucher disease.



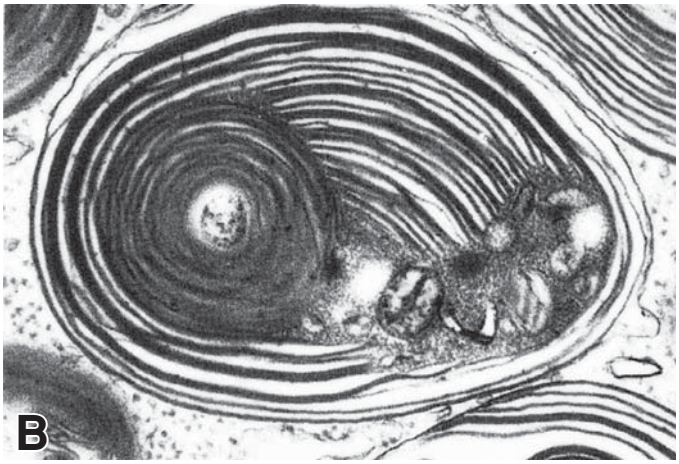


FIGURE 32-76. Tay-Sachs Disease A. The cytoplasm of the neurons is distended by the accumulation of eosinophilic storage material. **B.** Ultrastructurally, whorled "myelin bodies" composed of accumulated gangliosides are present within the cytoplasm.

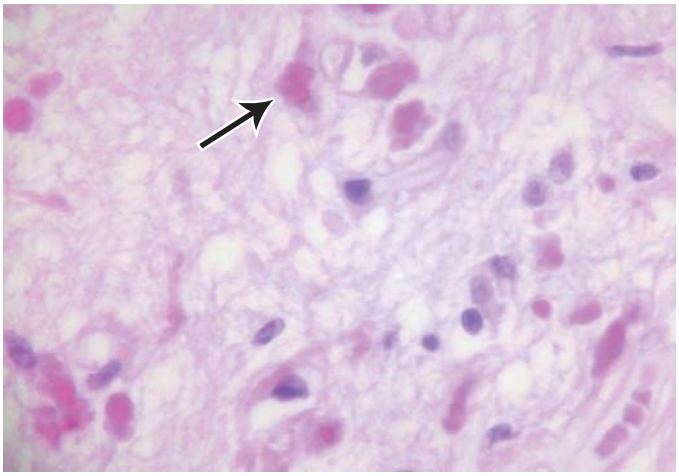

FIGURE 32-77. Alexander disease. This disease reflecting a mutation in the glial fibrillary acidic protein (GFAP) gene is characterized by accumulation of aggregated GFAP into eosinophilic bodies called Rosenthal fibers (*arrows*). Rosenthal fibers are seen in Alexander disease, in pilocytic astrocytoma and as a reaction adjacent to chronic compressive lesions.

Although intraneuronal accumulation of glucocerebroside is not conspicuous, neuronal loss is severe and is accompanied by diffuse astrogliosis. These infants fail to thrive and die at an early age.

Niemann-Pick Disease

Niemann-Pick disease is an autosomal recessive disorder in which a deficiency of sphingomyelinase leads to intraneuronal storage of sphingomyelin. Symptoms occur early, with failure of the infant to develop and thrive. The mononuclear phagocyte system is targeted for storage, but the nervous system may predominate symptomatically during infancy. The brain becomes atrophic, with marked astrogliosis. Retinal degeneration may produce a cherry-red spot, like that in Tay-Sachs disease.

Alexander Disease

Alexander disease is an astrocytic storage disease. It is an uncommon neurologic disorder of infants, children and rarely adults, and is characterized by a loss of myelin in the brain and striking eosinophilic collections of GFAP in astrocytic processes (Rosenthal fibers; Fig. 32-77). The Rosenthal fibers are abundant, particularly in a perivascular and subpial distribution. Clinically, children have psychomotor retardation, progressive dementia and paralysis and eventually die. The disease is caused by mutations in the gene encoding GFAP. It is not yet clear how this process impairs myelin formation and induces degeneration of oligodendrocytes and myelin.

Phenylketonuria Is a Deficiency in Phenylalanine Hydroxylase

Phenylketonuria (PKU) is an autosomal recessive disease (see Chapter 6) in which phenylalanine accumulates in blood and tissues because its conversion to tyrosine is blocked. Symptoms appear in the early months of life, with mental retardation, seizures and impaired physical development. Treatment consists of restricting dietary phenylalanine. Untreated patients rarely obtain an IQ above 50, but those on the diet do well. Since the morbidity of PKU is preventable by a simple dietary restriction, all newborns are now screened for it. Although there are no consistent morphologic alterations, the brain may be underweight and deficient in myelination.

Wilson Disease Is an Autosomal Recessive Disorder of Copper Metabolism

Wilson disease, or **"hepatolenticular degeneration,"** affects the brain and the liver and is caused by mutations of the *WD* gene (see Chapter 20). Defective excretion of copper in the bile leads to copper deposition in the brain.

CLINICAL FEATURES: Symptoms of cerebral involvement appear as a movement disorder with a tendency to choreoathetosis, usually in the second decade, but the disease may not become apparent until as late as the eighth decade. The movement disorder may be associated with psychosis. Before, during or after the appearance of neurologic symptoms, an insidiously developing cirrhosis may result in hepatic failure. Copper deposition in the limbus of the cornea produces a visible golden-brown band, the **Kayser-Fleischer ring,** seen on slit lamp examination.

The lenticular nuclei of the brain show a light golden discoloration, and 25% of cases have small cysts or clefts in the putamen or in deep layers of the neocortex. Mild neuron loss and gliosis are characteristic.

Some patients are "presymptomatic," never developing high enough levels of copper to accumulate in the brain or eyes or developing cirrhosis. Diagnosis is critical as Wilson disease is treatable, and failure to treat can lead to irreversible hepatic and CNS damage. Anyone presenting with a hyperkinetic movement disorder, particularly with onset in early adult life, in association with psychiatric or hepatic manifestations must be evaluated for Wilson disease.

Brain Dysfunction in Systemic Metabolic Disease Is Metabolic Encephalopathy

Such metabolic derangements may be caused by cardiopulmonary, renal, hepatic or endocrine diseases occurring singly or in combination. Clinically, patients show declining level of consciousness, starting with inattentiveness that may include rowdiness, progressing to lethargy and finally lack of arousal, regardless of level of stimulation. The change in consciousness may be accompanied by tremor, asterixis and changing multifocal neurologic signs. Computed tomography (CT) and MRI scans show no structural abnormality, and EEG shows progressive slowing of rhythmic cortical activity, sometimes accompanied by periodic high-amplitude discharges known as triphasic waves (which are seen most often in hepatic encephalopathy but are not specific for this condition). Biochemically, metabolic encephalopathy is characterized by lower cerebral glucose and oxygen utilization regardless of the underlying disorder. There are no specific morphologic features in metabolic encephalopathy, but presence of Alzheimer type II astrocytes suggests, but is not diagnostic of, hepatic encephalopathy.

Hepatic Encephalopathy

Hepatic encephalopathy is a common clinical expression of liver failure, with delirium, seizures and coma. Symptoms generally greatly exceed their morphologic correlates, which are restricted to the appearance of altered astroglia **(Alzheimer type II astrocytes)** with enlarged nuclei and marginated chromatin, especially in the thalamus.

Osmotic Demyelination Syndrome (Central Pontine Myelinolysis)

This is a rare demyelinating disorder of the pons, where discrete areas of selective demyelination occur (Fig. 32-78). Lesions often are too small to manifest clinically and are evident only at autopsy. In a few patients, quadriparesis, pseudobulbar palsy or locked-in syndrome may occur. Central pontine myelinolysis (CPM) arises from overly rapid correction of hyponatremia in alcoholics, malnourished people or patients with marked electrolyte instability, including those with renal failure and liver transplant recipients. Demyelination is not confined to the pons, and other extrapontine white matter areas may be involved; thus, CPM is now considered part of a broader disorder called osmotic demyelination syndrome. A classical corpus callosal demyelination process, called Marchiafava Bignami syndrome, is now considered to be part of osmotic demyelination, but internal capsule, corona radiata and cerebellar white matter tracts may be involved as well.

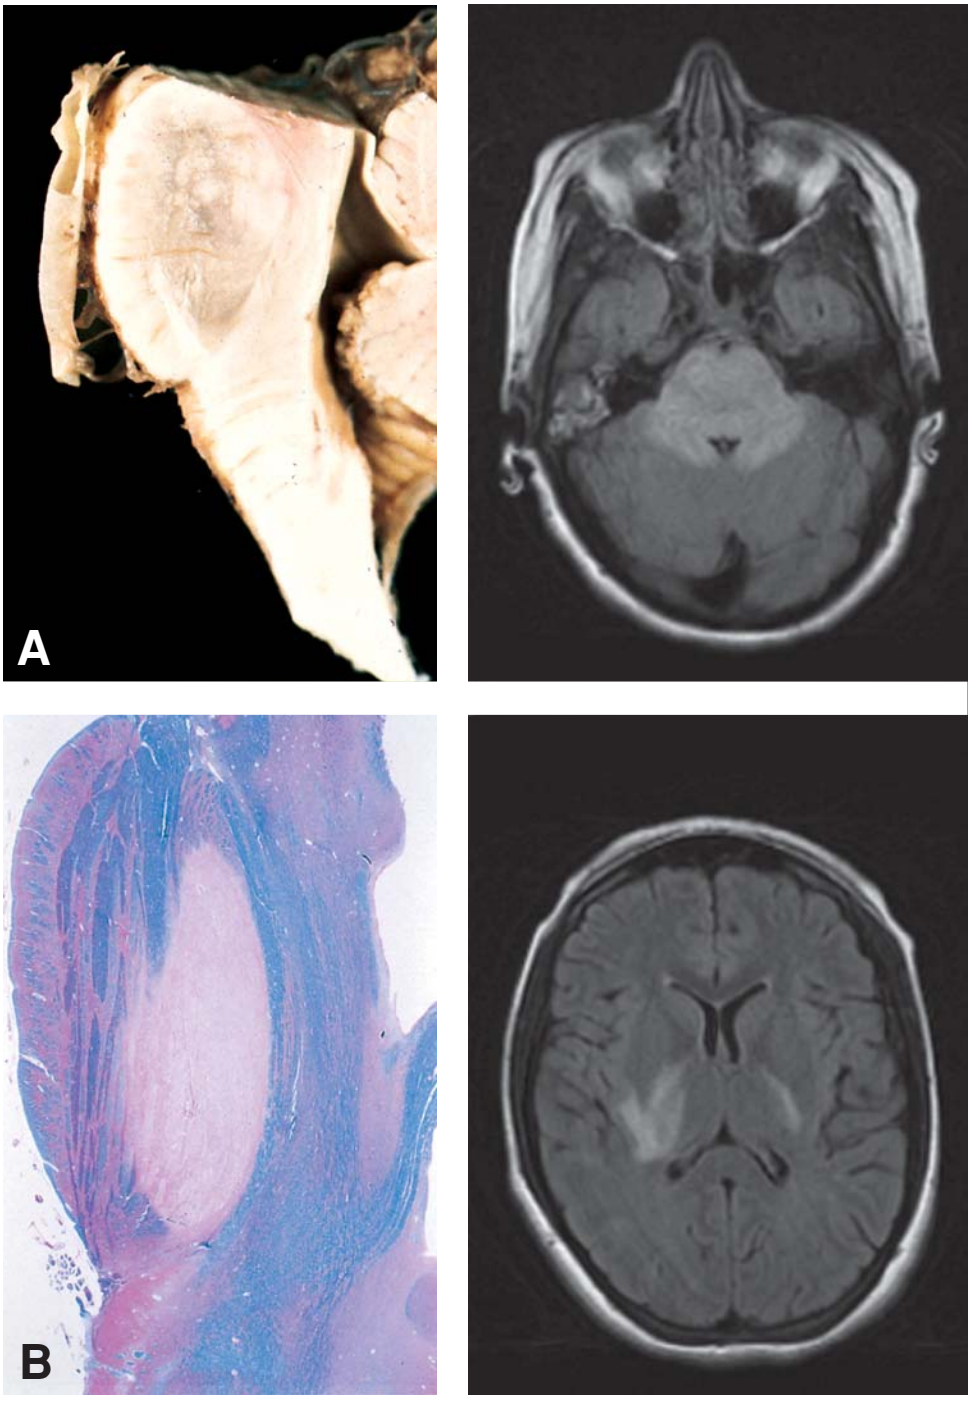

FIGURE 32-78. Osmotic demyelination syndrome with central pontine myelinolysis. A. This sagittal section of the brainstem shows a soft, discolored, midpontine lesion. **B.** A myelin-stained section reveals a sharply demarcated loss of myelin appearing as a pink ovoid zone. (A and B Courtesy of Dr. F. Stephen Vogel, Duke University.)

FIGURE 32-79. Wernicke encephalopathy. This coronal section shows hemorrhagic petechiae in the mamillary bodies and periventricular anterior thalamus (*arrows*). (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Vitamin Deficiencies

Vitamin deficiencies and their systemic consequences are discussed in Chapter 8.

Wernicke Syndrome

Wernicke syndrome results from thiamine (vitamin B_1) deficiency and is characterized clinically by rapid onset of altered consciousness with dramatically impaired short-term memory, ophthalmoplegia and nystagmus. Lesions are seen in the hypothalamus and mamillary bodies, the periaqueductal regions of the midbrain and the pontine tegmentum (Fig. 32-79). The syndrome is most common in chronic alcoholics but may occur in others whose diets lack thiamine. It may progress rapidly to death, but it is reversed by administration of thiamine. In fatal cases, petechiae form around capillaries in the mamillary bodies, hypothalamus, periaqueductal region and floor of the fourth ventricle (Fig. 32-80). Over time, hemosiderin deposition identifies regions where petechiae occurred. Neurons and myelin are generally spared, but mamillary body atrophy and capillary proliferation may be prominent.

FIGURE 32-80. Wernicke encephalopathy with petechial hemorrhage in mammillary bodies. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Wernicke-Korsakoff syndrome is a state of disordered recent memory often compensated for by confabulation. It resembles Wernicke syndrome pathologically but may show degeneration of neurons in the medial–dorsal thalamic nucleus.

Many chronic alcoholics have cerebral atrophy of uncertain cause and for which the relative contributions of alcohol toxicity, malnutrition and other factors are not defined. Similar uncertainties prevail with regard to atrophy of the Purkinje and granular cells of the cerebellum. These changes are common in chronic alcoholism and are the cause of truncal ataxia, which persists during periods of sobriety.

Subacute Combined Degeneration

Subacute combined degeneration of the spinal cord results from vitamin B_{12} deficiency (pernicious anemia) and leads to lesions in the posterolateral portions of the spinal cord. Initially, there is symmetric myelin and axonal loss in the thoracic spinal cord. Astrogliosis is mild in the acute lesions, but with time, gliosis and atrophy develop, especially in the posterolateral areas of the cord.

A burning sensation in the soles of the feet and other paresthesias herald the onset of this rapidly progressive and poorly reversible neurologic disorder. Weakness emerges in all four limbs, then defective postural sensibility, incoordination and ataxia. Subacute combined degeneration may complicate a rare case of extensive gastric resection and other malabsorption syndromes. As vitamin B_{12} is not found in plants, some extreme vegetarians who eschew all animal products, even milk and eggs, develop subacute combined degeneration after many years on a restricted diet.

Iatrogenic, occupational or recreational exposure to the anesthetic gas nitrous oxide (N_2O) may lead to a clinically and morphologically indistinguishable condition. N_2O interferes with vitamin B_{12}–dependent enzymes. Hypocupric (low serum copper) myelopathy after bariatric surgery or zinc overdosage is also similar.

Intoxication

Neurotoxicology is a major aspect of contemporary neuropathology. The breadth of this area far exceeds the scope of this chapter, so we concentrate on the more common and better-understood toxic injuries to the brain.

ETHANOL: Acute and chronic alcohol intake has widespread harmful effects and more widespread societal repercussions owing to its behavioral consequences. Acute alcohol intoxication signs and symptoms correspond to dose-related blood level, such that 0.05–0.1 mg/dL is associated with disinhibition and motor impairment; 0.1–0.3 mg/dL with frank inebriation and ataxia; and 0.3–0.35 mg/dL with extreme intoxication and sleepiness, nausea and vomiting. Over 0.35 mg/dL is potentially lethal owing to respiratory depression and inability to protect the airway from aspiration. Lethal intoxication may tragically occur during competitive drinking among college students.

Chronic alcohol use is associated with neurologic complications caused by nutritional deficiencies, including Wernicke-Korsakoff syndrome and possibly peripheral neuropathy; liver failure with hepatic encephalopathy and non-Wilsonian hepatocerebral degeneration; and metabolic derangements including central pontine myelinolysis from rapid correction of hyponatremia (Fig. 32-81). Alcoholics may also develop

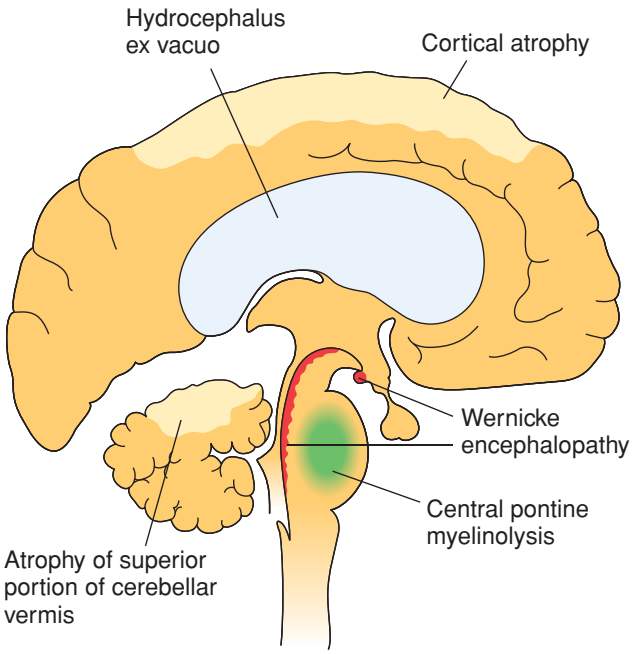

FIGURE 32-81. Regions of the brain with lesions associated with chronic ethanol abuse.

central necrosis of the corpus callosum or Marchiafava-Bignami disease (see above). This disease is part of the osmotic demyelination syndrome caused by overly rapid correction of hyponatremia. Less well understood is anterior superior vermal cerebellar degeneration, which occurs mainly in alcoholic men, presents with truncal ataxia and is grossly evident as atrophy of the vermis (Fig. 32-82).

METHANOL: In their quest for ethanol, alcoholics may from time to time drink methanol, which is oxidized to formaldehyde and formic acid. Patients dying of methanol intoxication have severe cerebral edema with hemorrhagic necrosis of the lateral putamen. Retinal edema and ganglion cell degeneration account for the blindness that afflicts these patients. Blindness may result from ingestion of as little as 4 mL, while a lethal dose is in the range of 8–10 mL of pure methanol, although usually 70–100 mL is consumed in fatal cases.

ETHYLENE GLYCOL: Similarly, ethylene glycol (automotive antifreeze) is sometimes consumed as an alternative to ethanol or by children or animals because of its sweet taste. Oxalate is its metabolic product. Severe organic acidosis may lead to coma and renal failure, and survivors may have residual neurologic deficits. Tissue oxalate crystal deposition may be seen.

CARBON MONOXIDE (CO): This colorless, odorless, tasteless gas is formed by incomplete combustion. CO binds hemoglobin far more avidly than oxygen. It thus displaces oxygen from hemoglobin, to form carboxyhemoglobin (COHb), which in turn reduces the oxygen-carrying capacity of blood. COHb is red and imparts a "cherry-red" hue to victims of CO poisoning. Severe intoxication causes almost pathognomonic bilateral liquefactive necrosis of the globus pallidus. Other areas of CNS ischemic injury may be seen. The mechanism of the selective globus pallidus injury is unclear, but the recent discovery that CO may act as a neurotransmitter suggests that areas rich in heme-iron (such as the basal ganglia) may use CO under physiologic conditions for cell-to-cell signaling. As in amino acid excitotoxicity (see above), an excess neurotransmitter such as CO might injure the areas where it normally plays a physiologic role.

METAL INTOXICATION OR DEFICIENCY: Many metals employed in industry and medicine can cause neurologic disease; additionally, the biocidal properties of some of these substances, such as arsenic and thallium, have made them favorite tools of murderers, suicidal individuals and pesticide users.

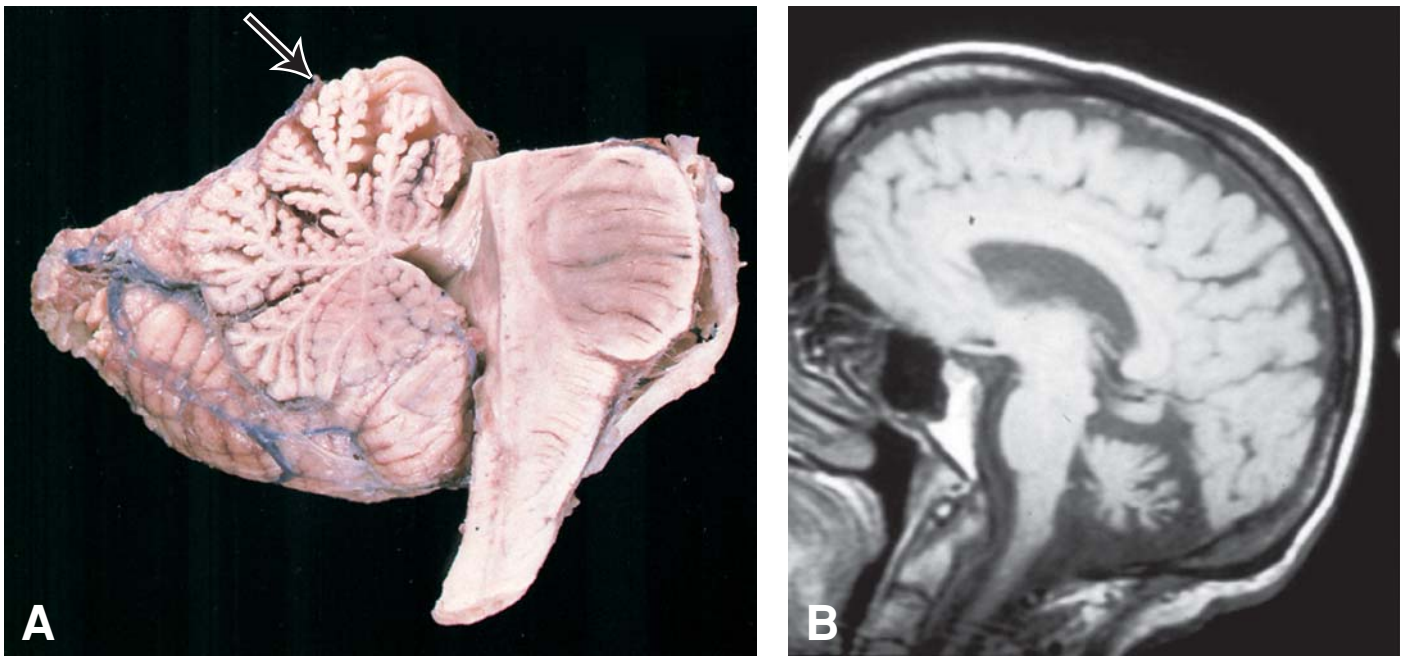

FIGURE 32-82. Chronic alcoholism. A. The superior and anterior portions of the cerebellar vermis are atrophic (*arrow*), leading to truncal ataxia. (Courtesy of Dr. F. Stephen Vogel, Duke University.) **B.** Coronal noncontrast computed tomography showing profound vermal atrophy in an alcoholic individual.

- **Lead:** Lead intoxication produces an edema-based encephalopathy in acute poisoning, especially in childhood. An amorphous exudate around microvessels may be seen, as may some vascular proliferation. Excess exposure in children may entail their ingesting lead-based paint, fishing sinkers and other lead weights. In adults, lead poisoning more commonly presents as a neuropathy rather than as an encephalopathy.
- **Mercury:** Chronic inorganic mercury intoxication may present with dementia, delirium, tremor, irritability and insomnia. Now rare, mercury poisoning in the 19th century decimated workers in cinnabar mines, hat manufacturing ("mad as a hatter"), mirror silvering plants and manufacturing of scientific instruments. Cerebellar atrophy with loss of Purkinje cells was seen.
- Organomercurial poisoning is now more prevalent. In Japan, in Minamata Bay, industrial mercuric chloride from the manufacture of vinyl chloride was dumped into the bay. The marine food chain concentrated the metal. Fishermen and local inhabitants then ate contaminated seafood. Many people were injured or died. These patients developed ataxia and blindness. Cerebellar and cerebrocortical atrophy occurred, with some cortical damage elsewhere. Congenital methylmercury neurotoxicity from in utero exposure results in severe mental retardation, athetosis, ataxia and spastic quadriparesis. Severe atrophy of the cerebrum with milder cerebellar atrophy is evident, with loss of the cortical lamellar organization perhaps indicating a defect in neuronal migration and organization in development.
- **Arsenic:** Arsenical intoxication manifests with gastrointestinal complaints including nausea, vomiting and diarrhea; cutaneous features including hyperkeratosis and increased pigmentation of the soles and palms and Mees lines on the nails; and a severe axonal neuropathy. In the brain, swelling and petechiae may be present. Long-term exposure has other risks (see Chapter 8).
- **Thallium:** Like arsenic, gastrointestinal disturbances are evident, with major cutaneous manifestations of late alopecia and Mees lines occasionally, and a severe axonal neuropathy.
- **Manganese:** Basal ganglionic damage producing parkinsonism is seen in manganese miners. This may be associated with a psychosis known as "manganese madness."

Metal deficiencies may also occur. For example, copper deficiency may follow bariatric surgery due to insufficient absorption or competitive malabsorption if the patient consumes excessive zinc or bismuth. Hypocupric myelopathy results with dorsal column and lateral column loss.

NEURODEGENERATIVE DISORDERS

Neurodegenerative disorders involve death of functionally related neurons; hence, these disorders can be classified by the primary functional system involved. **Cortical** degeneration leads to dementia, **basal ganglia** degeneration to movement disorders, **spinocerebellar** degeneration to ataxia and **motor neuron** degeneration to upper and lower motor neuron weakness. ***Neuropathologically, there is loss of neurons in these systems. There are often characteristic cellular inclusions and extracellular protein accumulations in these disorders and variable glial and microglial activation.***

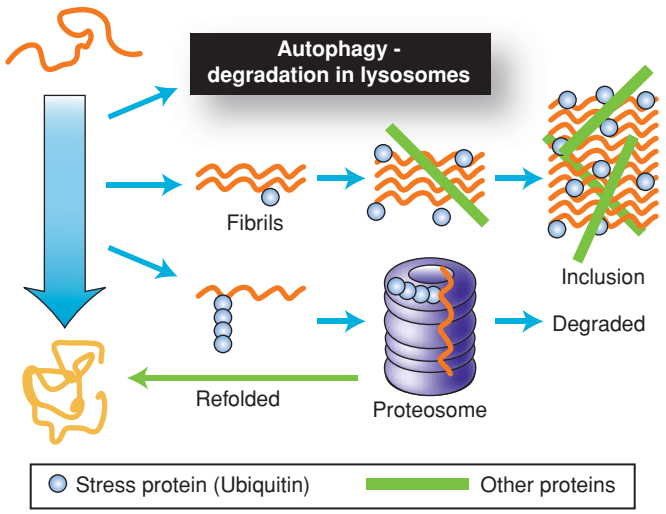

FIGURE 32-83. Possible fates of misfolded proteins. Many of the neurodegenerative diseases appear to be, at least in part, disorders of proteostasis, which consist of the cellular pathways that control protein synthesis, folding, trafficking, aggregation, disaggregation and degradation.

PATHOPHYSIOLOGY: Neurodegenerative disorders are classified according to which neuronal systems are most involved and the biochemistry of the proteins that accumulate in those cells.

Intracellular, and particularly intracytoplasmic, inclusions have a history that is inextricably bound to neurodegenerative disorders, as these engaging features of diseased cells were among the first histologic nervous system abnormalities recognized. We now understand them to be markers of cellular stress: cytoplasmic landfills made of abnormal cellular proteins and heat shock proteins. Abnormal protein homeostasis is probably central to the development of these disorders (Fig. 32-83; see Chapter 1).

When a cell is stressed, its intermediate filament network collapses into perinuclear bundles or clumps. This may reflect increased phosphorylation or proteolysis of these proteins due to calcium influx into the stressed cell. If the stress is not lethal, the cell deploys an adaptive **heat shock response**. The cell produces several proteins that may restore functional activity of partially denatured proteins or, if the insult is too severe to allow restoration, the proteins are polyubiquitinated for subsequent proteolysis. However, their highly stable β-pleated sheet structure leads to aggregation and prevents their effective removal by proteasomal or other means. Other stress proteins may include crystallin and a family of heat shock proteins. If the proteins conjugated to these stress proteins are not successfully degraded, the conjugated complexes aggregate as intracellular inclusions.

The inclusions in neurodegenerative disorders ***reflect damaged native cellular proteins and their stress response conjugates***. Cells activate stress responses whenever they are damaged; thus, stress response inclusions do not identify the inciting insult, but rather indicate that cells are trying to protect themselves. Neuropathologic inclusions are made from relatively few permutations of cytoskeletal

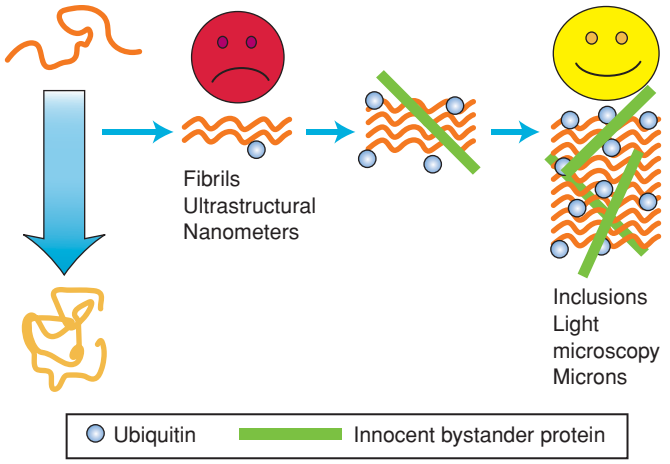

FIGURE 32-84. Fibrillogenesis and inclusions. Misfolded proteins with a tendency toward polymerization may form extremely cytoxic fibrils that are only visible by electron microscopy. The cellular stress response may facilitate hyperaggregation to inclusions that are visible by light microscopy. Such inclusions may be considered "toxic landfills" and may be protective.

and stress proteins—fewer, in fact, than the number of apparently discrete types of inclusions described. Ubiquitin is present in many intracellular inclusions. While itself not "diagnostic" of any particular disease, ubiquitin immunostaining is the most sensitive technique for detecting such aggregated proteins. Combined with the morphology, cellular distribution and clinical context, it may be helpful diagnostically. Available antibodies allow identification of ubiquitinated proteins: tau, neurofilament, α-synuclein and others. In summary, inclusions give limited data about the precise stress damaging the cell, their biochemical compositions often overlap and final diagnostic categorization depends on clinical data, immunohistochemical characterization of inclusions and analysis of the cell populations affected.

These protein aggregates may cause disease (Fig. 32-84; Table 32-3) by several routes. Sequestering protein or other macromolecules makes them unavailable for their normal functions. As aggregates enlarge, they may physically obstruct axons, dendrites or movement of material within the cytoplasm. They may also act as ubiquitin sinks, depleting cell ubiquitin that is needed to send misfolded proteins to be recycled. Thus, cellular protein recycling and homeostasis are impaired. As these proteins aggregate, they initially form ultrastructural fibrils that may be extremely cytotoxic. Thus, it appears that cellular stresses from a variety of causes may disrupt proteostasis and generate toxic fibrils that themselves can perpetuate and amplify the cellular stress.

Neurodegenerative disorders often begin focally and then spread in reasonably predictable ways throughout the CNS. This stereotypical dissemination likely involves abnormally folded pathogenic proteins recruiting and transforming native protein. This phenomenon is reminiscent of the molecular pathogenesis of prion diseases and is called "prion-like" protein misfolding or "templating."

At their core, the neurodegenerative diseases are largely disorders of proteostasis, involving impaired cellular pathways that control protein synthesis, folding, trafficking, aggregation, disaggregation and degradation. Because of this unifying theme, fundamental pathogenetic insights derived from one neurodegenerative disease may be generalizable to others.

TABLE 32-3
REPRESENTATIVE NEURODEGENERATIVE DISEASES WITH FIBRILLOGENESIS

Disease	Lesion	Components	Location
Alzheimer disease	Senile plaques Neurofibrillary tangles	β-Amyloid Tau	Extracellular Intracytoplasmic
Amyotrophic lateral sclerosis	Spheroids	Neurofilament Superoxide dismutase (SOD-1) TDP43 FUS	Intracytoplasmic
Dementia with Lewy bodies	Lewy bodies	α-Synuclein	Intracytoplasmic
Frontotemporal dementias	Neurofibrillary tangles	Tau TDP43, progranulin and other proteins	Intracytoplasmic
Multiple system atrophy	Glial inclusions	α-Synuclein	Intracytoplasmic
Parkinson disease	Lewy bodies	α-Synuclein	Intracytoplasmic
Prion diseases	Prion deposits	Prions	Extracellular
Trinucleotide repeat diseases	Inclusions	Polyglutamine tracts	Intranuclear and cytoplasmic

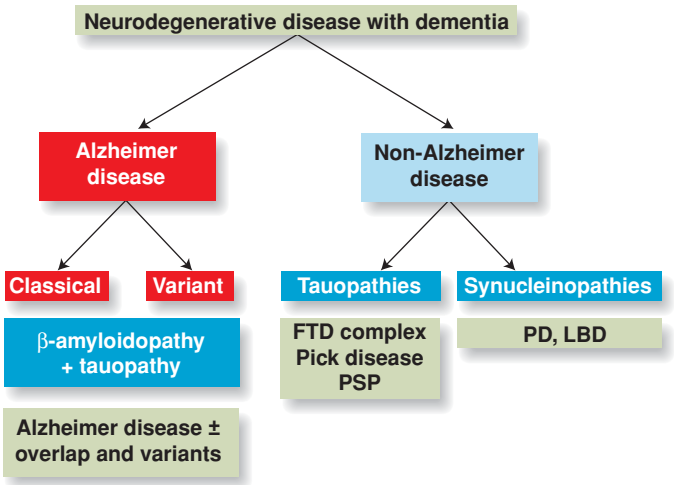

FIGURE 32-85. Protein fibrillogenesis. Molecular classification of the dementias and other neurodegenerative diseases now recognizes disorders based on the proteins that undergo fibrillogenesis. Alzheimer disease (AD) is a combination of a β-amyloidopathy and a tauopathy. Most of the frontotemporal lobar degenerations (FTDs) such as Pick disease and progressive supranuclear palsy (PSP) are pure tauopathies. Lewy body dementia (LBD) and Parkinson disease (PD) complex are α-synucleinopathies.

There Are Three Major Cerebral Cortical Neurodegenerative Diseases

Their clinical and pathologic features are distinctive, as different polymerized proteins accumulate (Fig. 32-85). These cortical degenerations ultimately lead to dementia.

- **Alzheimer disease (AD)** accounts for the majority of neurodegenerative dementia. It is characterized by abnormal accumulation of two proteins: β-amyloid and tau.
- **Pick disease,** which is the prototypical frontotemporal lobar dementia, is characterized by accumulation of abnormal tau without β-amyloid.
- **Lewy body dementia** features accumulation of α-synuclein.

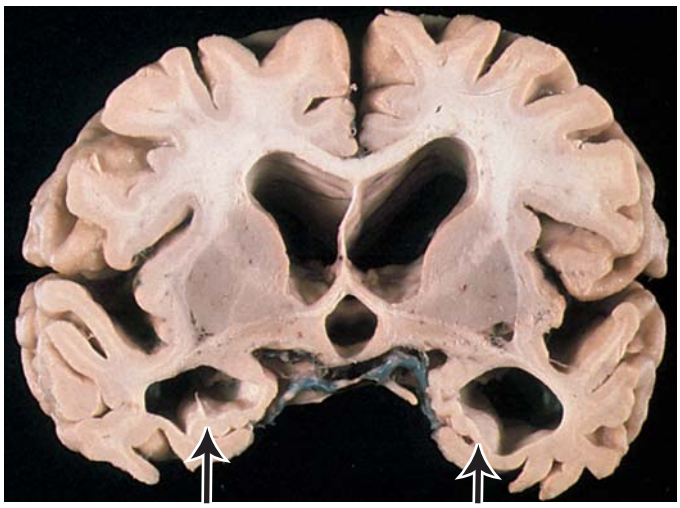

FIGURE 32-87. Cerebral atrophy with hydrocephalus ex vacuo in Alzheimer disease. Note also the severe atrophy of the hippocampus (*arrows*) leading to early memory disturbances in this disease. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Alzheimer Disease

EPIDEMIOLOGY: AD is an insidious progressive neurologic disorder characterized clinically by loss of memory, cognitive impairment and, eventually, dementia. Although Alzheimer's original patients were younger than 65 and suffered "presenile dementia," the term is now used for dementia at any age with characteristic pathologic changes. ***It is the most common dementia in the elderly, accounting for over half of cases.*** The prevalence of the condition is closely related to age. In patients younger than 65, Alzheimer disease affects at most 1%–2%, but it occurs in 40% or more of patients older than 85. Women are affected twice as often as men. Most cases are sporadic, but familial variants are reported.

PATHOLOGY: AD brains show cortical atrophy with hydrocephalus ex vacuo (Figs. 32-86 and 32-87). Gyri narrow, sulci widen and cortical

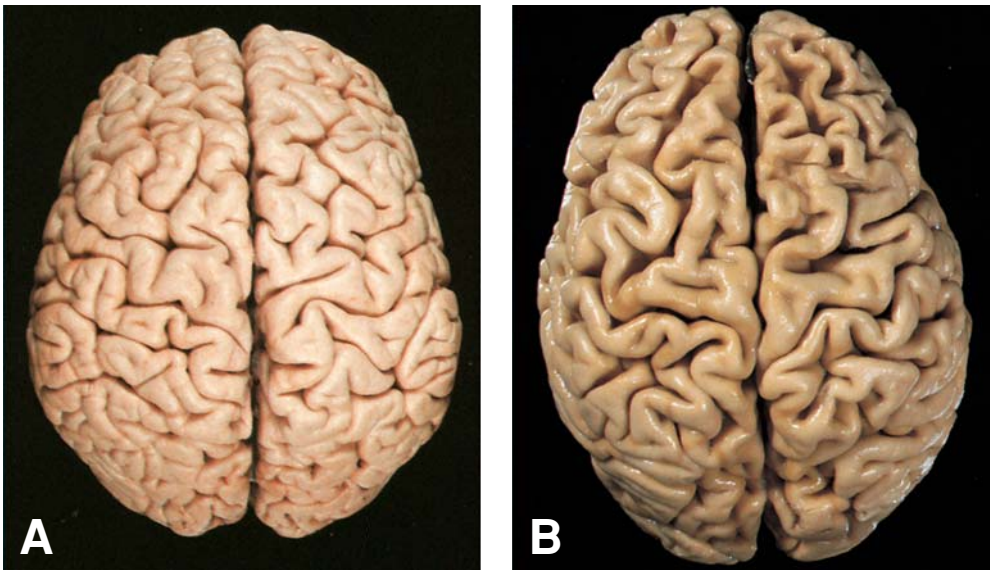

FIGURE 32-86. Cortical atrophy. A normal brain is shown on the left **(A)** and a brain with cortical atrophy caused by Alzheimer disease is shown on the right **(B)** with thinning of the gyri and prominent sulci. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

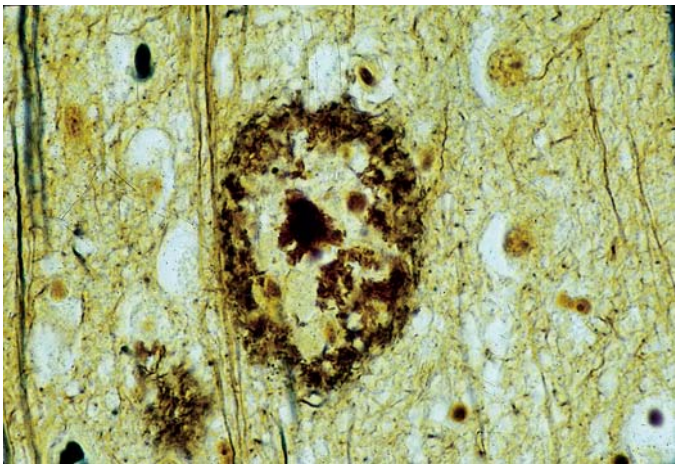

FIGURE 32-88. Neuritic plaques are extracellular accumulations of polymerized β-amyloid centrally with a rim of dystrophic neuritic processes. The number of plaques in the cerebral cortex does not correlate well with the severity of dementia in Alzheimer disease.

atrophy is especially apparent in the parahippocampal regions. However, as the disease progresses, atrophy of temporal, frontal and parietal cortex becomes more severe.

Senile plaques and neurofibrillary tangles (NFTs) dominate the histology. Small numbers of plaques and tangles are common in elderly patients with mild forgetfulness and mild cognitive impairment, which in half of cases is a prodrome of AD.

NEURITIC PLAQUES: The most conspicuous histologic lesions, senile or neuritic plaques, are ***extracellular*** spherical deposits of β-amyloid several hundred microns in diameter. In end-stage disease, senile plaques occupy large volumes of affected cerebral gray matter (Fig. 32-88). They bind planar amyloid binding dyes such as Congo red and thioflavin S, and silver containing dyes (argentophilic), and are immunoreactive for β-amyloid protein (Aβ) at the core and periphery. They are surrounded by reactive astrocytes and microglia and display swollen distorted neuronal processes (dystrophic neurites). Detection of plaques is necessary to diagnose AD; their number and distribution do not correlate well with clinical disease severity.

NEUROFIBRILLARY TANGLES: NFTs are ***intracytoplasmic*** collections of polymerized tau filaments (Fig. 32-89). NFTs contain irregular bundles of fibrils that are positive by Congo red and thioflavin S and immunoreactive for tau. The tangles are paired, 10-nm-thick, helical filaments with abundant insoluble tau proteins. Their distribution correlates with the clinical severity of AD. Tangles in the entorhinal cortex and parahippocampal gyrus can be seen in asymptomatic people decades before the usual age of onset of AD and may represent the disease's earliest phases. As more temporal neocortex comes to possess tangles, mild cognitive impairment may develop. Finally, when large swaths of neocortex, deep nuclei and brainstem are involved, full-blown AD is present. As this concept of gradual accretion of neurofibrillary tangles is increasingly validated, efforts are increasingly directed at early diagnosis during the asymptomatic phase and development of drugs that will arrest progression.

NFTs are not unique to AD. They also occur in other neurodegenerative diseases including dementia pugilistica (punch drunk syndrome in boxers), postencephalitic parkinsonism, Guam ALS/parkinsonism dementia complex, Pick disease, corticobasal degeneration, sporadic frontotemporal dementias and hereditary frontotemporal lobe dementia with parkinsonism associated with mutations on chromosome 17 (FTDP-17). Collectively, these hereditary and sporadic neurodegenerative diseases showing abnormal tau aggregation are called **tauopathies**. They may share common mechanisms of brain degeneration. ***Alzheimer disease is both a tauopathy and a β-amyloidopathy, leading to intracellular and extracellular tangles and plaques, respectively, seen in this disorder.***

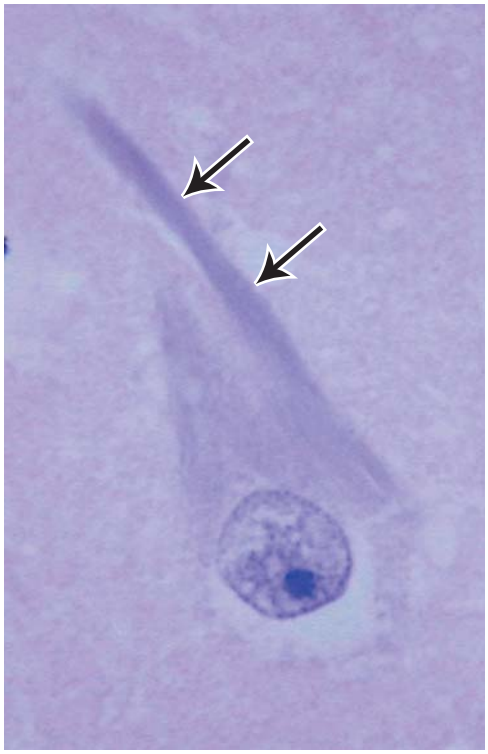

FIGURE 32-89. Neurofibrillary tangles are intracytoplasmic intraneuronal accumulations of polymerized hyperphosphorylated tau protein (*arrows*). The sites and degree of distribution of neurofibrillary tangles correlate with clinical symptoms.

There are minor histologic changes—granulovacuolar degeneration and Hirano bodies—in AD and normal aging that can be visually arresting but lack diagnostic significance. **Granulovacuolar degeneration** is largely restricted to the cytoplasm of hippocampal pyramidal cells, where it is evident as circular clear zones containing basophilic and argentophilic granules (Fig. 32-90A). **Hirano bodies,** like granulovacuolar degeneration, occur almost exclusively in hippocampal pyramidal neurons, especially in their processes (Fig. 32-90B). Hirano bodies are 10–15-micron-thick eosinophilic rods composed of polymerized action.

PATHOPHYSIOLOGY AND MOLECULAR PATHOGENESIS: The cause of AD is not known, but the origins of associated amyloid and NFTs are increasingly understood.

- **β-Amyloid protein (Aβ):** Increasing evidence points to the importance of deposition of Aβ protein in **neuritic**

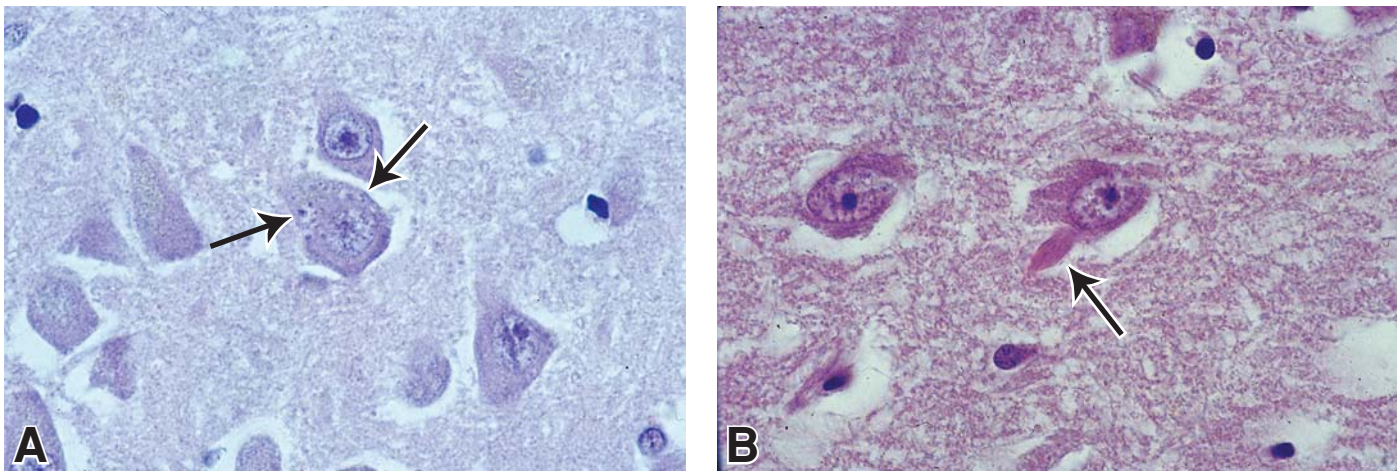

FIGURE 32-90. A. Granulovacuolar degeneration (*arrows*) is seen in hippocampal pyramidal neurons in both normal aging and Alzheimer disease. **B. Hirano bodies** are eosinophilic cytoplasmic accumulations of actin (*arrow*) seen in the cytoplasm of hippocampal pyramidal neurons in normal aging and Alzheimer disease.

plaques of Alzheimer disease. The core of these plaques contains a distinct form of Aβ peptide, which is mainly 42 amino acids long. Aβ is derived by proteolysis from a much larger (695 amino acids) membrane-spanning APP. Full-length APP has an extracellular region, a transmembrane sequence and a cytoplasmic domain. The region comprising Aβ anchors the amino-terminal portion of APP to the membrane. The physiologic functions of APP and Aβ remain obscure.

The normal degradation of APP involves proteolytic cleavage in the middle of the Aβ domain, to release a nonamyloidogenic fragment from the middle of the Aβ domain to the amino end of APP. Proteolysis at either end of the Aβ domain then releases intact and highly amyloidogenic Aβ that accumulates in senile plaques as amyloid fibrils.

Aβ deposition may be needed for Alzheimer disease to develop because:

1. Patients with **Down syndrome** (trisomy 21) develop clinical and pathologic features of Alzheimer disease, including deposition of Aβ in neuritic plaques, generally by age 40. The gene for APP is on chromosome 21, and the additional dose of the gene product in trisomy 21 may predispose to precocious accumulation of Aβ.
2. Some patients with familial Alzheimer disease carry mutant *APP* genes or mutant presenilin genes. These mutations lead to increased production of Aβ, the amyloidogenic part of APP.
3. Transgenic mice expressing mutant human *APP* genes develop senile plaques in the brain very similar to those of Alzheimer disease. However, these mice lack other critical features of Alzheimer disease, such as NFTs, and evidence of neurodegeneration, such as significant loss of neurons.

Neurons and glial cells are sites of APP synthesis in the brain, but Aβ also accumulates in cerebral blood vessel walls.

- **Neurofibrillary tangles:** NFTs are paired helical filaments that contain tau abnormally phosphorylated at aberrant sites. The resultant protein does not associate with microtubules but instead aggregates to form paired helical filaments. Release of tau from microtubules may deprive cells of tau's microtubule-stabilizing effects, thus impairing axonal transport and compromising neuron function. Alternatively, fibril formation occurring as the hyperphosphorylated tau aggregates may itself be cytotoxic.

  There are several genetic risk factors for AD. Mutations in the *APP* gene have been associated with early-onset familial variants of Alzheimer disease. Additional genetic associations (Table 32-4) involve apolipoprotein E (apoE) genotype and the genes for presenilin 1 (*PS1*) and 2 (*PS2*).

APOLIPOPROTEIN E: Apolipoprotein E (apoE) has long been known for its role in cholesterol metabolism. In 1993, it was reported that specific apoE isoforms confer differential susceptibility to sporadic and late-onset familial subtypes of AD. The human apoE gene is on chromosome 19 (19q13.2). The three common alleles—ε2, ε3 and ε4—all occur in North American apoE genotypes. Inheritance of the ε4 allele, particularly the homozygous ε4/ε4 genotype, confers increased risk of late-onset familial and sporadic AD. This genotype occurs in 2% of the population. Conversely, the ε2 allele may confer some protection. The age at which symptoms appear in late-onset AD also correlates with the ε4 allele, with ε4/ε4 homozygotes showing the earliest onset (younger than 70) and patients with the ε2 allele having the latest onset (older than 90). The ε4 allele also correlates with increased numbers of senile plaques in patients with Alzheimer disease, but the apoE genotype is not an absolute determinant of the disease and does not predict who will develop it. How these different apoE alleles influence the risk of Alzheimer disease remains poorly understood.

PRESENILIN: Two genes with significant homology are associated with different kindreds of familial AD. Mutations of the *PS1* gene, on chromosome 14, are linked to the most common form of autosomal dominant early-onset Alzheimer disease. The *PS2* gene on chromosome

TABLE 32-4
GENETIC FACTORS IN ALZHEIMER DISEASE

Gene	Chromosome	Disease Association
Amyloid precursor protein (*APP*)	21	Mutations of the *APP* gene are associated with early-onset familial Alzheimer disease
Presenilin 1 (*PS1*)	14	Mutations of the *PS1* gene are associated with early-onset familial Alzheimer disease
Presenilin 2 (*PS2*)	1	Mutations of the *PS2* gene are associated with Volga German familial Alzheimer disease
Apolipoprotein E (*apoE*)	19	Presence of the ε4 allele is associated with increased risk and younger age of onset of both inherited and sporadic forms of late-onset Alzheimer disease

1 is associated with Alzheimer disease in Volga German pedigrees (Table 32-4). Presenilin mutations occur in half of cases of inherited AD, compared with only a few percent for mutant *APP* genes. There is some evidence that mutant PS1 and PS2 proteins alter processing of β-APP to favor increased production and deposition of Aβ. Cell processing of APP releases Aβ fragments of varying lengths, but the Aβ42 variant seems to be especially amyloidogenic. It is the Aβ molecule whose production is enhanced by mutant *PS1.*

Proposed mechanisms leading to development of AD are shown in Fig. 32-91.

It is now recognized that AD evolves over a period of years, if not decades. In 2011, a National Institute on Aging/Alzheimer Association (NIA/AA) consensus statement was released indicating at AD occurs in three stages:

1. **Presymptomatic:** The patient has no cognitive impairment. There is growing evidence, however, that extracellular β-amyloid is accumulating and tangles are beginning to form, especially in the hippocampus and adjacent temporal cortex.
2. **Mild cognitive impairment (MCI):** Patients experience mild deterioration of memory and cognitive function that worries the patient but does not interfere with daily living. A significant number of patients with MCI will go on to develop frank AD, but many do not. People with low levels of CSF β-amyloid 1-42 or high levels of amyloid load detected by positron emission tomography (PET) scanning appear more likely to progress to AD.
3. **Alzheimer disease:** These patients are frankly demented on clinical examination and neuropsychological evaluation. Activities of daily living are impaired.

In parallel with the development of these clinical consensus guidelines, new neuropathologic criteria for diagnosing AD were postulated. Neurofibrillary tangles, neuritic plaques and β-amyloid distribution are assessed in standardized sections. β-Amyloid distribution is assessed by immunohistochemistry and described as absent (A0), neocortical and allocortical only (A1), diencephalon and striatum (A2) and brainstem and cerebellum (A3). The distribution of neurofibrillary tangles is absent (B0), trans-entorhinal (B1), limbic system and hippocampus (B2) and neocortical and brainstem (B3). Numbers of neuritic plaques are absent (C0), sparse (C1), moderate (C2) or frequent (C3). These changes are then Ax, Bx and Cx, with higher values in each dimension corresponding to a higher probability of AD. Comorbidities such as vascular disease, hippocampal sclerosis and Lewy bodies are also described.

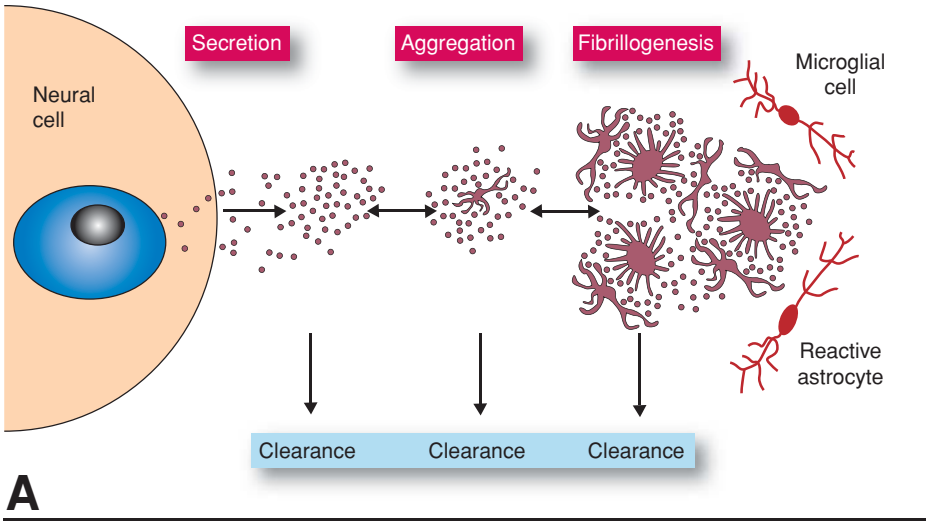
CLINICAL FEATURES: Patients with AD come to medical attention because of gradual loss of memory and cognitive function, difficulty with language and changes in behavior. Those with mild cognitive impairment are increasingly being recognized, since they move on to full-blown dementia at a rate of about 15% per year. Alzheimer disease progresses inexorably, so that previously intelligent and productive people become demented, mute, incontinent and bedridden. Bronchopneumonia, urinary tract infections and pressure decubiti are common medical complications that lead to death.

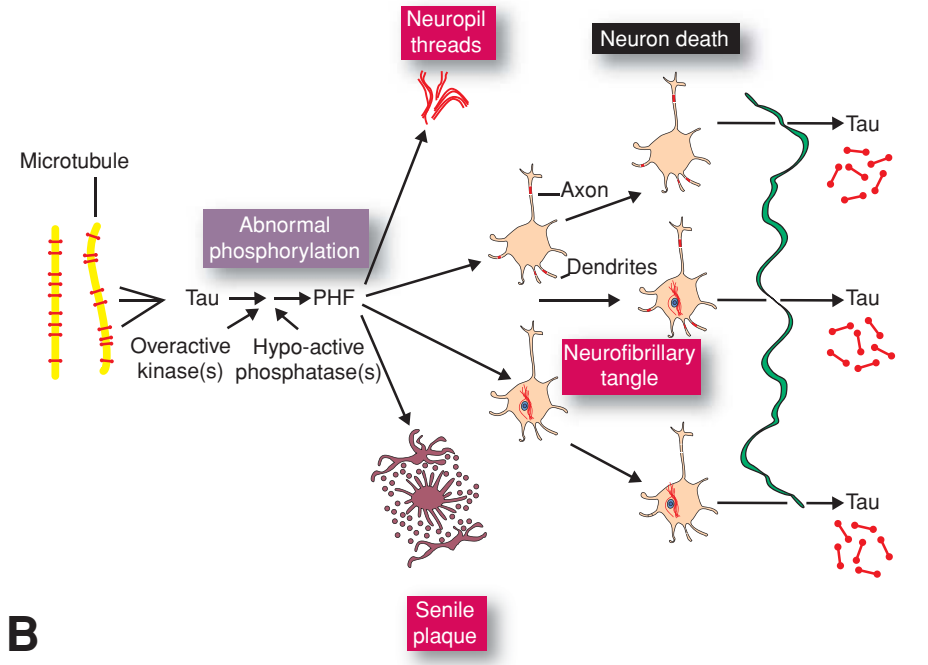
Frontotemporal Lobar Degeneration: Pick Disease Complex

CLINICAL FEATURES: The frontotemporal lobar degenerations (FTLDs) are mainly tauopathies in which the frontal and temporal lobes bear the early brunt of the disease. The prototype eponymic disorder of the FTLDs is **Pick disease,** which manifests clinically as loss of frontal executive function causing disinhibition, loss of judgment about social propriety and inability to plan or foresee the consequences of one's actions. Most cases are sporadic, although Pick disease kindreds have been described. Sporadic Pick disease becomes symptomatic in midadult life and progresses relentlessly to death in 3–10 years. A respected pillar of the community may be reduced to a vulgar, disheveled derelict as this tragedy unfolds. Unlike AD, which generally begins with memory difficulties, FTLD starts with disruptive, inappropriate behavior. These dementias converge clinically at the end.

PATHOLOGY: Cortical atrophy is mostly in the frontotemporal regions in Pick disease (Fig. 32-92). The atrophy may attain extreme proportions, so that affected gyri are reduced to thin slivers **(knife-edge atrophy)**. The involved cortex is severely depleted of neurons and shows intense astrogliosis. Residual neurons have intensely argentophilic and tau-immunoreactive round cytoplasmic inclusions called **Pick bodies** (Fig. 32-93A,B). These are formed by densely aggregated straight tau filaments.

Pick disease is the prototypical FTLD, but there are others that only recently have begun to reveal their molecular secrets. In any cohort of patients with clinical FTLD, many have Pick disease, but a significant number do not. Often, their neurons are immunoreactive for ubiquitin, implying an as yet unidentified protein triggering an unfulfilled degradative response. These are classified at FTLD-U, the U for ubiquitin immunoreactivity. Several of these proteins have recently been identified.





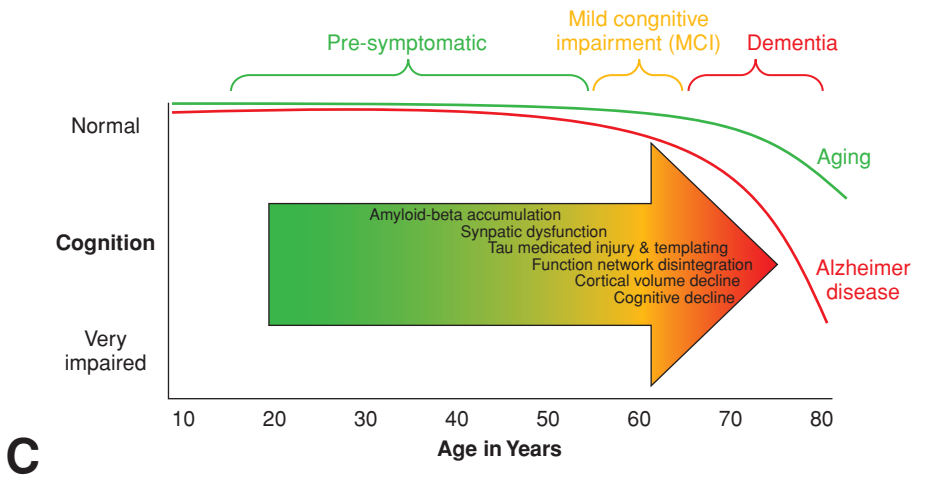


FIGURE 32-91. Mechanisms of amyloidosis and brain degeneration in Alzheimer disease. A. This schematic illustrates a hypothetical mechanism for the formation of senile plaques (SPs) from soluble Aβ peptides produced inside cells and secreted into the extracellular space. Amyloidogenic Aβ may encounter fibril-inducing cofactors and go on to form A fibrils to deposit in SPs (*far right*). SPs are surrounded by reactive astrocytes and microglial cells, which secrete cytokines that may contribute to the toxicity of the SPs. These steps may be reversible. Increasing Aβ clearance or reducing its production, as well as modulating the inflammatory response, may be effective therapeutic interventions for Alzheimer disease, in combination with therapies that target brain degeneration caused by neurofibrillary tangles (NFTs). **B.** This schematic illustrates a hypothetical mechanism leading to the conversion of normal human central nervous system (CNS) tau overlying two microtubules into paired helical filaments (PHFs). PHFs are generated in neuronal perikarya and their processes. Overactive kinase(s) or hypoactive phosphatase(s) may contribute to this effect. Abnormally phosphorylated tau forms PHFs in neuronal processes (neuropil threads) and neuronal perikarya (NFTs). Tau in PHFs loses the ability to bind microtubules, thus causing their depolymerization, disruption of axonal transport and degeneration of neurons. Accumulation of PHFs in neurons could exacerbate this process by physically blocking transport in neurons. The death of affected neurons would release tau and increase the levels of tau in the cerebrospinal fluid (CSF) of patients with Alzheimer disease. NFT formation may be reversible, and drugs that block NFT formation, reverse it or stabilize microtubules may be effective therapeutic interventions for Alzheimer disease. **C.** The National Institute on Aging/Alzheimer Association (NIA/AA) 2011 formulation on Alzheimer disease formally recognizes the temporal evolution of the disease from a long presymptomatic phase in which amyloid-β is accumulated and the pathophysiologic cascade is initiated. The pathogenic mechanisms interact to move the disease to mild cognitive impairment (MCI) and finally to frank dementia. Interventions during the symptomatic phase may be too late to fundamentally change the trajectory of the disease, and increased attention is being directed at the pr-symptomatic phase of the illness. This would be a primary prevention approach not unlike the highly successful presymptomatic intervention in myocardial infarction and stroke by exercise and control of hypertension and hyperlipidemia.

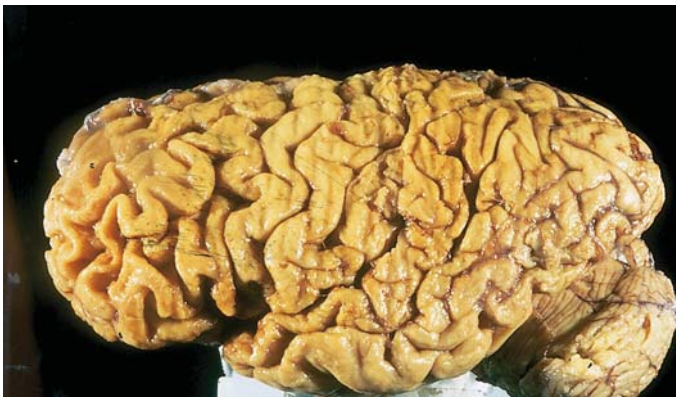

FIGURE 32-92. Severe cortical atrophy with marked frontotemporal atrophy is characteristic of the frontotemporal lobar degenerations, such as Pick disease, but may be seen in Alzheimer disease. Frontal atrophy correlates with loss of executive function, impaired judgment and disinhibition.

The protein TDP43 bears brief consideration, since its abnormal accumulation occurs in both FTLD and motor neuron disease. This molecular commonality coincides with the increasingly recognized coexistence of FTLD and motor neuron disease.

Lewy Body Dementia

Lewy body dementia (LBD), also known as Lewy body disease or diffuse Lewy body disease, is characterized by intracytoplasmic α-synuclein inclusions in a relatively small number of cortical neurons, mostly in the cingulate cortex. AD pathology may coexist with Lewy body inclusions at the end stage of the disease.

CLINICAL FEATURES: LBD is distinctive in that cognitive function fluctuates greatly from day to day, subtle extrapyramidal manifestations may be present and the patient may experience fascinating well-formed visual hallucinations. LBD exists on a continuum with the other α-synucleinopathies that include Parkinson disease and multiple system atrophy.

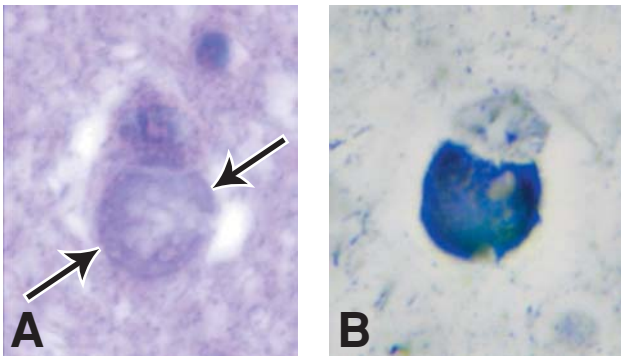

FIGURE 32-93. Pick bodies. A. In hematoxylin and eosin–stained sections, Pick bodies are basophilic, spherical, intracytoplasmic, intraneuronal aggregates of tau protein (*arrows*). They tend to be round rather than angular like the neurofibrillary tangles (NFTs) in Alzheimer disease, but like NFTs, they are argentophilic (silver impregnation) **(B)**.

Neurodegeneration of the Basal Ganglia

CLINICAL FEATURES: Movement disorders may result in too little **(bradykinetic)** or too much involuntary **(hyperkinetic)** movement. Parkinson disease is the prototypical bradykinetic movement disorder, characterized by difficulty initiating and sustaining voluntary movement, resting tremor and postural instability. This clinical triad is **"parkinsonism,"** and while the most common cause is Parkinson disease, other disorders such as progressive supranuclear palsy, multiple system atrophy and even neuro-AIDS may result in parkinsonism.

The prototypical hyperkinetic movement disorder is Huntington disease, with progressive development of involuntary rapid twitching movements (chorea) and writhing dance-like movements (athetosis) that may conflate as choreoathetosis.

Parkinson Disease

First described in 1817, Parkinson disease (PD) is characterized clinically by tremors at rest, cogwheel rigidity, expressionless countenance, postural instability and, less often, cognitive impairment. Pathologically, neurons are lost, largely in the substantia nigra, and Lewy bodies, filamentous aggregates of α-synuclein, accumulate. Dopaminergic neurons that project from the substantia nigra to the striatum are diminished.

EPIDEMIOLOGY: Parkinson disease typically appears in the sixth to eighth decades. It is common: 1%–2% of the population in North America eventually develops it. PD prevalence has remained unchanged for at least the past 40 years. No racial differences are apparent, but men are more affected than women.

PATHOPHYSIOLOGY: Most cases are sporadic, but missense mutations in the α-synuclein gene cause rare autosomal dominant, early-onset, familial PD. The finding that wild-type α-synuclein is the major polymerized protein in Lewy bodies led to consideration of fibrillogenesis as a major contributor to the pathogenesis of neurodegenerative diseases. Accumulating evidence suggests that oxidative stress due to auto-oxidation of catecholamines during melanin formation injures neurons in the substantia nigra by promoting misfolding of α-synuclein and formation of filamentous inclusions.

In addition to PD, accumulation of filamentous α-synuclein inclusions is seen in other diseases, including multiple system atrophy, dementia with Lewy bodies, progressive autonomic failure and rapid eye movement (REM) sleep behavior disorder. These disorders are now called **α-synucleinopathies** and, like the tauopathies, are considered brain-specific amyloidoses.

PATHOLOGY: Brains of PD patients show loss of pigmentation in the substantia nigra and locus ceruleus (Fig. 32-94). Other brain regions are less affected. Pigmented neurons are scarce, and small extracellular deposits of melanin are derived from dying neurons.

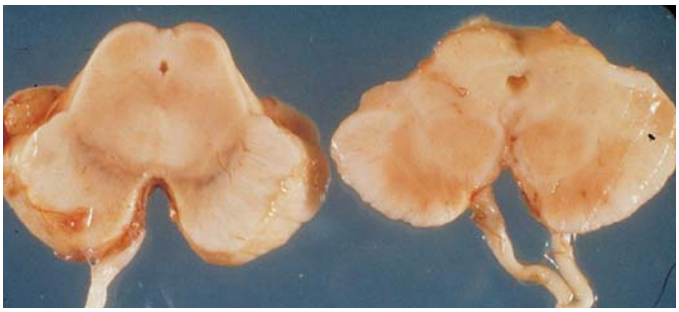

FIGURE 32-94. Parkinson disease. The normal substantia nigra on the left in an adult is heavily pigmented, while the substantia nigra in a patient with Parkinson disease has lost pigmented neurons and the nucleus now blends inconspicuously with the rest of the midbrain. The locus ceruleus in the pons is also depigmented (not shown). (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Some residual neurons are atrophic, and a few contain Lewy bodies, which are spherical, eosinophilic cytoplasmic inclusions (Fig. 32-95). By electron microscopy, Lewy bodies show amyloid-like filaments of insoluble α-synuclein.

Other Disorders Causing Parkinsonism

PD is not the sole cause of parkinsonism. Other disorders share a common theme of loss of pigmented dopaminergic neurons in the substantia nigra. Normal aging is associated with some neuron loss in the substantia nigra and reduced dopamine levels, but these features are exaggerated in PD and these other causes of parkinsonism.

- **MPTP-induced parkinsonism** was discovered the late 1970s when there was an epidemic of parkinsonism among intravenous drug abusers that was ultimately linked to a toxic byproduct of the illicit synthesis of a meperidine (Demerol). That contaminant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), is turned by the brain's own monoamine oxidase into a highly reactive free radical.
- **Postinfectious parkinsonism** occurred after viral encephalitis (von Economo encephalitis) associated with the influenza pandemic after World War I and has not recurred to a major degree since. It was characterized by loss of substantia nigra neurons but no Lewy bodies being present. How this disorder develops is unknown, but there is concern that a similar combination of influenza antigens may lead to a recurrence of this epidemic. The 2009 H1N1 influenza virus, for example, was very similar antigenically to that seen in the earlier pandemic.
- **Striatonigral degeneration** is a rare disorder that closely mimics PD. At autopsy, the striatum (caudate and putamen) is visibly atrophied, with severe loss of neurons in this region. Changes in the substantia nigra and locus ceruleus are less severe. This condition may coexist with Shy-Drager disease (dysautonomia) and olivopontocerebellar atrophy (OPCA) as part of a unified disorder of **multiple system atrophy (MSA),** in which filamentous α-synuclein inclusions, known as **glial cytoplasmic inclusions,** accumulate primarily in oligodendroglia. They also occur to a lesser extent in neurons, where they resemble the Lewy bodies of Parkinson disease and Lewy body dementia.
- **Progressive supranuclear palsy (PSP)** is an uncommon disorder characterized by parkinsonism, severe postural instability with falls and progressive paralysis of vertical eye movements. Pathologic changes in the brain are more widespread than in PD, but the hallmark is atrophy of the midbrain tegmentum, leading to an exaggerated contribution of the cerebral peduncles to the profile of the midbrain in axial sections—a profile that is referred to by some as "Mickey Mouse" midbrain. Since the midbrain, as well as the substantia nigra, is the locus of integration of vertical eye movement, the combination of parkinsonism and vertical gaze dysfunction makes anatomic sense. PSP is a **tauopathy:** the sole inclusions are tau-rich NFTs. PSP spreads throughout the nervous system, and cognitive impairment complicates the disease course.

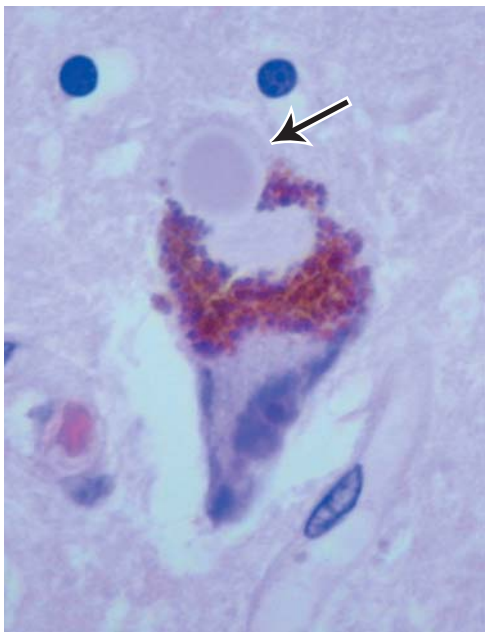

FIGURE 32-95. Lewy body in Parkinson disease. Examination of residual neurons in the substantia nigra show intracytoplasmic, intraneuronal, spherical eosinophilic inclusions composed of polymerized α-synuclein called Lewy bodies (*arrow*). These inclusions often have a thin clear halo.

Huntington Disease

EPIDEMIOLOGY: First described in 1872, Huntington disease (HD) is an autosomal dominant genetic disorder characterized by involuntary movements, deterioration of cognitive function and often severe emotional disturbances. It mainly affects whites of northwestern European ancestry, with an incidence of 1 in 20,000. Genealogic studies indicate that all cases derive from an original founder in northern Europe; the disease is very rare in Asia and Africa.

CLINICAL FEATURES: Symptoms of HD usually begin by age 40, but 5% of patients with the disorder develop neurologic signs before age 20, and a similar proportion first present after age 60. Cognitive and emotional disturbances precede the onset of abnormal movements by several years in over half of patients. Once it develops, choreoathetosis may be incapacitating. Cortical involvement leads to a severe loss of cognitive function and

intellectual deterioration, often accompanied by paranoia and delusions. The interval from the onset of symptoms to death averages 15 years.

MOLECULAR PATHOGENESIS: The *HD* gene, on chromosome 4 (4p16.3), codes for the protein **huntingtin.** The aberration at this locus is expansion of a trinucleotide (CAG) repeat (see Chapter 6). The repeat is within a coding region of the gene and yields an altered protein, with a polyglutamine tract near the N-terminus. In agreement with the dominant mode of inheritance, the triplet expansion causes a toxic gain of function.

Huntingtin is widely expressed in tissues throughout the body and in all regions of the CNS by neurons and glia, but its function is unknown. As with other CAG repeat expansion diseases (see Chapter 6), the longer the CAG repeat, the more severe the disease phenotype and the earlier the age of clinical onset. In HD, CAG length is more unstable and tends to be longer when inherited from the father than in maternal transmission. As a result, transmission of the *HD* mutation from the father results in clinical disease some 3 years earlier than when it is passed on from the mother. Of children with juvenile-onset HD, the ratio of those who inherit the expanded CAG allele from their father to those who inherit it from their mother is 10:1.

PATHOLOGY: The frontal cortex is symmetrically and moderately atrophic, while the lateral ventricles are disproportionately large, owing to loss of the normal convex curvature of the caudate nuclei (Fig. 32-96). There is symmetric atrophy of the caudate nuclei, with lesser involvement of the putamen. Neuron populations of the caudate and putamen, especially the small neurons, are severely depleted, with accompanying astrogliosis. The cerebral cortical neurons are similarly, but less severely, lost. Huntingtin aggregates in neurons, mainly in nuclei, but also in neuronal processes, potentially impairing axodendritic transport. γ-Aminobutyric acid (GABA) and glutamic acid decarboxylase are markedly decreased.

Nucleotide Repeat Expansion Disorders

HD is one of an ever-increasing group of neurologic diseases that are nucleotide repeat expansion syndromes (see Chapter 6). These are not rare, but rather include the most common cause of mental retardation in boys (fragile X syndrome), the most common adult-onset muscular dystrophy (myotonic dystrophy) and the most common hereditary spinocerebellar ataxia (Friedreich ataxia).

MOLECULAR PATHOGENESIS: Trinucleotide repeats are a normal feature of many genes, and expansion of the number of triplet repeats confers pathogenicity. Some triplet repeat diseases show only a small expansion compared with their normal counterparts (e.g., Huntington disease), but in others, the expansion is quite large (e.g., fragile X syndrome and Friedreich ataxia). This class of diseases includes examples of all forms of inheritance: X-linked, autosomal dominant and autosomal recessive. In most of the autosomal dominant CAG expansion disorders, the abnormal expansion is in the coding region of a gene and causes production of an abnormal protein. In other disorders, the expansion is in a noncoding part of the gene and may interfere with transcription or message processing. Resulting decreased protein levels constitute a loss-of-function mutation (as appears to be the case with GAA expansion in Friedreich ataxia). In myotonic dystrophy, a noncoding region expansion yields a transcript that interferes with correct mRNA splicing for multiple gene products, leading to the multiorgan multiprotein manifestations of this condition.

Spinocerebellar Neurodegeneration

The spinocerebellar ataxias are a heterogeneous group of genetic disorders that impact cerebellar inflow and outflow pathways, or the cerebellar parenchyma itself. The cerebellum plays a key role in helping the cerebral motor cortex and basal ganglia in motor functions, and in ensuring smooth performance of repetitive motor tasks such as playing the piano, riding a bicycle or speaking. Once the cerebellum is exposed to motor tasks, it acts as a repository of motor programs (i.e., a "motor memory").

Cerebellar dysfunction leads to ataxia—the inability to execute motor tasks smoothly, particularly those requiring rapid alternating movement or precise motor control. Ataxia may result from defects in the major cerebellar input pathways including the middle cerebellar peduncle, which conveys motor execution commands from the cerebral motor and premotor cortex, and the inferior cerebellar peduncle,

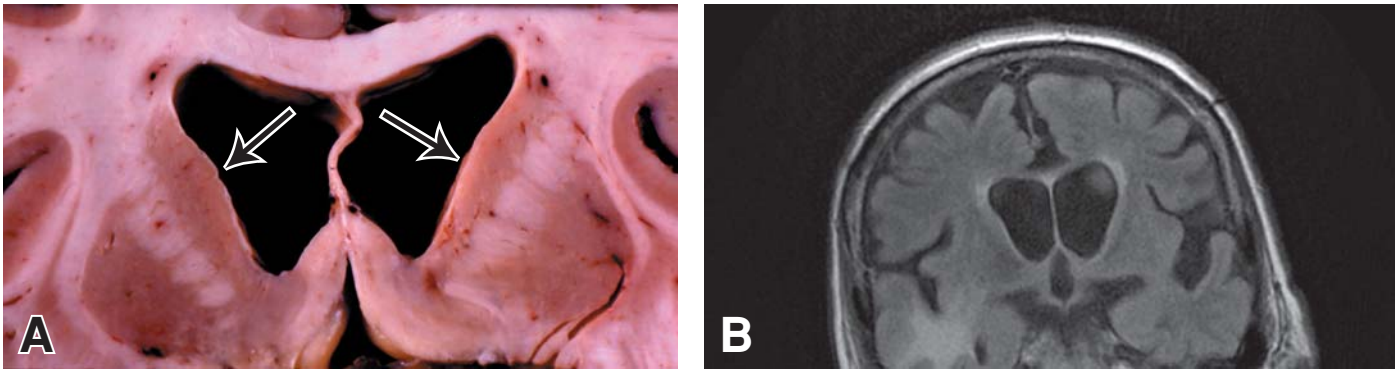

FIGURE 32-96. Huntington disease. A. The caudate nuclei (*arrows*) bilaterally are atrophic, leading to enlarged lateral ventricles. Some cortical atrophy is also seen, but it is usually not as severe as that seen in the primary cortical dementias such as Alzheimer and Pick disease. **B.** Axial magnetic resonance image showing the enlarged lateral ventricles accompanied by modest cortical atrophy. The square-shaped lateral ventricles of Huntington disease are sometimes called "box-car ventricles."

which receives proprioceptive data from the spinal cord via the spinocerebellar tracts. If the cerebellar parenchyma itself degenerates, ataxia will reflect a distribution congruent to the functional portion of the cerebellum involved—vermal degeneration leads to truncal ataxia, while cerebellar hemispheric degeneration leads to appendicular ataxia. Finally, the cerebral outflow—the dentatorubrothalamic pathway—may degenerate, leading to a peculiarly high-amplitude ataxia called "wing-beating ataxia."

Friedreich Ataxia

EPIDEMIOLOGY: Friedreich ataxia is the most common inherited ataxia. Its prevalence in European populations is 1 in 50,000. Inheritance is autosomal recessive, but many cases arise sporadically without prior family history.

CLINICAL FEATURES: Symptoms usually begin before age 25, followed by an unremittingly progressive course of about 30 years to death. Friedreich ataxia is a cerebellar inflow disorder with ataxia of both the upper and lower limbs, dysarthria, lower limb areflexia, extensor plantar reflexes and sensory loss reflecting concurrent degeneration of spinal long tracts. Common concomitants include deformities of the skeletal system (e.g., scoliosis, pes cavus), hypertrophic cardiomyopathy (which commonly causes death) and diabetes mellitus.

MOLECULAR PATHOGENESIS: The genetic defect in Friedreich ataxia is autosomal recessive loss of function of the genes encoding a mitochondrial protein **(frataxin)** that is involved in iron transport into mitochondria. In most cases the mutation is an unstable expansion of a trinucleotide (GAA) repeat in the first intron of this gene (9q13.3–21.1). The recessive pattern of inheritance means that both frataxin alleles must be lost—both may bear the trinucleotide repeat expansion. Or, one may have the repeat expansion while the other allele may be compromised by a different mutation. The expansion mutation may impede transcription or RNA processing. In unaffected people, levels of frataxin protein are highest in the heart and spinal cord. Lack of frataxin is thus probably responsible for neurologic and cardiac manifestations of Friedreich ataxia. The longer the repeat, the earlier the age of disease onset, the faster the rate of progression and the greater the frequency of hypertrophic cardiomyopathy.

PATHOLOGY: The most prominent postmortem findings in Friedreich ataxia are in the spinal cord, which shows degeneration of the posterior columns, corticospinal pathways and spinocerebellar tracts (Fig. 32-97). Posterior column degeneration accounts for the sensory loss experienced by these patients and results from loss of the parent neuronal cell bodies in the dorsal root ganglia. In advanced cases, this degeneration appears grossly as shrinkage of dorsal spinal roots and posterior funiculi. Similarly, spinocerebellar tract atrophy, with attendant ataxia, follows neuronal degeneration in the dorsal nucleus of Clarke. The corticospinal tracts show the most pronounced degeneration more distally in the cord leading to weakness and release of the plantar extensor reflex.

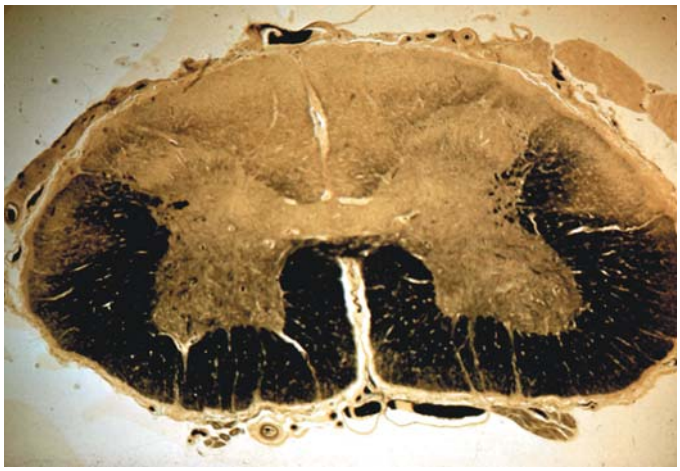

FIGURE 32-97. Friedreich ataxia. This is the most common hereditary ataxia. Myelin-stained sections show secondary degeneration of the dorsal columns, lateral corticospinal tracts and spinocerebellar tracts. This is predominantly an inflow ataxia and the cerebellum is usually not atrophic.

Amyotrophic Lateral Sclerosis Is the Most Common Motor Neuron Disease

Amyotrophic Lateral Sclerosis

ALS is a degenerative disease of upper and lower motor neurons of the brain and spinal cord, with progressive weakness and wasting of extremities and tongue, a sometimes confusing combination of hyperreflexia and hyporeflexia and eventual impairment of respiratory muscles.

EPIDEMIOLOGY: It is a worldwide disease with an incidence of 1 in 100,000. It peaks in the fifth decade, and it is rare in people before age 35. There is a 1.5–2-fold excess of ALS in men. Restricted geographic areas with a particularly high incidence of ALS exist in Guam and parts of Japan and Papua New Guinea, but these cases differ from ALS in the rest of the world. Cases in the Chamorro people indigenous to Guam are characterized by abundant accumulations of tau-rich NFTs and are now classified as **tauopathies**. Moreover, ALS in Guam is part of a spectrum of disorders that includes dementia and parkinsonism.

MOLECULAR PATHOGENESIS: Familial ALS cases, with an autosomal dominant pattern, account for 5% of ALS. The most common form has been associated with missense mutations in the gene that codes for the cytosolic form of the antioxidant enzyme superoxide dismutase (Cu/Zn SOD, or SOD1; see Chapter 1). Since SOD1 is a key free radical detoxifying enzyme, SOD1 mutations might lead to increased free radical damage. The extent to which enzyme activity is lost is unclear, but mutant SOD1 is more prone to aggregation than wild-type SOD1, so familial ALS may be a **protein conformational disorder**.

PATHOLOGY: ALS affects lower motor neurons, including anterior horn cells of the spinal cord and the motor nuclei of the brainstem, especially the hypoglossal nuclei; and the upper motor neurons of the cerebral cortex. Loss of the upper motor neurons leads to

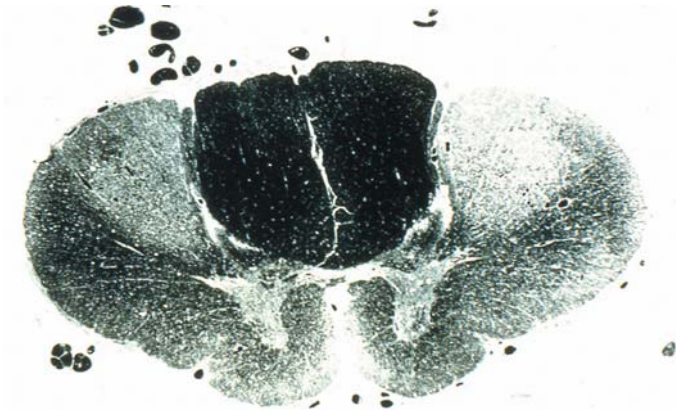

FIGURE 32-98. Amyotrophic lateral sclerosis (ALS) spinal cord showing upper motor neuron loss. Myelin-stained sections show degeneration of the lateral corticospinal tracts reflecting degeneration of the axons of the upper motor neurons originating in the motor strip of the cerebral cortex. Note the preservation of the dorsal columns, spinothalamic tracts and spinocerebellar pathways.

degeneration of their axons, with secondary demyelination visualized in myelin-stained axial sections of the spinal cord as loss of the lateral and anterior corticospinal pathways (Fig. 32-98).

The main histologic change in ALS is loss of large motor neurons, with mild gliosis (Fig. 32-99). This is most apparent in the anterior horns of the lumbar and cervical enlargements of the spinal cord, and the hypoglossal nuclei. There is also a loss of the giant pyramidal Betz cells in the cerebral motor cortex. The anterior nerve roots bearing the few remaining axons of the dying lower motor neurons become atrophic, and affected muscles are pale and shrunken, reflecting severe neurogenic atrophy.

CLINICAL FEATURES: ALS often begins asymmetrically as weakness and wasting of muscles of one hand. Irregular rapid involuntary contractions of small muscle groups (fasciculations) are characteristic and are felt to arise from hyperirritability of terminal arborizations of dying lower motor neurons. The disease is inexorably progressive, with increasing weakness of the limbs leading to total disability. Speech may become unintelligible, and respiratory weakness supervenes. Despite the dramatic wasting of the body, intellectual capacity is preserved to the end, although some patients with ALS also suffer dementia of the frontotemporal lobar type. The clinical course does not usually exceed a decade.

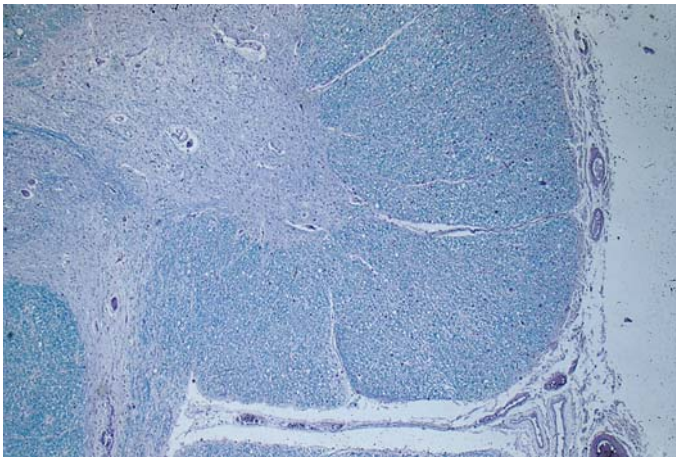

FIGURE 32-99. Amyotrophic lateral sclerosis (ALS) spinal cord showing lower motor neuron loss. The anterior horn of the spinal cord normally contains numerous very large lower motor neurons. In ALS, there is anterior horn cell loss and gliosis.

Spinal muscular atrophy (Werdnig-Hoffman disease) is the second most common lethal autosomal recessive condition in white populations. It usually presents in infancy with extreme muscle weakness and atrophy due to severe loss of anterior horn cells. Death from respiratory failure or aspiration pneumonia usually occurs within a few months of diagnosis. Accurate diagnosis is critical for genetic risk management. This disorder results from a loss-of-function mutation of a neuronal apoptosis inhibitor protein resulting in neurons having an extremely low threshold for initiating programmed cell death.

Several neurodegenerative, infectious and vitamin deficiency disorders impact the spinal long tracts and are summarized in Fig. 32-100.

DEVELOPMENTAL MALFORMATIONS

CNS development unfolds according to a precise schedule, with each morphologic event being the foundation for those that follow. Thus, congenital anomalies reflect interruptions in the completion of developmental processes. ***Congenital malformations are defined more by the timing than the specific nature of an insult.***

ETIOLOGIC FACTORS: There are 3 critical stages of CNS development: (1) neurulation, (2) segmentation and cleavage and (3) proliferation and migration. Neurulation consists of formation and closure of the neural tube and is complete by 4 weeks of gestation, often before a woman is aware that she is pregnant. This step establishes the cranial–caudal, dorsal–ventral and left–right axes of the embryo. From weeks 4 to 8, the neural tube segments into neighborhoods that will ultimately become the spinal cord, medulla, pons and cerebellum, midbrain, diencephalon and telencephalon. The diencephalon and telencephalon then split into the paired basal ganglia, thalami and cerebral hemispheres. By the end of 8 weeks of gestation, basic CNS architecture is established. For the rest of gestation and beyond into postnatal life, cell proliferation creates the *trillions* of neuroglia that ultimately populate the mature CNS. These cells are mostly born in the periventricular germinal matrix and must successfully migrate to their ultimate destinations. In humans, defects of proliferation and migration mainly impact the formation of cerebral cortex and cause mental retardation and seizures. Once neurons and glia reach their destinations, they must wire the brain correctly using axonal pathfinding and oligodendroglial myelination.

Defects of Neurulation Are the Neural Tube Defects

Anencephaly

Anencephaly is the congenital absence of all or part of the brain as a result of unsuccessful closure of the cephalad (anterior neuropore) portion of the neural tube.

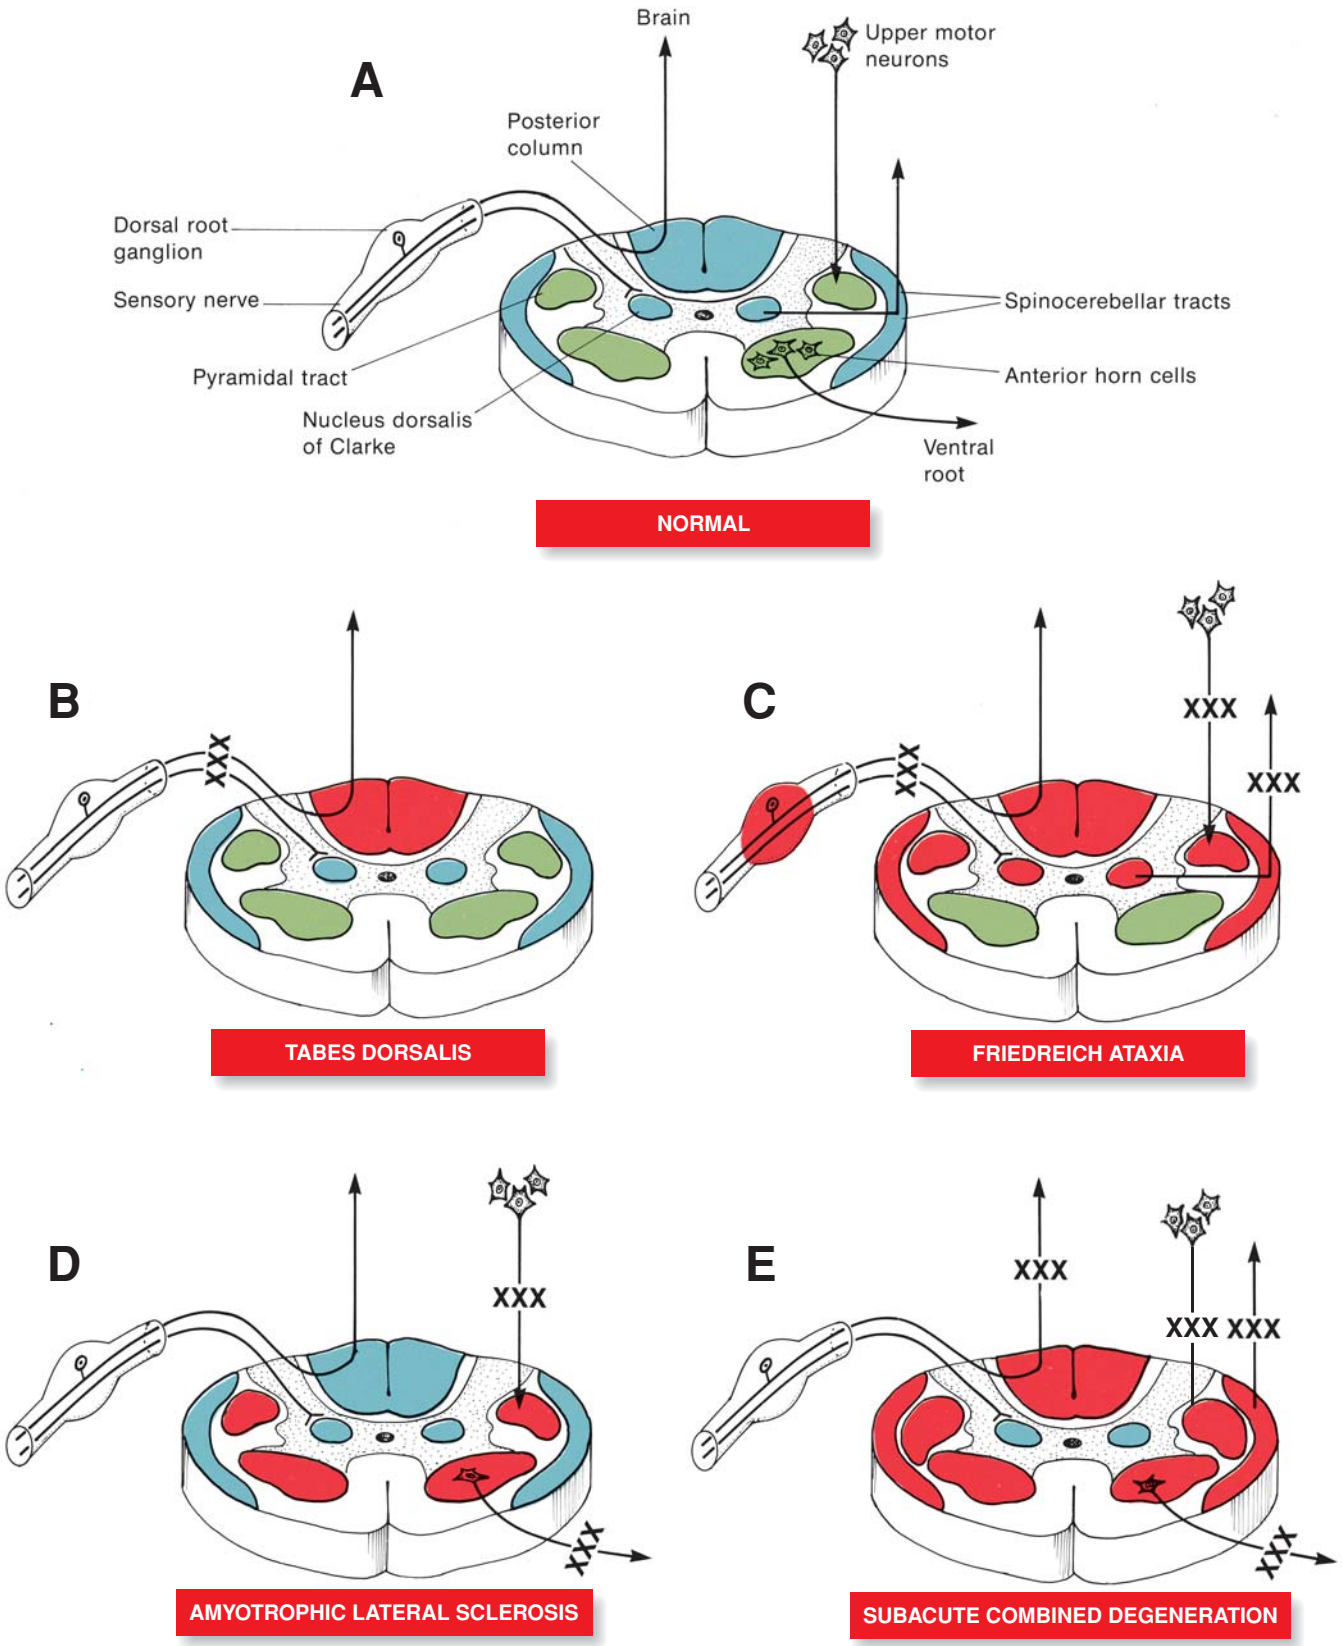

FIGURE 32-100. Tract degeneration in diseases of the spinal cord. Ascending (*blue*) sensory and descending (*green*) pathways travel through the spinal cord. These tracts may be differentially affected (*red*) depending on the nature of the underlying disease, as shown in this example of four diseases that we have considered.

EPIDEMIOLOGY: Anencephaly is the second most common CNS malformation after spina bifida (0.5–2.0 per 1000 births, with females predominating) and is the most common lethal CNS malformation. Anencephalic fetuses are stillborn or die in the first few days of life.

Anencephaly is a multifactorial birth defect exhibiting geographic variation in incidence. In the United States, it occurs in 0.3 per 1000 live births and stillbirths. In Ireland, the frequency is 20-fold greater (5–6 per 1000). Incidence declines to 2–3 per 1000 among Irish immigrants to North America. It is rare among blacks.

ETIOLOGIC FACTORS: Anencephaly is a dysraphic defect of neural tube closure (Fig. 32-101). Its concurrence with other neural tube defects (NTDs), such as spina bifida, suggests shared pathogenic mechanisms. During development, the neural plate invaginates and is transformed into the neural tube by fusion of the posterior surfaces. Mesenchymal tissue overlying the primitive neural tube then forms the skull and vertebral arches posterior to the spinal cord, while ectoderm forms the overlying skin. If the neural tube does not close, neither will the overlying bony structures of the cranium. The calvarium, skin and subcutaneous tissues will be absent in this region. The exposed brain is incompletely formed or even entirely absent. Most often, the base of the skull has only bits of neural and ependymal tissue and residues of meninges.

Genetic factors contribute to the pathogenesis of anencephaly. The anomaly is twice as common in female as in male fetuses, and it occurs with higher frequency in certain families. The risk of a second anencephalic fetus is 2%–5%. After two anencephalic fetuses, the risk reaches 25% for each subsequent pregnancy.

Folic acid supplied in the periconceptional period lowers the incidence of NTDs. In 1998, the U.S. Food and Drug Administration began requiring supplemental folate to be added to enriched flour, bread, cereals and some other products. This led to a significant decrease in the incidence of NTDs of all types (see Chapters 6 and 14).

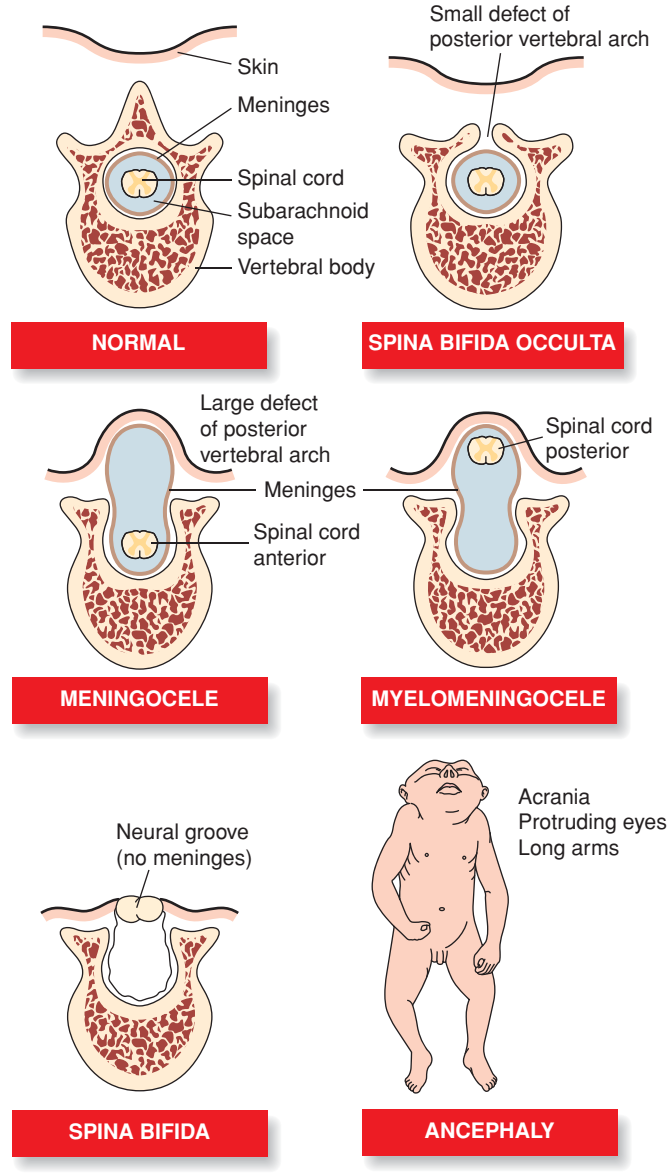

FIGURE 32-101. Defects of the neural tube. The first critical step in neural development is neurulation—formation and closure of the neural tube. Incomplete fusion of the neural tube and overlying bone, soft tissues or skin leads to several defects, varying from mild anomalies (e.g., spina bifida occulta) to severe anomalies (e.g., anencephaly).

PATHOLOGY: The cranial vault is absent. The cerebral hemispheres are replaced by a highly vascularized, disorganized neuroglial tissue, the **cerebrovasculosa** (Fig. 32-102), on the flattened base of the skull. Two well-formed eyes with well-differentiated retinas mark the anterior margin of disturbed organogenesis. Short segments of optic nerves extend posteriorly. The posterior aspect of the malformation forms a variable transitional zone with a recognizable midbrain, but the brainstem and cerebellum are usually rudimentary. The upper spinal cord is hypoplastic, and a dysraphic bony posterior spinal column defect **(rachischisis)** may affect the cervical area. Vertebral and basilar arteries usually are identifiable amid the meningeal vessels.

The cerebrovasculosa typically contains islands of immature neural tissue. It also encloses cavities partly lined by ependyma, with or without choroid plexus. However, the mass mainly consists of abnormal vascular channels that vary considerably in size.

Two thirds of anencephalic fetuses die in utero; those that are alive at birth rarely survive more than a week. Screening of pregnant women for serum α-fetoprotein and ultrasonography detect virtually all anencephalic fetuses.

FIGURE 32-102. Anencephaly is the most severe defect of neurulation. The cerebral vault is absent (*right panel*), and the absence of a calvarium exposes a mass of vascularized tissue (cerebrovasculosa, *left panel*), in which there are rudimentary neuroectodermal structures. The lesion is bounded anteriorly by normally formed eyes and posteriorly by the brainstem.

Spina Bifida

Spina bifida is a group of NTDs that are due to failure of neural tube closure in the more caudal regions. These anomalies are usually in the lumbar region and vary in severity from asymptomatic to disabling. They are not usually lethal. Spina bifida results from an insult between the 25th and 30th days of gestation, reflecting the timing of neural tube closure. These anomalies are subclassified by the severity of the defect:

- **Spina bifida occulta:** This defect is restricted to the vertebral arches and is usually asymptomatic. It frequently manifests externally only by a dimple or small tuft of hair on the lower back.
- **Meningocele:** This condition features a greater bone and soft tissue defect that permits the meninges to protrude as a fluid-filled sac visible on the external surface of the back, in the midline. The sides of the sac are usually covered by a thin layer of skin. Its apex may be ulcerated, allowing microorganisms to enter the CSF.
- **Meningomyelocele:** This is an even more extensive defect that exposes the spinal canal and causes nerve roots (particularly those of the cauda equina) and spinal cord to be entrapped in an externally visible protruding CSF-filled sac (Fig. 32-103). Usually, the spinal cord is a flattened, ribbon-like structure. Severe neurologic consequences include lower extremity motor and sensory defects and compromise of bowel and bladder neurogenic control.
- **Rachischisis:** In this extreme defect, the spinal column is a gaping canal, often without a recognizable spinal cord (Fig. 32-104). Rachischisis is usually lethal and seen in abortuses.

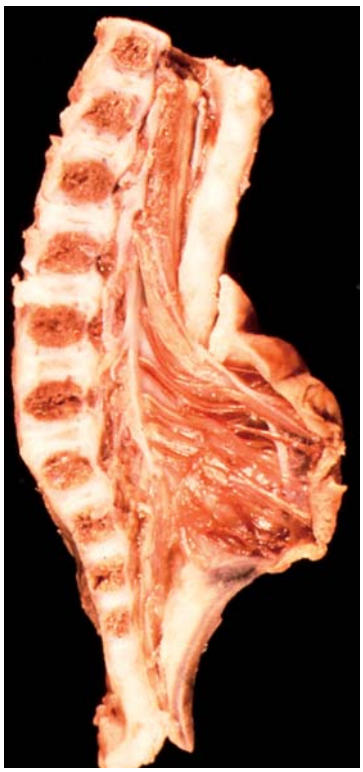

FIGURE 32-103. Meningomyelocele. This dysraphic defect, which is caused by lack of fusion of the spinal canal usually in the lumbar region, reveals disorganized spinal cord tissue with entrapment of nerve roots in a cerebrospinal fluid–filled sac. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

FIGURE 32-104. Rachischisis. A view of the vertebral column shows a bony, cutaneous defect with segmental thoracic absence of the spinal cord and overlying vertebral arches and soft tissues.

Spina bifida is induced readily in rats and chicks at the 8th to 9th gestational day by chemicals such as trypan blue or by hypervitaminosis A. It probably reflects failure of the neural tube to close, but this concept is not established. As mentioned above, maternal folate deficiency is implicated in NTDs. Some drugs, notably retinoids used for acne and valproic acid used to manage seizures, must be avoided by women of childbearing age because of their association with NTDs.

CLINICAL FEATURES: Clinical neurologic deficits in NTDs range from no symptoms in spina bifida occulta to lower limb paralysis, sensory loss and incontinence in meningomyelocele. One must be aware of potential associated malformations such as Arnold-Chiari malformation, hydrocephalus, polymicrogyria and hydromyelia of the spinal central canal (see below).

Malformations of the Spinal Cord

Other spinal cord malformations that are less apparent at birth than NTDs include rare total **(dimyelia)** to partial duplication of spinal cord into two separate structures **(diastematomyelia)**. **Hydromyelia** is dilation of the central spinal cord canal.

Syringomyelia is a congenital malformation, a tubular cavitation (syrinx), which may or may not communicate with the central canal, that extends for variable distances within the spinal cord. Many cases represent congenital malformations, but the condition progresses slowly and usually first presents clinically in adults. Some cases of syringomyelia are not congenital but are caused by trauma, ischemia or tumors. The syrinx is filled with a clear fluid similar to CSF. **Syringobulbia** is a variant of syringomyelia in which the syrinx is located in the medulla.

CLINICAL FEATURES: The symptoms of syringomyelia are present at the spinal level of the syrinx. At that point, the centrally located syrinx

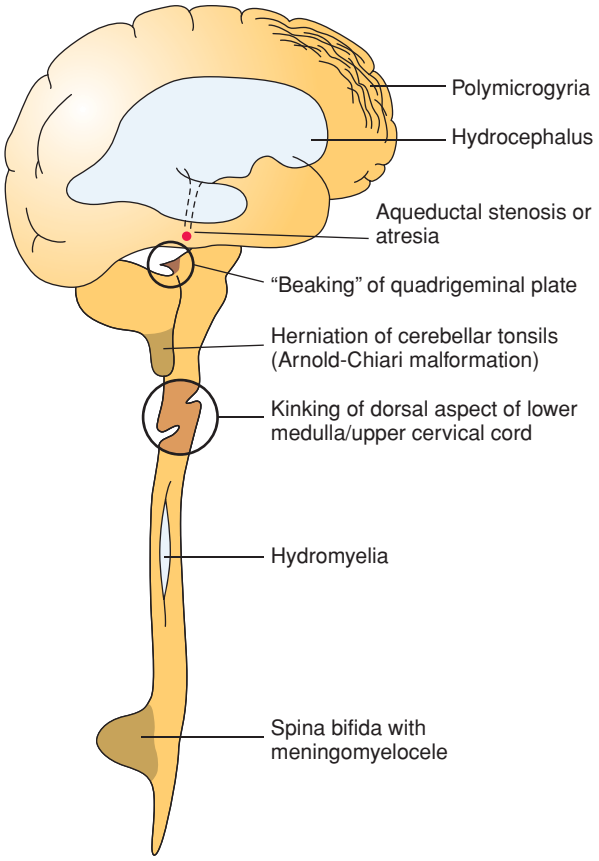

FIGURE 32-105. Arnold-Chiari malformation and associated lesions.

disrupts the segmentally crossing secondary axons of the spinothalamic pathway. This leads to loss of pain and thermal sensation bilaterally at the spinal level of the syrinx with relative sparing of fine touch and proprioception as well as motor pathways.

Arnold-Chiari Malformation

Arnold-Chiari malformation is a complex condition in which the brainstem and cerebellum are compacted into a shallow, bowl-shaped posterior fossa with a low-positioned tentorium. It is often associated with syringomyelia or a lumbosacral meningomyelocele. Symptoms depend on the severity of the defect (Fig. 32-105). ***Since this malformation involves segmentation of the medulla and cerebellum as well as neural tube closure, it represents a defect of both neurulation and segmentation.***

PATHOPHYSIOLOGY: The genesis of Arnold-Chiari malformation is obscure. It has spawned much speculation, but no one theory covers all features of the condition. One theory posits that a meningomyelocele anchors the lower end of the spinal cord, causing downward growth of the vertebral column, and creating traction on the medulla. This theory does not explain other facets of the malformation (curvature of the medulla, beaking of the quadrigeminal plate). Other proposals include increased intracranial pressure plus hydrocephalus or limited size of the posterior fossa.

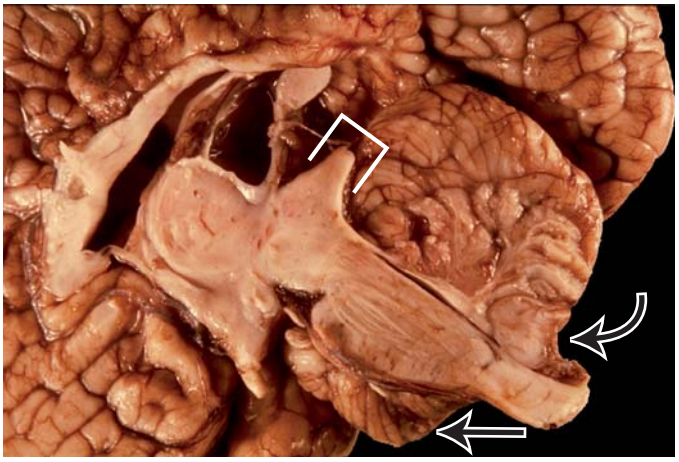

FIGURE 32-106. Arnold-Chiari malformation. The cerebellar vermis is herniated below the level of the foramen magnum (*arrow*). The downward displacement of the dorsal portion of the cord causes the obex of the fourth ventricle to occupy a position below the foramen magnum (*curved arrow*). The midbrain shows extreme "beaking" of the tectum with the four colliculi being replaced by a single pyramidal-shaped structure (*bracket*).

PATHOLOGY: In Arnold-Chiari malformation, the caudal aspect of the cerebellar vermis is herniated through an enlarged foramen magnum and protrudes onto the dorsal cervical cord, often reaching C3–C5 (Fig. 32-106). The herniated tissue is held in position by thickened meninges and shows pressure atrophy (i.e., depletion of Purkinje and granular cells). The brainstem also is displaced caudally. Typically, the displacement is more exaggerated dorsally than ventrally, and landmarks (e.g., the obex of the fourth ventricle) are more caudal than ventral structures such as the inferior olive. From a lateral perspective, the lower medulla is angulated in its midsegment, creating a dorsal protrusion. The foramina of Magendie and Luschka are compressed by the bony ridge of the foramen magnum, causing hydrocephalus. The cerebellum is flattened to a discoid contour, and the quadrigeminal plate is often deformed by a "beak-shaped" dorsal protrusion of the inferior colliculi.

Defects of Segmentation and Cleavage Cause Loss of Key Structures

Holoprosencephaly

This represents a series of defects in which the interhemispheric fissure is absent or partly formed owing to a failure of the telencephalon to divide into the two hemispheres. Holoprosencephaly is a continuum: complete cleavage failure gives rise to **alobar holoprosencephaly,** partial failure leads to **lobar holoprosencephaly** and the subtlest form is failure of olfactory nerves to form, causing **arrhinencephaly**. In alobar holoprosencephaly, there is a bulbous horseshoe-shaped cortical dome consisting of fused frontal poles, across which the gyri show an irregular horizontal orientation (Fig. 32-107). A common ventricular chamber is created by lateral displacement of the posterior portions of the telencephalon. Bilobed caudate nuclei and thalami are prominent. In lobar holoprosencephaly, there is partial cleavage in the posterior portion of the telencephalon, but there remains a single gaping

FIGURE 32-107. Holoprosencephaly. The brain exhibits a lack of separation of the hemispheres and a single large ventricle when viewed from an anterior perspective. No interhemispheric fissure is present; therefore, this is alobar holoprosencephaly.

ventricular chamber. Holoprosencephaly is rarely compatible with life beyond a few weeks or months, and survival is associated with severe mental retardation and seizures.

MOLECULAR PATHOGENESIS: About 25%–50% of patients with holoprosencephaly have numerical or structural chromosomal abnormalities. Monogenic holoprosencephaly is sometimes associated with mutations in *sonic hedgehog,* an important signaling molecule.

Arrhinencephaly

The absence of the olfactory tracts and bulbs (rhinencephalon) is the least severe of the holoprosencephaly defects (Fig. 32-108). It is clinically manifested by lack of a sense of smell **(anosmia)** and may be associated with mental retardation.

Agenesis of the Corpus Callosum

This anomaly is a regular feature of holoprosencephaly but can also be a solitary lesion. Lack of a corpus callosum does not entail significant loss of interhemispheric functional coordination, but it is associated with seizures. The corpus callosum physically tethers and functionally interconnects the hemispheres, so its absence permits the lateral ventricles to drift outward and upward, a radiographically diagnostic finding of "bat-wing" ventricles (Fig. 32-109).

Congenital Atresia of the Aqueduct of Sylvius

This is the most common cause of congenital obstructive hydrocephalus. It may result from deranged mesencephalic (midbrain) development and occurs in 1 in 1000 live births. The brain is enlarged owing to grotesque ventricular enlargement, with thinning of the cerebral cortex and stretching of white matter tracts. The midbrain may show multiple atretic channels or an aqueduct narrowed by gliosis, which may

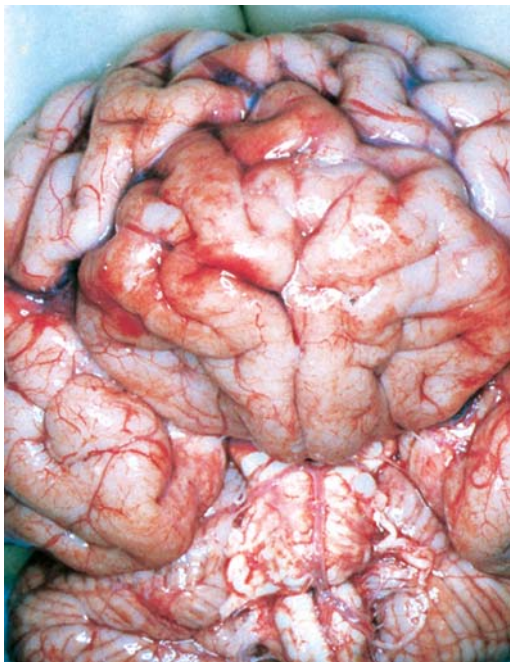

FIGURE 32-108. Arrhinencephaly is the least severe form of holoprosencephaly and consists grossly solely of absence of the olfactory bulbs and nerves, hence the name ("a," *without,* and "rhinencephaly," *nose brain*). There are usually more subtle microscopic abnormalities, and most of these individuals have some degree of mental retardation. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

result from developmental failure during segmentation or later in gestation as a result of transplacental transmission of infections that induce ependymitis.

Cortical Malformations Arise from Defects of Neuroglial Proliferation and Migration

ETIOLOGIC FACTORS: Neuroglial proliferation and migration begin in the first trimester of embryonic development and continue throughout

FIGURE 32-109. Congenital absence of the corpus callosum. A coronal section of the brain at the level of the thalamus reveals absence of the corpus callosum and "bat-wing" shape of the lateral ventricles. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

prenatal life. Primitive neurons and glia move centrifugally from the periventricular germinal matrix to populate the cortex. The number and positions of neurons in the cortex determine the cortical infolding that creates sulci and gyri.

These disorders of cortical development thus reflect the nature and severity of disruption of gyral patterning. A cortical defect may be global or focal. Portions of the germinal matrix induce formation of specific overlying portions of the cerebral cortex; that is, there is a spatial destiny of neuroglial cells in a given region of germinal matrix. If a focal region of germinal matrix is destroyed or damaged, the cortical destination of the cells spawned in that region will reflect this damage. **Schizencephaly** is an example of such a failure of focal cortical development due to damage to the germinal matrix. Here, a patch of cortex is "missing." Cortex built from undamaged germinal matrix will be structurally normal. More global, often genetically determined defects of neuroglial proliferation and migration result in a more widespread and severe cortical defect, called lissencephaly, meaning "smooth brain."

- **Lissencephaly** is the most severe congenital disorder of cortical development. The cortical surface of the cerebral hemispheres is smooth or has imperfectly formed gyri. Some 60% of patients with lissencephaly show deletions in the region of the *LIS1* gene on chromosome 17p13.3, which encodes a protein involved in cytoskeletal dynamics that affects cell proliferation and motility. The white matter contains clusters of neurons that failed to reach the cortex.
- **Heterotopias** are focal disturbances in neuronal migration that lead to nodules of ectopic neurons and glia, usually in white matter. They are often associated with mental retardation and seizures and may be caused by maternal alcoholism.
- **Polymicrogyria** describes the presence of small and excessive gyri (Fig. 32-110). The brain surface appears to be textured with many small bumps.
- **Pachygyria** is a condition in which the gyri are reduced in number and unusually broad (Fig. 32-111).

Late-Term and Perinatal Insults May Lead to Severe Brain Damage

Sometimes the CNS develops successfully, only to suffer catastrophic damage late in pregnancy or in the perinatal period. If the brain is deprived of blood or oxygen, the cerebral hemispheres may liquify, leaving a fluid-filled cranial cavity, a state called **hydranencephaly**. The head circumference reflects the largest size that the brain attained before the insult, and the head can be transilluminated as no tissue remains to block the passage of light through the cranial vault. The cranial sutures may override as the nascent brain degenerates.

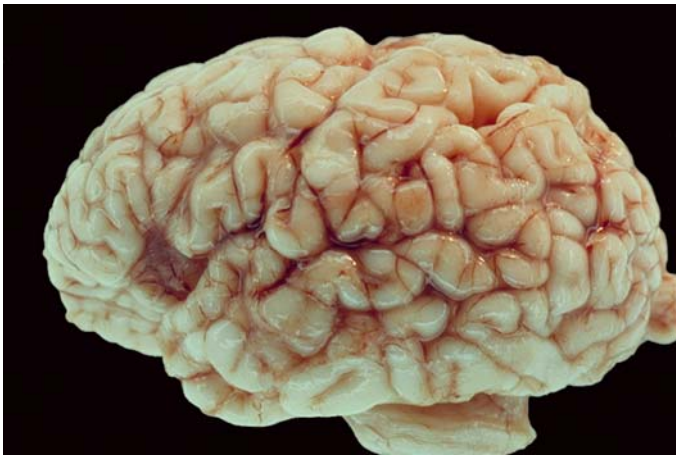

FIGURE 32-110. Polymicrogyria. The surface of the brain exhibits an excessive number of small, irregularly sized, randomly distributed gyral folds.

FIGURE 32-111. Pachygyria. Broad textured gyri are seen here in the superior frontal region, indicating a defect in cortical formation. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Less severe, but still devastating, hypoxia/ischemia may lead to late-term and perinatal cerebral infarcts. Developing brains are unique bioenergetically. In adults, the gray matter receives 3 times the blood and consumes 3 times the oxygen as the white matter. In developing brains, the periventricular germinal matrix and streams of migrating neuroglia equalize bioenergetic demand, so that deep structures and cerebral cortex have similar huge energy and substrate requirements. The deep periventricular white matter is a watershed perfusion zone and is at highest risk for infarction. Thus, intrauterine or perinatal hypoxia ischemia may cause chalky white, sometimes calcific **periventricular leukomalacia**. Infarcted areas may undergo resorption, leading to **multicystic leukoencephalopathy,** with numerous interconnected cystic cavities deep in the white matter near the ventricles.

The germinal matrix is active during later phases of gestation but gradually involutes as term approaches. If a baby is born prematurely, its metabolically active germinal matrix is perfused by delicate capillaries floating in a frenzied sea of stem cells and newly spawned neuroglia. Such an infant is ill equipped for cerebrovascular regulation. These delicate vessels may be exposed to dramatic swings in perfusion pressure, leading to **germinal matrix hemorrhage**. Hemorrhage may remain confined to a small region of the germinal matrix or it may spread catastrophically as intraventricular hemorrhage. Germinal matrix hemorrhage is a major challenge in clinical management of premature newborns.

Congenital Defects May Be Associated with Chromosomal Abnormalities

Derangements of the larger autosomes, 1 through 12, are incompatible with sustained intrauterine life: affected fetuses

are spontaneously aborted. Structural and functional abnormalities may be attributed to gross chromosomal derangements of the smaller autosomes (e.g., trisomies of chromosomes 13–15 and 21 [Down syndrome]). Trisomies 13 or 15 occur in 1 per 5000 births, with a modest female predominance. The congenital deformities involve the brain, facial features and extremities: holoprosencephaly, arrhinencephaly, microphthalmia, cyclopia, low-set ears, harelip and cleft palate. The extremities exhibit polydactyly and "rocker bottom" feet.

CENTRAL NERVOUS SYSTEM NEOPLASIA

Primary CNS cancers represent 1.5% of all primary malignant tumors. Metastatic tumors to the CNS are far more common than are primary tumors and are a major problem in clinical management. The broad spectrum of cellular constituents of the CNS—all of the diverse cell types that are represented in the CNS—is mirrored by the wide range of tumor types that arise within the brain and spinal cord and their overlying meninges. Over 130 different types of CNS neoplasms are recognized and formally codified by the World Health Organization (WHO), but most are very rare. By far the most common are meningiomas and gliomas, each of which accounts for 1/3 of CNS tumors (Table 32-5). While most brain tumors arise in adults, some are more common in childhood, the most prominent being medulloblastoma, pilocytic astrocytoma and diffuse pontine astrocytoma. Together, primary brain tumors are second only to leukemia as the most common childhood malignancy, and are the most common pediatric solid tumors.

Diagnosing a brain tumor entails generating a preoperative differential diagnosis of the most likely possibilities based on the patient's clinical information (Table 32-6), then obtaining a definitive tissue-based diagnosis by biopsy or resection. Further clinical management requires a definitive diagnosis. This approach integrates the key characteristics of different brain and spinal cord tumors and other kinds of diseases, plus the patient's age, the location of the lesion, specific neuroimaging features, the nature and time course of preceding clinical signs and symptoms and major elements of the clinical history, such as the presence of a systemic primary tumor or of a tumor predisposition syndrome.

TABLE 32-5
MAJOR TYPES OF PRIMARY CENTRAL NERVOUS SYSTEM (CNS) TUMORS

Meningioma
Gliomas (including diffuse and circumscribed astrocytomas, oligodendroglioma, ependymoma, choroid plexus tumors, several rare glioma subtypes)
Medulloblastoma and other primitive neuroectodermal tumors
Craniopharyngioma
Germ cell tumors
Hemangioblastoma
Neuronal and mixed glioneuronal tumors
Pineal tumors
Primary CNS lymphoma

TABLE 32-6
ESSENTIAL CLINICAL INFORMATION

Patient age and gender
Anatomic location and compartment of the lesion
Neuroimaging (computed tomography, magnetic resonance imaging) features
Nature and time course of presenting signs and symptoms
Relevant clinical history

PATIENT AGE: Different types of brain tumors tend to arise at particular ages. The two most common brain tumors of childhood are medulloblastoma and pilocytic astrocytoma. Other, rarer tumors also tend to occur in children, such as diffuse pontine glioma, atypical teratoid/rhabdoid tumor and choroid plexus carcinoma. Similarly, metastatic carcinomas from the lung, breast and colon mainly affect older adults. Still others have a peak incidence in young adulthood, such as ganglioglioma and central neurocytoma. Some tumors may be most common in adults but spare no age group: glioblastomas are the most common and most malignant gliomas and may occur at any time in life.

PATIENT GENDER: Most primary brain tumors are more common in males, with two notable exceptions being pituitary adenomas and meningiomas, which are more common in young adult and middle-aged to older adult women, respectively. Brain metastases of primary tumors elsewhere follow the gender patterns of incidence of those tumor types (e.g., breast, prostate).

ANATOMIC LOCATION AND COMPARTMENT OF THE LESION: Anatomic localization of brain lesions includes two components: the region of the CNS involved, such as the cerebrum, cerebellum or spinal cord, and the compartment(s). Examples of the latter include intraparenchymal (e.g., within the brain substance), intraventricular or intradural–extra-axial (within the spinal subarachnoid space). Such information greatly facilitates formulation of a differential diagnosis. Thus, intradural, extra-axial spinal cord masses would be meningioma and peripheral nerve sheath tumors; masses within a cerebral lateral ventricle are more likely to be choroid plexus papillomas, ependymomas or other tumors that frequent those haunts.

NEUROIMAGING FEATURES: Preoperative imaging of a CNS lesion provides critical data that bear directly on the differential diagnosis (Table 32-7; Fig. 32-112). The most obvious are the number and distribution of lesions, as noted above. The nature of the interface between the lesion and the surrounding brain is also important. For example, the borders of highly infiltrative tumors, such as fibrillary astrocytomas and lymphomas, are subtle and diffuse, but interfaces with the surrounding brain are much better circumscribed for metastases or minimally infiltrative primary tumors, such as pilocytic astrocytoma or ganglioglioma.

TABLE 32-7

MAJOR NEUROIMAGING (COMPUTED TOMOGRAPHY, MAGNETIC RESONANCE IMAGING) FEATURES

Anatomic location and compartment of the lesion(s)
Nature of the interface between the lesion and the surrounding parenchyma (e.g., sharply circumscribed vs. diffuse)
Presence or absence of enhancement following contrast agent administration
If contrast enhancing, the pattern of enhancement (e.g., solid uniform enhancement, ring enhancement around a central area of necrosis, C-shaped open ring enhancement, enhancing nodule within the wall of a cyst)

Vascularity, when contrast agents are given, is also helpful, since some tumor types, such as glioblastoma, meningioma, medulloblastoma and metastatic carcinomas, are more vascular, while others usually are not, such as low-grade diffuse fibrillary astrocytoma. Some tumor types tend to show relatively solid, even enhancement, such as meningiomas and primary CNS lymphoma, but for other types, ring enhancement around a central area of necrosis is typical, such as glioblastoma. Nontumor diseases, many of which mimic tumor radiologically, also often have characteristic enhancement patterns; for example, demyelinating pseudotumor frequently presents as a mass lesion with "open ring" or "C-shaped" enhancement, while cerebral abscesses typically show a very smooth-walled enhancing ring (Fig. 32-112).

NATURE AND TIME COURSE OF CLINICAL SIGNS AND SYMPTOMS: In general, a long history, such as several years of poorly controlled seizures, favors more indolent or

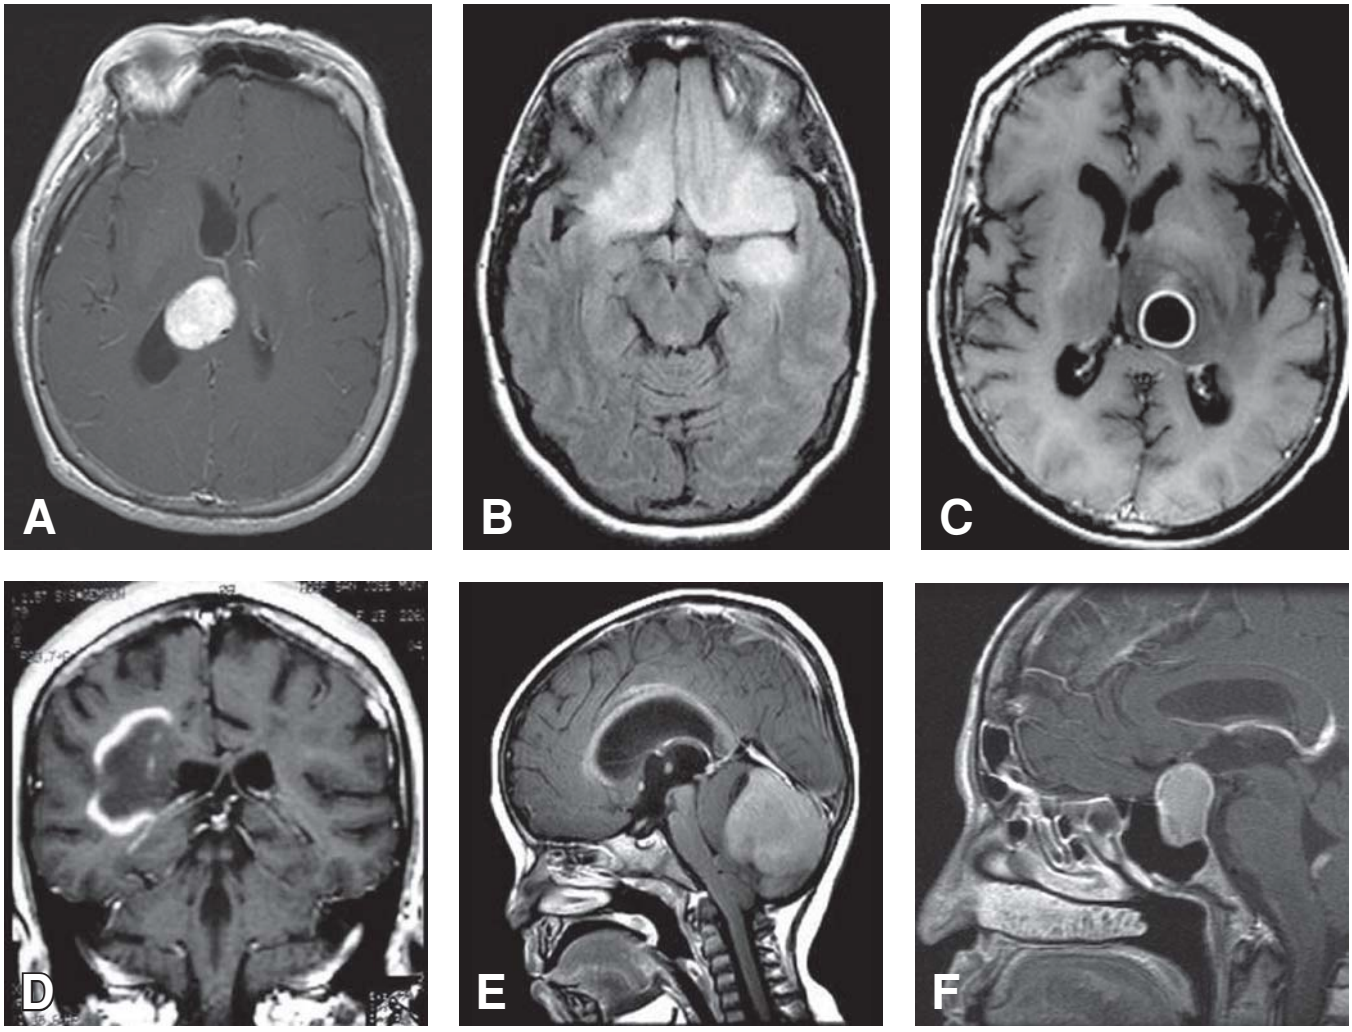

FIGURE 32-112. Neuroimaging—the modern pathologist's gross pathology. Contemporary neuroimaging techniques provide the first look at the "gross pathology" of a central nervous system lesion and constitute a rich source of information that can be utilized by the pathologist to formulate a refined differential diagnosis prior to surgical biopsy and tissue examination. Shown here are representative examples of magnetic resonance images that illustrate the highly informative features of six different brain lesions. **A.** A contrast-enhancing, circumscribed mass located within the lateral ventricle (choroid plexus meningioma). **B.** Diffuse hyperintensity involving both frontal lobes and the left temporal lobe (infiltrating glioma). **C.** Smooth-walled ring-enhancing mass in the left thalamus (pyogenic abscess). **D.** C-shaped open ring-enhancing lesion in the white matter of the right parietal lobe (demyelinating pseudotumor). **E.** Hyperintense midline mass of the cerebellar vermis and fourth ventricle (medulloblastoma). **F.** Contrast-enhancing midline mass of the sellar and suprasellar region (pituitary adenoma).

TABLE 32-8
MAJOR NERVOUS SYSTEM TUMOR PREDISPOSITION SYNDROMES

Syndrome	Chromosome Locus	Gene (protein)	Associated Nervous System Tumors
Neurofibromatosis type 1 (NF1)	17q11.2	*NF1* (neurofibromin)	Neurofibromas (dermal and plexiform) Malignant peripheral nerve sheath tumor (MPNST) Pilocytic astrocytoma ("optic glioma") Diffuse astrocytoma Glioblastoma
Neurofibromatosis type 2 (NF2)	22q12	*NF2* (merlin/schwanomin)	Vestibular schwannomas (bilateral) Other schwannomas Meningiomas (multiple) Meningioangiomatosis Ependymoma of spinal cord Diffuse astrocytoma
Schwannomatosis (sometimes referred to as "NF3")	Unknown	Unknown	Schwannomas (multiple, spinal roots, cranial nerves, skin, not vestibular)
von Hippel-Lindau (vHL)	3p25–26	*VHL* (pVHL)	Hemangioblastomas (multiple) of cerebellum, spinal cord, brainstem, retina, spinal peripheral nerve roots Endolymphatic sac tumor
Tuberous sclerosis complex	9q34 16p13.3	*TSC1* (hamartin) *TSC2* (tuberin)	Subependymal giant cell astrocytoma
Li-Fraumeni syndrome	17p13	*TP53* (TP53 protein)	Diffuse astrocytomas, including glioblastoma Medulloblastoma Choroid plexus papilloma Ependymoma Oligodendroglioma Meningioma
Cowden disease	10q23	*PTEN/MMAC1* (PTEN protein)	Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease)
Turcot type 1 syndrome (mismatch repair [MMR]/hereditary nonpolyposis colon cancer [HNPCC]– associated Turcot)	3p21.3 2p16 5q11–q13 2q32 7p22	*MLH1* *MSH2* and *MSH6 MSH3* *PMS1* *PMS2* *APC* (APC protein)	Glioblastoma
Turcot type 2 syndrome (familial adenomatous polyposis [FAP]–associated Turcot)	5q21		Medulloblastoma
Nevoid basal cell carcinoma (Gorlin) syndrome	9q22.3	*PTCH* (Ptch protein)	Medulloblastoma
Rhabdoid tumor predisposition syndrome	22q11.2	*INI1* (INI1 protein)	Atypical teratoid/rhabdoid tumor

low-grade disease, while a relatively brief history, such as a 2-week history of headache, nausea and emesis and localizing signs, favors a higher grade and more aggressively expanding lesion.

RELEVANT CLINICAL HISTORY: Histories of, for example, previous non-CNS tumors, systemic diseases or tumor predisposition syndromes are also useful (Table 32-8).

GRADING OF CENTRAL NERVOUS SYSTEM TUMORS: Tumors in brain and spinal cord are commonly graded according to criteria established in the *WHO Classification of Tumours of the Central Nervous System.* Tumor grades according to WHO criteria range from I to IV, with I being the lowest grade and IV the most malignant. The subjective and ill-defined term "benign" should be used with extreme caution, if at all, with respect to CNS tumors, even WHO grade I tumors, because anatomic location, growth pattern and other factors can result in a clinical course for a grade I CNS tumor that entails considerable morbidity and even mortality. For example, most meningiomas are grade I. However, there are those that grow en plaque (flat and plaque-like) along the skull base and surround cranial nerves and blood vessels as they enter and exit the cranial cavity. These can be very difficult to treat surgically and often do not respond well to radiation or chemotherapy. As well, the vast majority of low-grade diffuse gliomas (WHO grade II) are ultimately fatal, even though they are the lowest grade for this subtype of glioma.

Meningiomas Are the Most Common Central Nervous System Tumors

Meningiomas are derived from the middle layer of arachnoid (meningothelial) cells that form the outer boundary of the subarachnoid space. Thus, the anatomic locations in which meningiomas arise parallel the distribution of the arachnoid membrane, and these tumors can arise at any CNS site where arachnoid cells are present—including at the dural venous sinuses (such as the superior sagittal sinus), at the cerebral convexity, at the skull base, around the optic nerve, around the spinal cord and even within the choroid plexus in the cerebral ventricles as mentioned earlier.

MOLECULAR PATHOGENESIS: Meningiomas typically arise in one of three settings:

- **Sporadic:** ***The vast majority of meningiomas arise sporadically.*** Many show loss, partial deletion or mutation of the *NF2* locus (22q12). Disturbances of this tumor suppressor gene may thus be involved not only in neurofibromatosis type 2 (NF2)-associated tumors but also in the origin of many sporadic meningiomas (and schwannomas).
- **Iatrogenic:** Induction of meningiomas by radiation therapy generally involves a latent period of a decade or more and is directly related to radiation dosage. Low-dose scalp irradiation for tinea capitis was widely used until around 1960. The average interval between treatment and detection of a meningioma for such patients was 35 years. With higher radiation doses, such as are used for head and neck cancers, the interval may be as short as 5 years.
- **Tumor predisposition syndromes:** Meningiomas also occur in conjunction with several genetic syndromes, most importantly NF2. Additional rare multiple meningioma syndromes have also been documented.

PATHOLOGY: On MRI and gross examination, most meningiomas are well-circumscribed dura-based masses of variable size that compress, but do not invade, the underlying brain (Fig. 32-113A,B). The cut surface is fleshy and tan. The classic histologic hallmark of meningiomas is a whorled pattern, often in association with psammoma bodies (laminated, spherical calcospherites) (Fig. 32-113C,D). However, these tumors can show diverse morphologic patterns, and 13 subtypes are recognized by the WHO (Table 32-9). Most of these are WHO grade I, but two variants, clear cell and chordoid, behave more aggressively (WHO grade II), and two other variants, papillary and rhabdoid, are frankly anaplastic (WHO grade III). Meningiomas typically express epithelial membrane antigen (EMA) focally (Fig. 32-113C). They have many intercellular junctions, owing to their origin from the cohesive arachnoid barrier cell layer (Fig. 32-113E).

TABLE 32-9
MENINGIOMA SUBTYPES

World Health Organization (WHO) Grade I: Benign Meningioma
Meningothelial
Fibrous
Transitional
Psammomatous
Angiomatous
Microcystic
Secretory
Lymphoplasmacyte rich
Metaplastic
WHO Grade II: Atypical Meningioma
Chordoid
Clear cell
WHO Grade III: Anaplastic (Malignant) Meningioma
Rhabdoid
Papillary

CLINICAL FEATURES: The indolent growth of most meningiomas enables them to enlarge slowly for years before becoming symptomatic. During that time, they displace the brain but do not infiltrate it (Fig. 32-114A,B). Patients often have seizures, particularly with tumors at parasagittal sites over the convexity of the hemispheres. In other locations, meningiomas compress a variety of functional structures. Thus, tumors of the olfactory groove produce anosmia; those in the suprasellar region cause visual deficits by compressing the optic chiasm; meningiomas in the cerebellopontine angle cause cranial nerve dysfunction; and those along the spinal cord compromise spinal nerve root and spinal cord function. Invasion of cranial bone, often accompanied by hyperostosis on CT scans, is relatively common, and growth through the calvarium may create a tumor mass beneath the scalp. In contrast, meningiomas rarely invade the underlying brain. Such aggressive behavior warrants upgrading to WHO grade II (atypical). Tumors that are not completely excised tend to recur, and some may undergo anaplastic progression over time. Anaplastic (malignant) meningiomas (WHO grade III) may also rarely arise de novo.

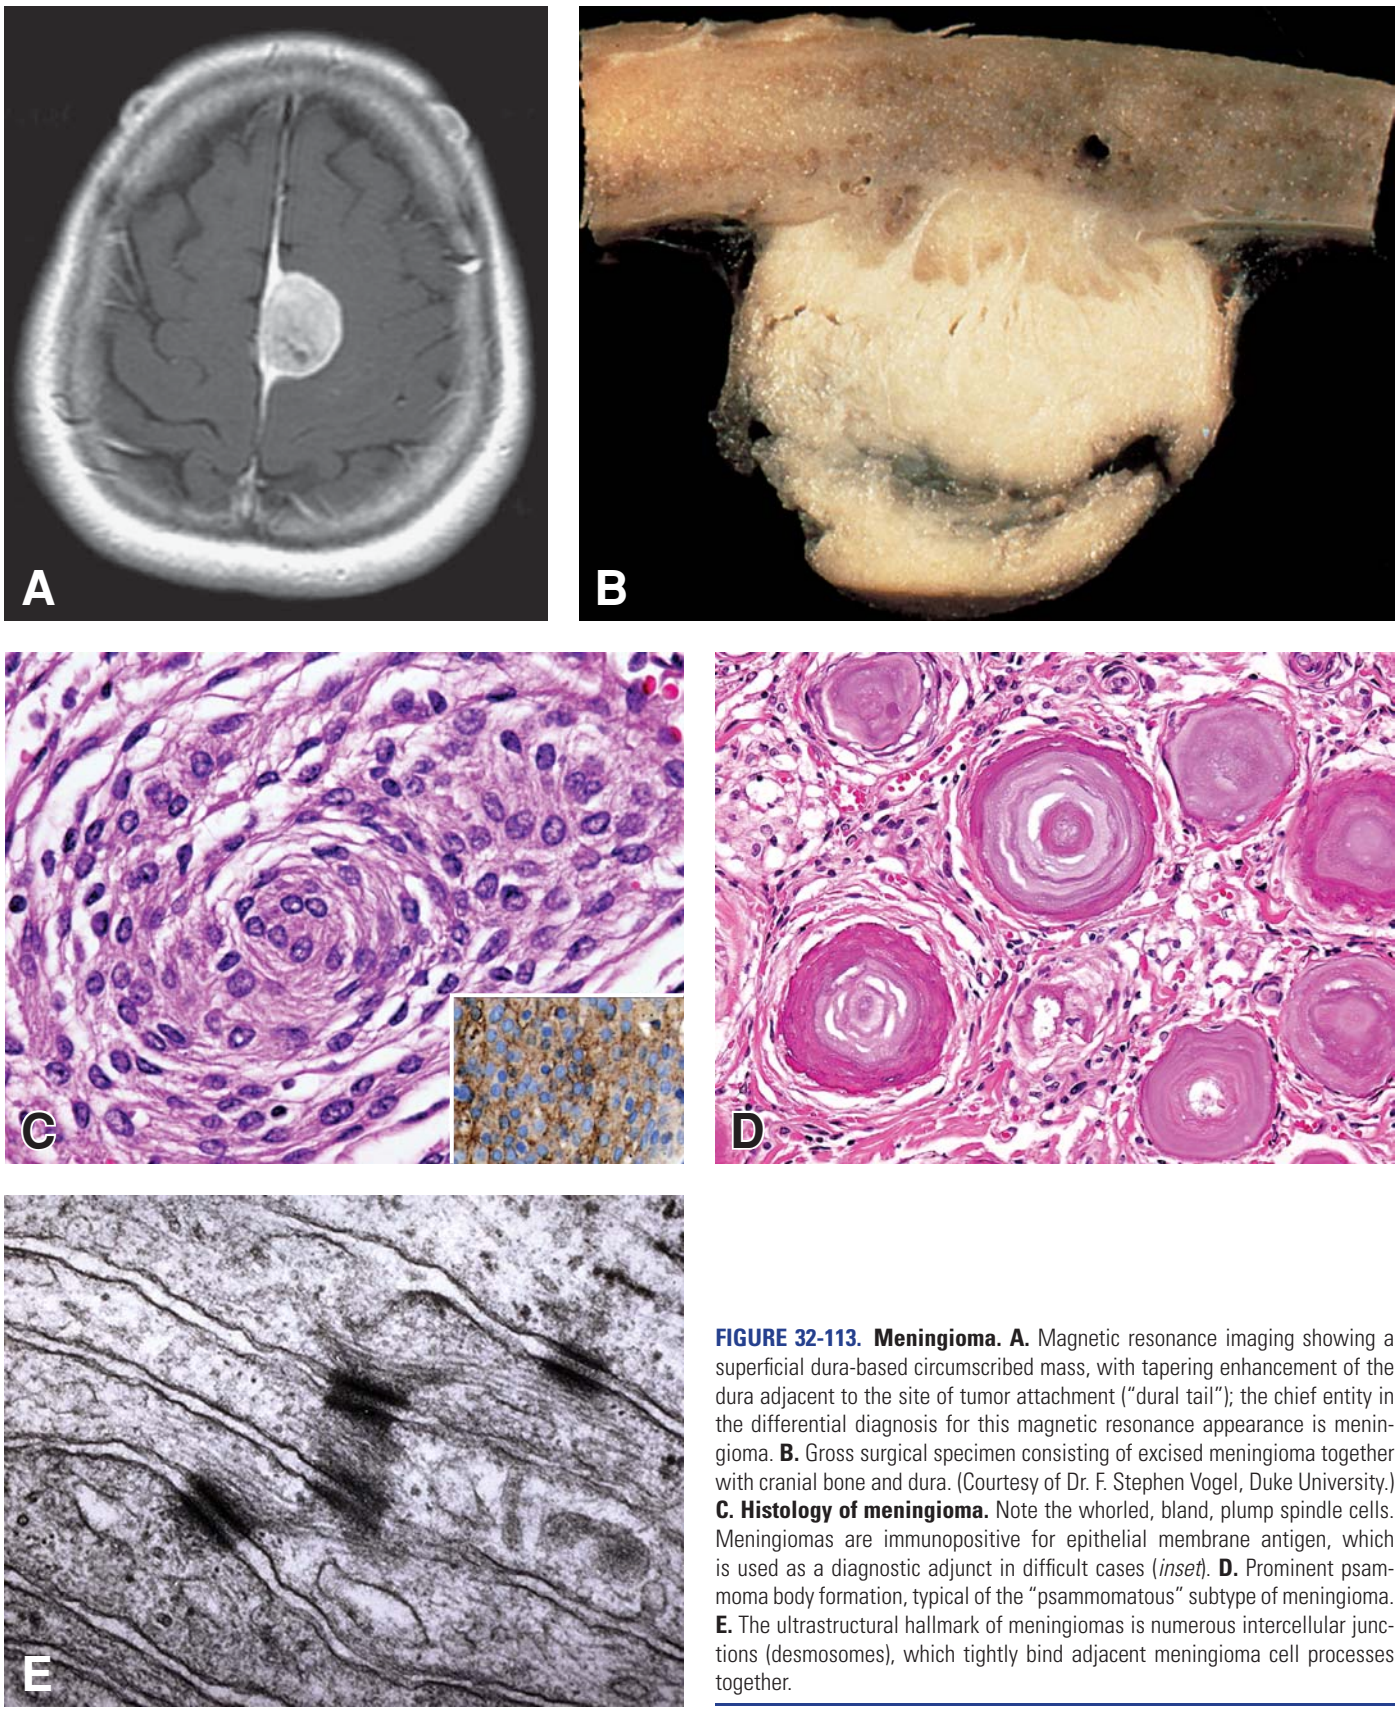

FIGURE 32-113. Meningioma. A. Magnetic resonance imaging showing a superficial dura-based circumscribed mass, with tapering enhancement of the dura adjacent to the site of tumor attachment ("dural tail"); the chief entity in the differential diagnosis for this magnetic resonance appearance is meningioma. **B.** Gross surgical specimen consisting of excised meningioma together with cranial bone and dura. (Courtesy of Dr. F. Stephen Vogel, Duke University.) **C. Histology of meningioma.** Note the whorled, bland, plump spindle cells. Meningiomas are immunopositive for epithelial membrane antigen, which is used as a diagnostic adjunct in difficult cases (*inset*). **D.** Prominent psammoma body formation, typical of the "psammomatous" subtype of meningioma. **E.** The ultrastructural hallmark of meningiomas is numerous intercellular junctions (desmosomes), which tightly bind adjacent meningioma cell processes together.

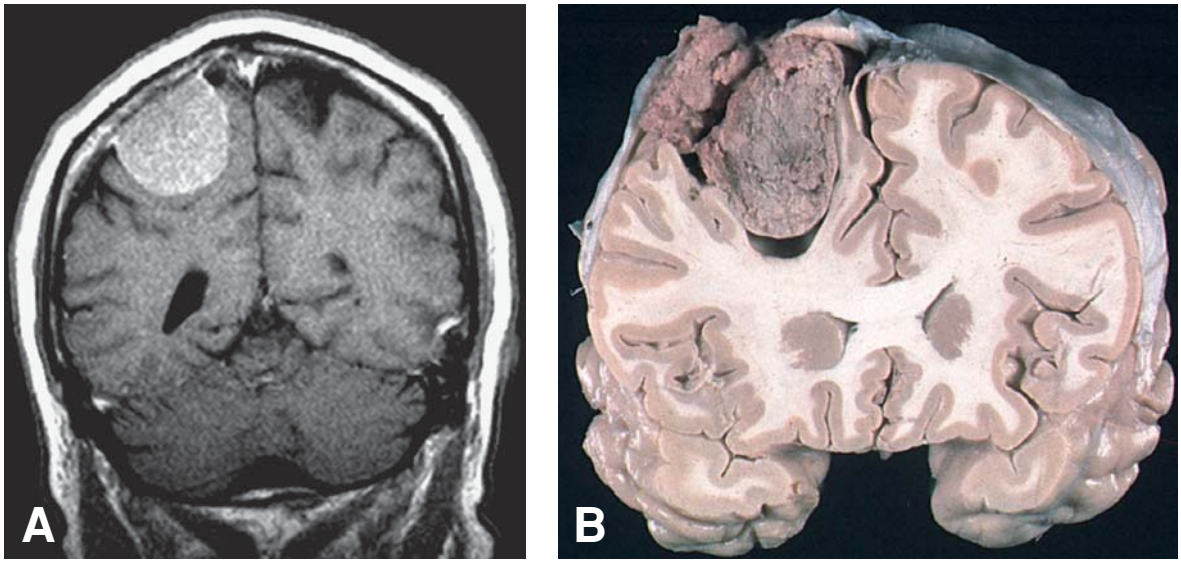

FIGURE 32-114. Meningioma. Meningiomas compress, but do not usually invade, the underlying brain. **A.** Magnetic resonance image. **B.** Gross specimen. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

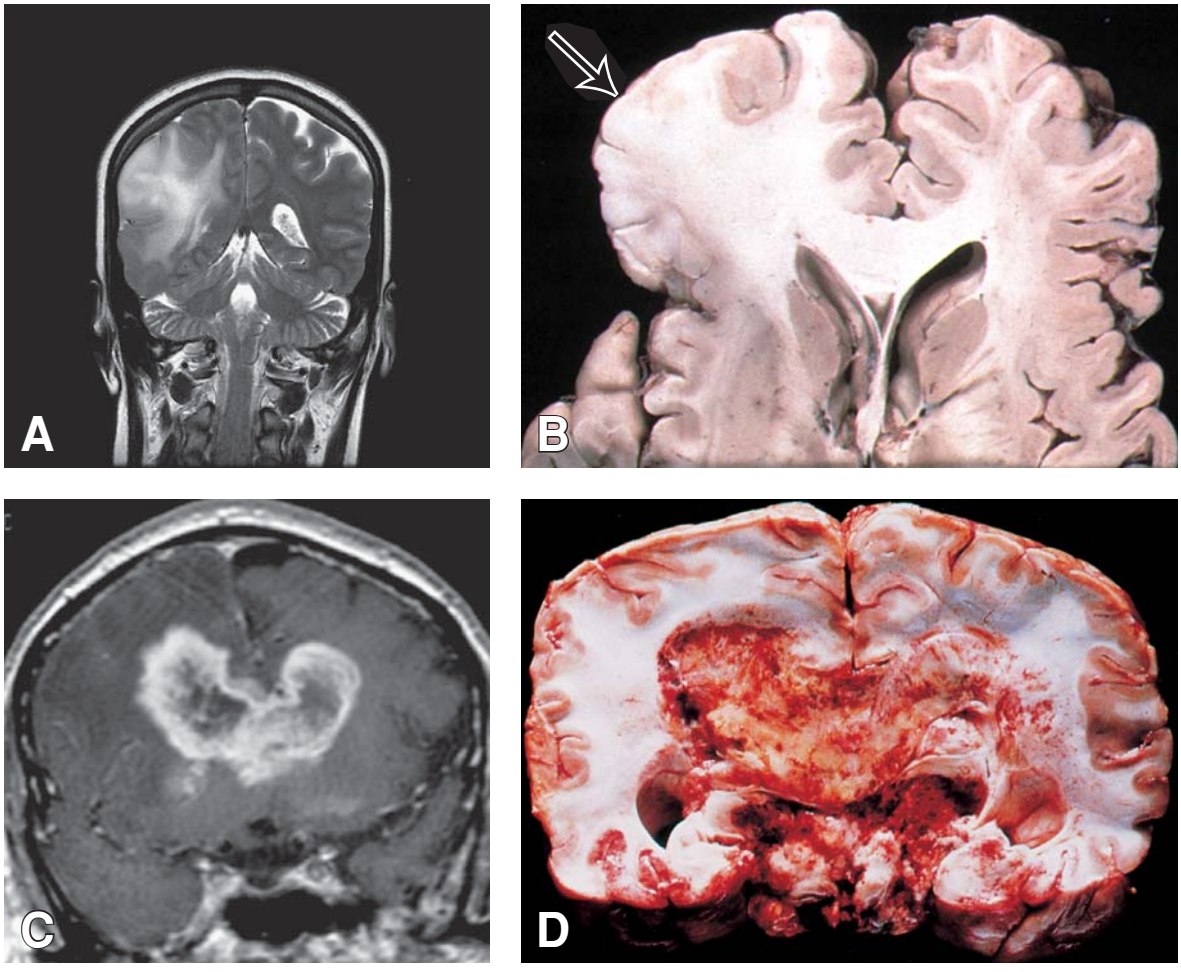

FIGURE 32-115. Gliomas. A. Infiltrating astrocytomas exhibit a diffuse, fuzzy interface with the adjacent brain tissue that is being invaded on magnetic resonance imaging. **B.** One manifestation of diffuse infiltration is "blurring" of the normally sharp interface between the gray matter and white matter as astrocytoma cells overrun the cortex, as seen (*arrow*) in this gross specimen. (Courtesy of Dr. F. Stephen Vogel, Duke University.) **C.** In contrast to low-grade diffuse astrocytomas, **glioblastomas** show prominent irregular ring contrast enhancement and often infiltrate across the corpus callosum to involve the contralateral hemisphere ("butterfly" glioblastoma), as seen in this preoperative magnetic resonance image. **D.** Autopsy gross specimen. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

Astrocytomas Are the Most Common Primary Brain Tumors

They can be divided into two major categories based on how diffusely they infiltrate the brain parenchyma. ***Diffuse astrocytomas*** infiltrate the brain widely and include low-grade fibrillary astrocytoma, anaplastic astrocytoma and the most malignant astrocytic tumor, glioblastoma. Members of the other major category of astrocytomas typically do not infiltrate the CNS but rather are slowly enlarging, compact masses that cause symptoms by compressing adjacent structures. These include pilocytic astrocytoma, pleomorphic xanthoastrocytoma and subependymal giant cell astrocytomas.

Diffuse Astrocytoma

The most salient biological characteristic of diffuse astrocytomas, as the name implies, is the ability of individual tumor cells to infiltrate widely through brain and spinal cord parenchyma (Fig. 32-115). This property reaches its extreme in **gliomatosis cerebri (WHO grade III),** in which infiltrating glioma cells (usually astrocytes but occasionally oligodendroglia) involve at least three cerebral lobes, and often more, with infiltration into both hemispheres, the brainstem, the cerebellum and even the spinal cord. Diffuse tumor infiltration of brain and spinal cord is a major reason there is little effective therapy for these tumors.

Glioblastoma typically presents as a large, ring-enhancing mass with an irregular central area of necrosis and prominent edema of surrounding white matter. The infiltrating component of glioblastomas often crosses to contralateral hemispheres via the corpus callosum; such cases are referred to as "butterfly" glioblastomas based on their appearance on coronal MRI (Fig. 32-115).

PATHOLOGY: Low-grade fibrillary astrocytomas (WHO grade II) have well-differentiated astrocytic tumor cells with little nuclear atypia or cell proliferation. Gemistocytic astrocytoma is a distinctive subtype of low-grade astrocytoma in which the main population of cells has prominent globular cytoplasm filled with glial intermediate filaments (Fig. 32-116). Despite a deceptively bland appearance, diffuse astrocytomas often undergo anaplastic progression, usually over several years, into high-grade astrocytoma (anaplastic astrocytoma, WHO grade III) and, ultimately, into glioblastoma (WHO grade IV). This tendency for anaplastic progression is even more pronounced with the gemistocytic variant. **Anaplastic astrocytoma (WHO grade III)** is more cellular than low-grade fibrillary

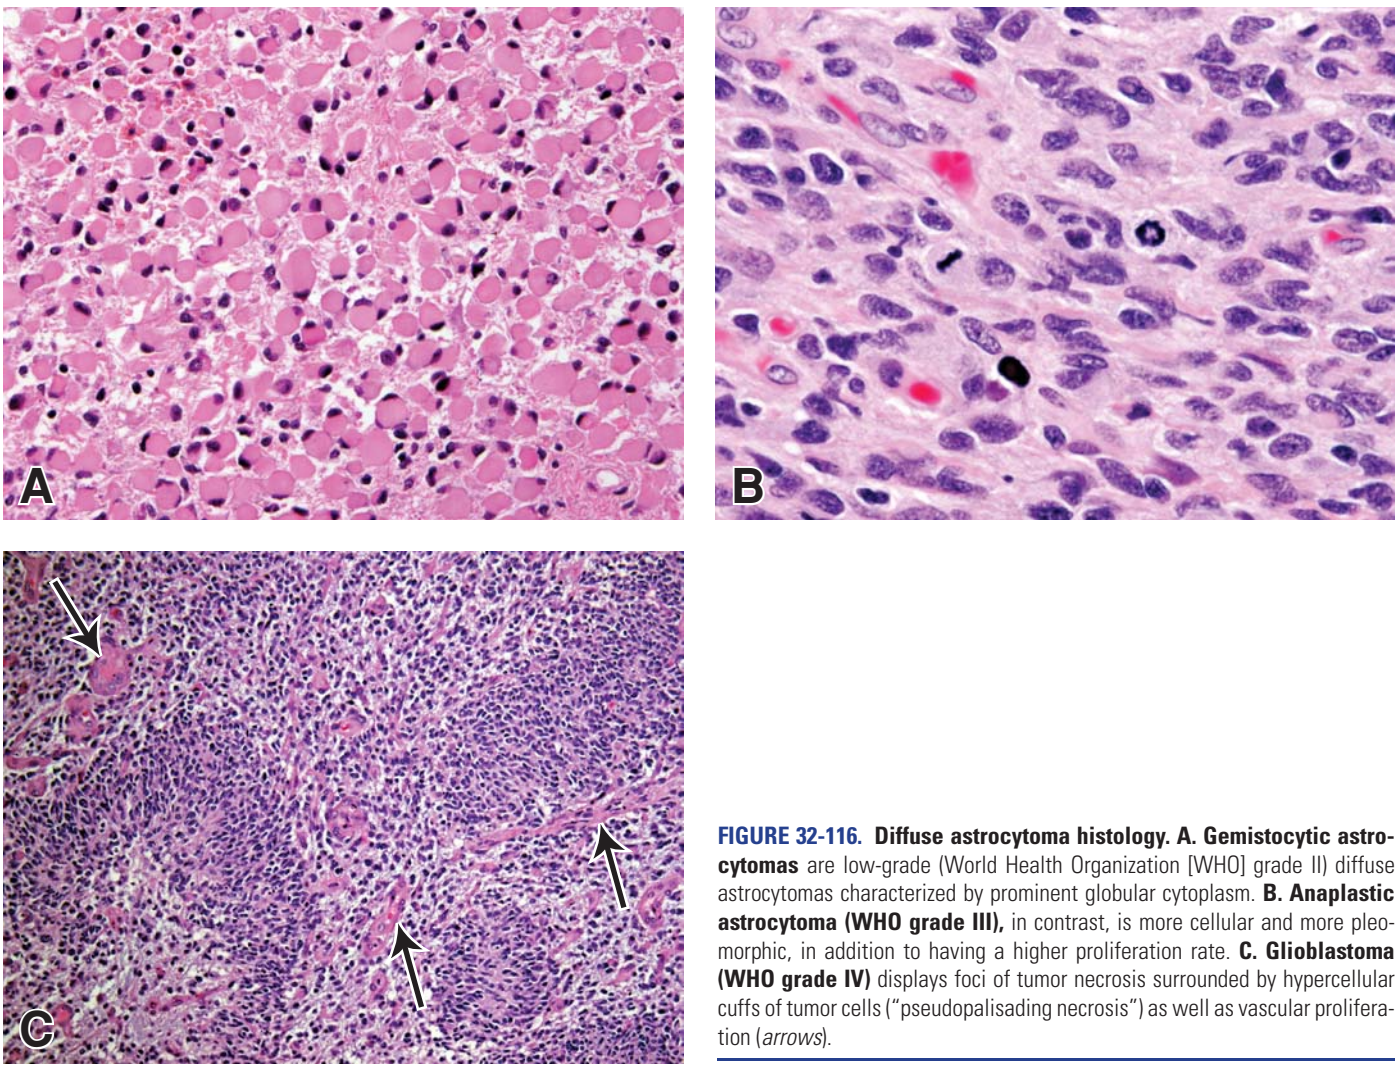

FIGURE 32-116. Diffuse astrocytoma histology. A. Gemistocytic astrocytomas are low-grade (World Health Organization [WHO] grade II) diffuse astrocytomas characterized by prominent globular cytoplasm. **B. Anaplastic astrocytoma (WHO grade III),** in contrast, is more cellular and more pleomorphic, in addition to having a higher proliferation rate. **C. Glioblastoma (WHO grade IV)** displays foci of tumor necrosis surrounded by hypercellular cuffs of tumor cells ("pseudopalisading necrosis") as well as vascular proliferation (*arrows*).

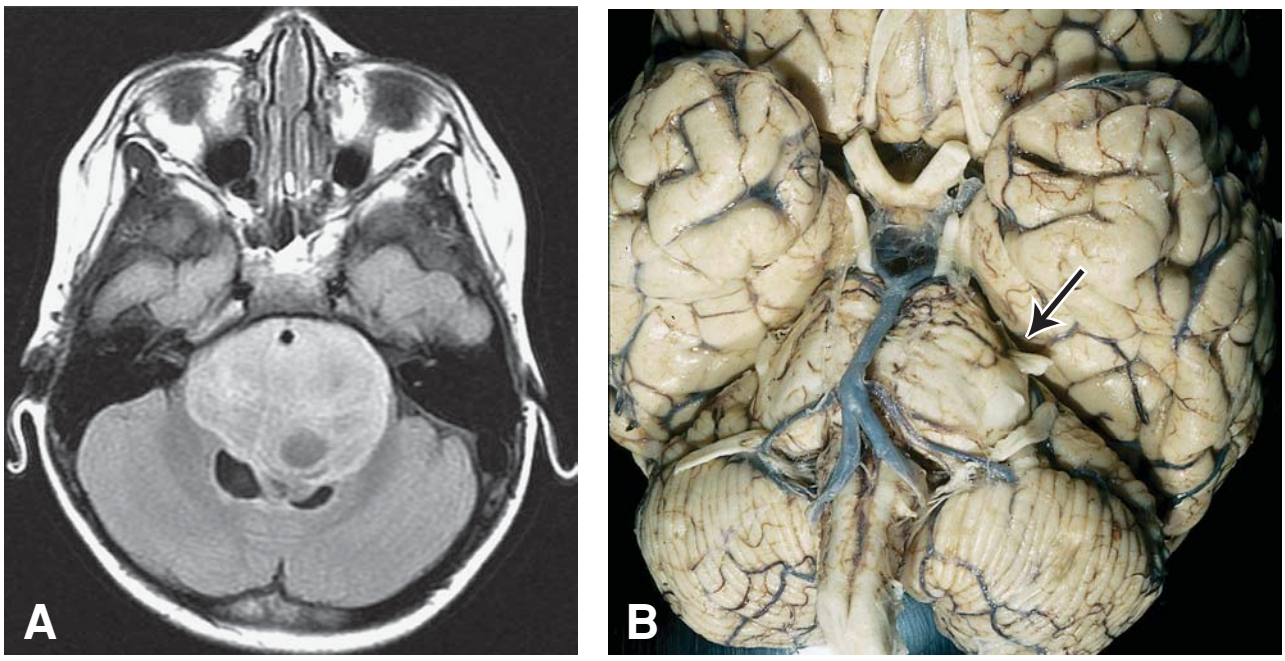

FIGURE 32-117. Diffuse pontine astrocytoma ("pontine glioma"). Diffuse astrocytomas of childhood, diffuse pontine astrocytomas infiltrate and expand the brainstem pons, often to the point of encircling the basilar artery. **A.** Magnetic resonance imaging. **B.** Autopsy gross specimen.

astrocytoma, and individual tumor cells are more pleomorphic (Fig. 32-116). Mitotic rates are elevated and mitoses are easily seen. Anaplastic astrocytomas typically progress to glioblastoma within a few years.

Glioblastoma multiforme (GBM; WHO grade IV) is the single most common primary malignant brain tumor. It accounts for about 20% of all CNS tumors. GBMs are cytologically highly pleomorphic, and constituent cells vary greatly in size and shape, with large bizarre nuclei and multinucleated cells. They may arise by anaplastic progression from lower-grade diffuse astrocytomas (secondary glioblastoma; 5% of GBMs) or, much more commonly, de novo (primary glioblastoma; 95% of GBMs). Although usually solitary, they may rarely present as two separate epicenters of enhancement within the brain. Such cases may closely mimic metastases radiologically, with biopsy providing a definitive diagnosis. Mitotic activity in GBMs is high; vascular proliferation and foci of tumor necrosis surrounded by a densely cellular cuff of tumor cells ("pseudopalisading necrosis") are characteristic (Fig. 32-116C).

Diffuse pontine astrocytoma (diffuse intrinsic pontine glioma; WHO grade II through IV) is a diffusely infiltrating astrocytoma that arises in, and expands, the pons of the brainstem of young children (Fig. 32-117). MRI plus clinical features are so distinctive that treatment is usually initiated without biopsy confirmation of the diagnosis. Their grade varies from II to IV, but despite aggressive treatment all cases are ultimately lethal, with infiltration and compromise of vital brainstem structures.

MOLECULAR PATHOGENESIS: *The vast majority of GBMs are sporadic,* but a minority arise in the setting of a genetic tumor predisposition syndrome (Table 32-8). Sporadic GBMs may arise de novo or via anaplastic progression from lower-grade astrocytoma (see above). Molecular characterization reveals differences in the mutations seen in these two major classes. Primary GBMs show amplification of the epidermal growth factor receptor (*EGFR*) gene and mutation of the *PTEN* gene more often, but *TP53* is more often mutated in secondary GBMs. More recent molecular and genomic profiling studies have identified mutation of the isocitrate-dehydrogenase genes 1 or 2 (*IDH1, IDH2*), and especially *IDH1,* as a very common signature of low-grade (grade II) and anaplastic (grade III) diffuse gliomas and also of a majority of secondary GBMs that arise from these lower-grade tumors (see Chapter 5). Primary GBMs generally do not show *IDH* mutations. Other mutations in specific molecular subsets of GBM include deletion or mutation of the *NF1* gene and amplification of the *ERBB2* gene.

Similarly, molecular insight into the basis for resistance to treatment is also beginning to be understood. GBMs can be stratified into two groups based on whether the promotor for the DNA repair gene *MGMT* is methylated, and hence inactivated, or unmethylated, and so capable of repairing damage caused by alkylating agents used in chemotherapy. Patients with *MGMT* promotor methylation (inactivation) respond significantly better to treatment. Gliomas with both IDH mutation and 1p/19q whole arm codeletion have a more favorable prognosis and response to therapy; this molecular signature is considered a favorable predictive molecular marker.

Pilocytic Astrocytoma (WHO Grade I)

Pilocytic astrocytomas (PAs) are circumscribed gliomas that typically arise in children and young adults and expand very slowly. Unlike diffuse astrocytomas, PAs do not infiltrate brain or spinal cord parenchyma diffusely and rarely progress to higher-grade tumors. Common locations include the cerebellum, brainstem, optic nerves and third ventricular region. PAs are contrast enhancing, may be associated with

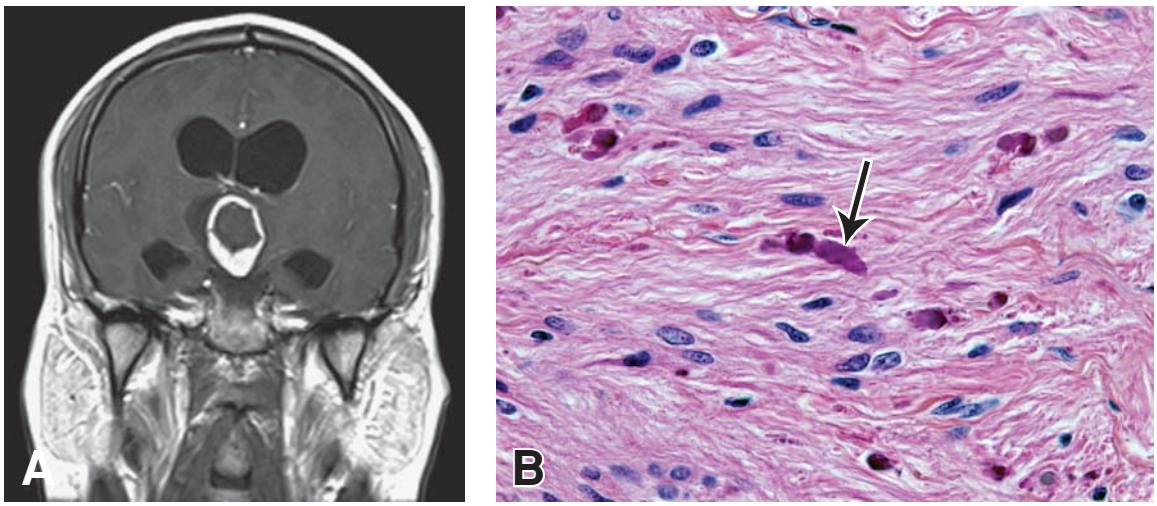

FIGURE 32-118. Pilocytic astrocytoma (World Health Organization grade I). A. Pilocytic astrocytomas are very low-grade circumscribed contrast-enhancing gliomas. **B.** Histologically, the neoplastic pilocytes ("hair cells") exhibit greatly elongated bipolar cytoplasmic processes that are prone to Rosenthal fiber formation (*arrow*).

a cystic component and are well circumscribed on preoperative imaging studies (Fig. 32-118).

PATHOLOGY: PAs consist of compact areas of tumor cells with elongated bipolar cytoplasmic processes (pilocytes) separated by prominent microcysts. The compact areas frequently have prominent **Rosenthal fibers,** a histologic hallmark of pilocytic astrocytoma. Vascular proliferation is typical and correlates with the contrast enhancement seen on preoperative MRI studies. Mitotic activity, vascular proliferation and foci of necrosis in pilocytic areas do not have the same kind of negative prognostic significance as in diffuse astrocytomas. In favorable anatomic locations, such as the cerebellum, surgical resection may be curative. **Pilomyxoid astrocytoma** (WHO grade II) is a recently recognized variant of PA, primarily arising in the hypothalamic region, that exhibits a more aggressive clinical behavior.

Pleomorphic Xanthoastrocytoma (WHO Grade II)

Pleomorphic xanthoastrocytoma (PXA) is another circumscribed astrocytoma variant of children and young adults (Fig. 32-119A). There is usually a several-year history of poorly controlled seizure activity; the temporal lobe is the most common location. In favorable anatomic locations, PXAs, like PAs, are amenable to surgical resection, but incompletely resected tumors frequently recur. About 15% of these undergo anaplastic progression to high-grade diffuse astrocytoma. Up to 66% of PXAs harbor a *BRAF* V600E mutation, which may indicate a greater tendency for progression.

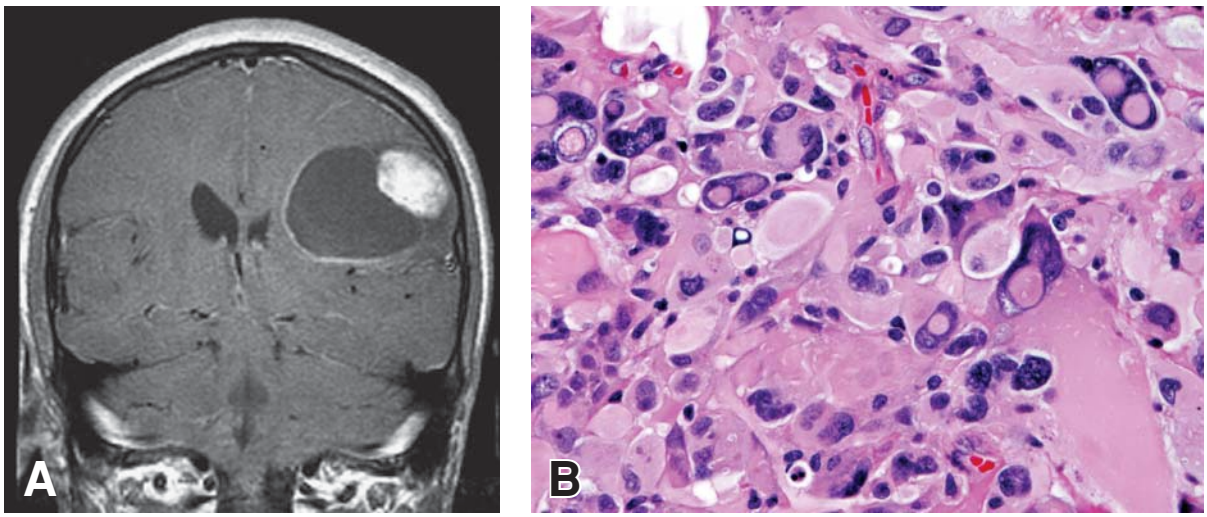

FIGURE 32-119. Pleomorphic xanthoastrocytoma (PXA). A. PXAs are low-grade (World Health Organization grade II) circumscribed astrocytomas that typically display a "cyst with enhancing mural nodule" pattern, similar to other low-grade tumors such as pilocytic astrocytoma and ganglioglioma, on imaging studies. **B.** Microscopically, PXAs superficially resemble giant cell glioblastoma, with strikingly bizarre giant cells (*B*), but pursue a much more indolent clinical course.

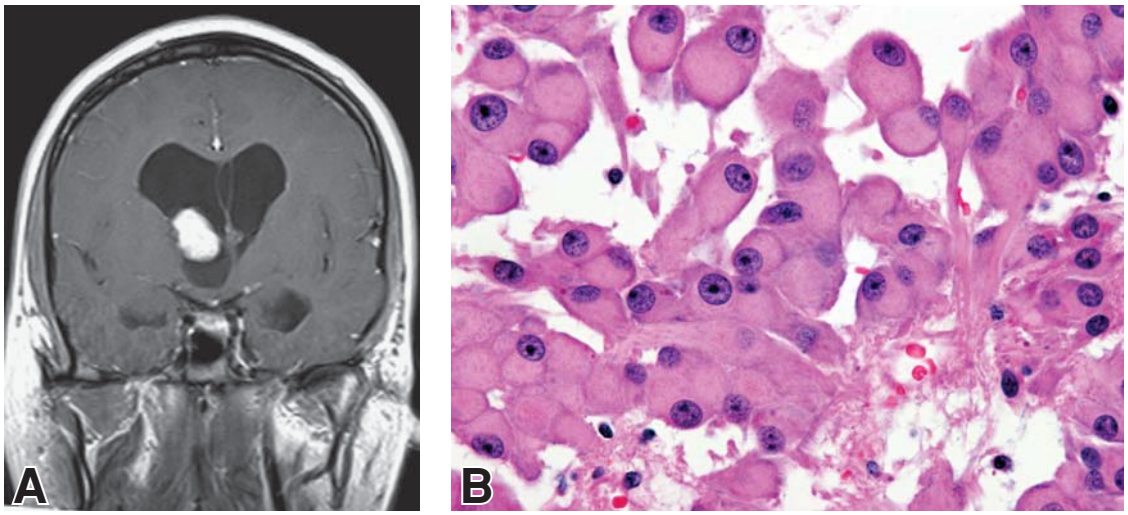

FIGURE 32-120. Subependymal giant cell astrocytoma (SEGA). A. This World Health Organization grade I astrocytoma arises within the lateral ventricle, often obstructing the interventricular foramen of Monro, resulting in obstructive hydrocephalus. **B.** Microscopically, SEGAs have globular eosinophilic cytoplasm and the nuclei often display single prominent nucleoli, thus mimicking gemistocytic astrocytoma or ganglion cell tumor. However, the anatomic location within the cerebral ventricle should preclude misdiagnosis.

PATHOLOGY: PXA mimics giant cell glioblastoma in having strikingly pleomorphic tumor cells (Fig. 32-119B). Unlike GBM, however, mitotic activity is very low, and vascular proliferation and necrosis are usually absent. The characteristic eosinophilic granular bodies, which are also seen in other low-grade circumscribed tumors such as pilocytic astrocytoma and ganglioglioma, are a strong signature of PXA.

Subependymal Giant Cell Astrocytoma (WHO Grade I)

Subependymal giant cell astrocytoma (SEGA) is a very indolent low-grade glioma that arises from the wall of the lateral ventricle. It grows slowly within the ventricular cavity until it causes obstructive hydrocephalus with the attendant signs and symptoms of increased intracranial pressure by encroaching on the interventricular foramen of Monro (Fig. 32-120A). SEGAs are densely compact mixtures of very plump epithelioid cells, often with elongated spindle cells (Fig. 32-120B). Based only on histology, SEGAs could be misconstrued as gemistocytic astrocytomas or gangliogliomas, but their intraventricular location, as readily identified by preoperative imaging and the young patient age, helps to guide diagnosis. SEGAs are associated with **tuberous sclerosis** and may be the presenting feature in a child with otherwise inconspicuous stigmata of that disease. In keeping with its WHO grade I assignment and favorable location within the lateral ventricle, surgical resection of SEGA is curative. Tuberous sclerosis entails loss of TSC1 or TSC2 inhibition of the mammalian target of rapamycin (mTOR). Thus, pharmacologic inhibitors of the mTOR pathway can shrink SEGAs and provide a medical approach in the management of these patients.

Oligodendrogliomas (WHO Grade II) Are Often More Indolent Than Diffuse Astrocytomas

Like diffuse astrocytomas, oligodendrogliomas (ODGs) are highly infiltrative. However, their response to treatment and overall survival are much more favorable than for diffuse astrocytomas of similar grade, so ODGs must be distinguished from their diffuse astrocytic cousins.

MOLECULAR PATHOGENESIS: Translocation between chromosomes 1 and 19 is a characteristic ODG molecular signature. This translocation causes complete loss of the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q). ***Combined whole arm deletion of 1p and 19q is a favorable genetic signature in diffuse gliomas and correlates closely with classic ODG morphologic features.***

PATHOLOGY: Most ODGs arise in adults in the fourth and fifth decades, largely in the white matter of cerebral hemispheres. They commonly infiltrate into overlying cerebral cortex. ODGs show a monotonous population of cells with regular round nuclei surrounded by a small rim of clear cytoplasm ("perinuclear halo" or "fried egg" appearance) like normal oligodendroglia (Fig. 32-121A). This halo is a diagnostically useful artifact of specimen processing by formalin fixation and paraffin embedding. Other characteristic features of ODGs include a network of delicate, branching blood vessels ("chicken wire" pattern) and scattered microcalcifications. In areas of cortical infiltration, ODG cells tend to cluster around neuron cell bodies (perineuronal satellitosis) and blood vessels (perivascular satellitosis). They also form an infiltrating layer just beneath the pia (subpial growth). These features, described by Scherer in 1938, are still called "secondary structures of Scherer." Mitotic activity is inconspicuous in low-grade (WHO grade II) ODG, but these tumors recur and ultimately undergo anaplastic progression.

Anaplastic Oligodendroglioma (WHO Grade III)

Anaplastic oligodendroglioma differs from WHO grade II ODG by showing increased mitotic activity and microvascular proliferation. These may sometimes be accompanied by foci of tumor necrosis (Fig. 32-121B).

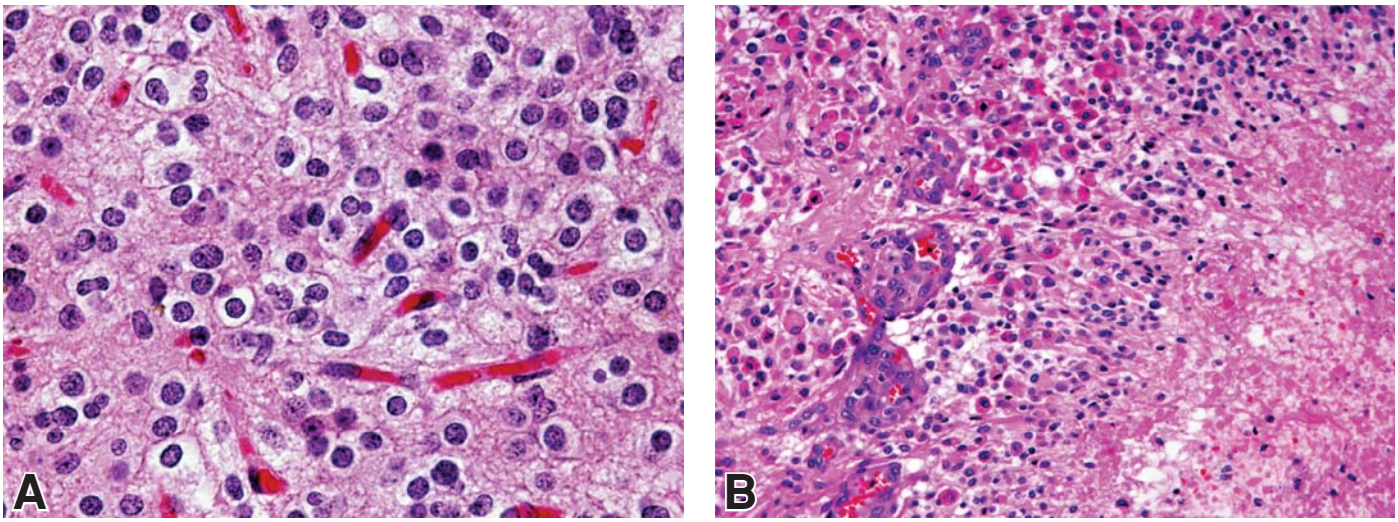

FIGURE 32-121. Oligodendroglioma. A. The cells of **low-grade oligodendroglioma** (World Health Organization grade II) closely resemble normal oligodendrocytes, with regular round nuclei surrounded by perinuclear halos. **B. Anaplastic oligodendroglioma** (AO) displays increased cellularity and brisk mitotic activity, with some tumors also developing foci of necrosis with tumor cell pseudopalisading.

Ependymomas (WHO Grade II) Derive from Ependymal Lining Cells

These are typically slow-growing tumors of children and young adults that originate in the cerebral ventricles or central canal of the spinal cord. In children, the posterior fossa fourth ventricle is the preferred location, while in adults most are in the supratentorial compartment and may arise in either the ventricle or in the cerebral hemisphere white matter. Ependymomas of the fourth ventricle tend to fill the ventricle and grow into the lateral recesses, occasionally even flowing through the lateral foramina of Luschka into the subarachnoid space (Fig. 32-122A,B). In the spinal cord, ependymomas are the most common intra-axial tumors, followed by diffuse astrocytoma.

PATHOLOGY: Ependymomas grow as relatively circumscribed masses, and so are amenable to surgical resection. Their histologic hallmark is perivascular pseudorosettes, cuffs of radiating tumor cell cytoplasmic processes around vessels (Fig. 32-122C). True ependymal rosettes, in which tumor cells surround a central lumen, can also be seen but are rarer. Ependymomas express epithelial membrane antigen (EMA; Fig. 32-122C, *inset*) and GFAP (Fig. 32-122D, *inset*). GFAP reactivity is often strongest in perivascular pseudorosettes, and—unlike the membranous pattern of EMA expression in meningiomas—ependymoma EMA positivity is characteristically in a cytoplasmic dot-like and ring-like distribution. This pattern correlates with the presence of intercellular lumina filled with microvilli and cilia, sealed by intercellular junctional complexes at the ultrastructural level. **Anaplastic ependymoma (WHO grade III)** shows increased mitotic activity and microvascular proliferation.

Myxopapillary Ependymoma (WHO Grade I)

Myxopapillary ependymomas (MPEs) are unique low-grade variants of ependymoma that arise almost exclusively in the spinal cords of adults from ependymal remnants in the conus medullaris or filum terminale (Fig. 32-123A). These tumors slowly enlarge as discrete, well-circumscribed, elongated masses in the lumbar CSF cistern. They are covered by an outer layer of investing leptomeninges. Nests and ribbons of epithelioid and spindled ependymal tumor cells are interspersed between myxoid microcysts, and perivascular cuffs of myxoid material are also prominent (Fig. 32-123B). The immunophenotype is similar to other ependymomas: they express both glial (S-100, GFAP) and epithelial markers (EMA). Because of their circumscription and favorable anatomic location in the lumbar cistern, complete surgical resection is the treatment of choice. Microscopic breach of the pial "capsule" may occur in some tumors before surgery, so that locally disseminated tumor grows around nerve roots in the cauda equina. Such cases are difficult to treat with conventional irradiation or chemotherapy, as their slow rate of growth makes them relatively resistant to cell cycle inhibitors.

Subependymoma (WHO Grade I)

Subependymomas are indolent intraventricular gliomas of adults (rare cases may arise in the spinal cord). These tumors are often small and asymptomatic and are found incidentally on imaging studies or at autopsy. Occasionally, however, they enlarge to block the interventricular foramen of Monro or fourth ventricle outlet foramina, causing obstructive hydrocephalus (Fig. 32-124A). Subependymomas show scattered clusters of small uniform glial cell nuclei separated by large zones of fibrillary matrix formed by tumor cell cytoplasmic processes (Fig. 32-124B). Surgical resection is curative.

Choroid Plexus Tumors Originate from Choroid Plexus Epithelium

Unlike other common childhood brain tumors, which favor the posterior fossa (cerebellum, fourth ventricle and brainstem), **choroid plexus papillomas (CPPs; WHO grade I)** in children most commonly arise in the lateral ventricles (Fig. 32-125A). In adults, the fourth ventricle is preferred.

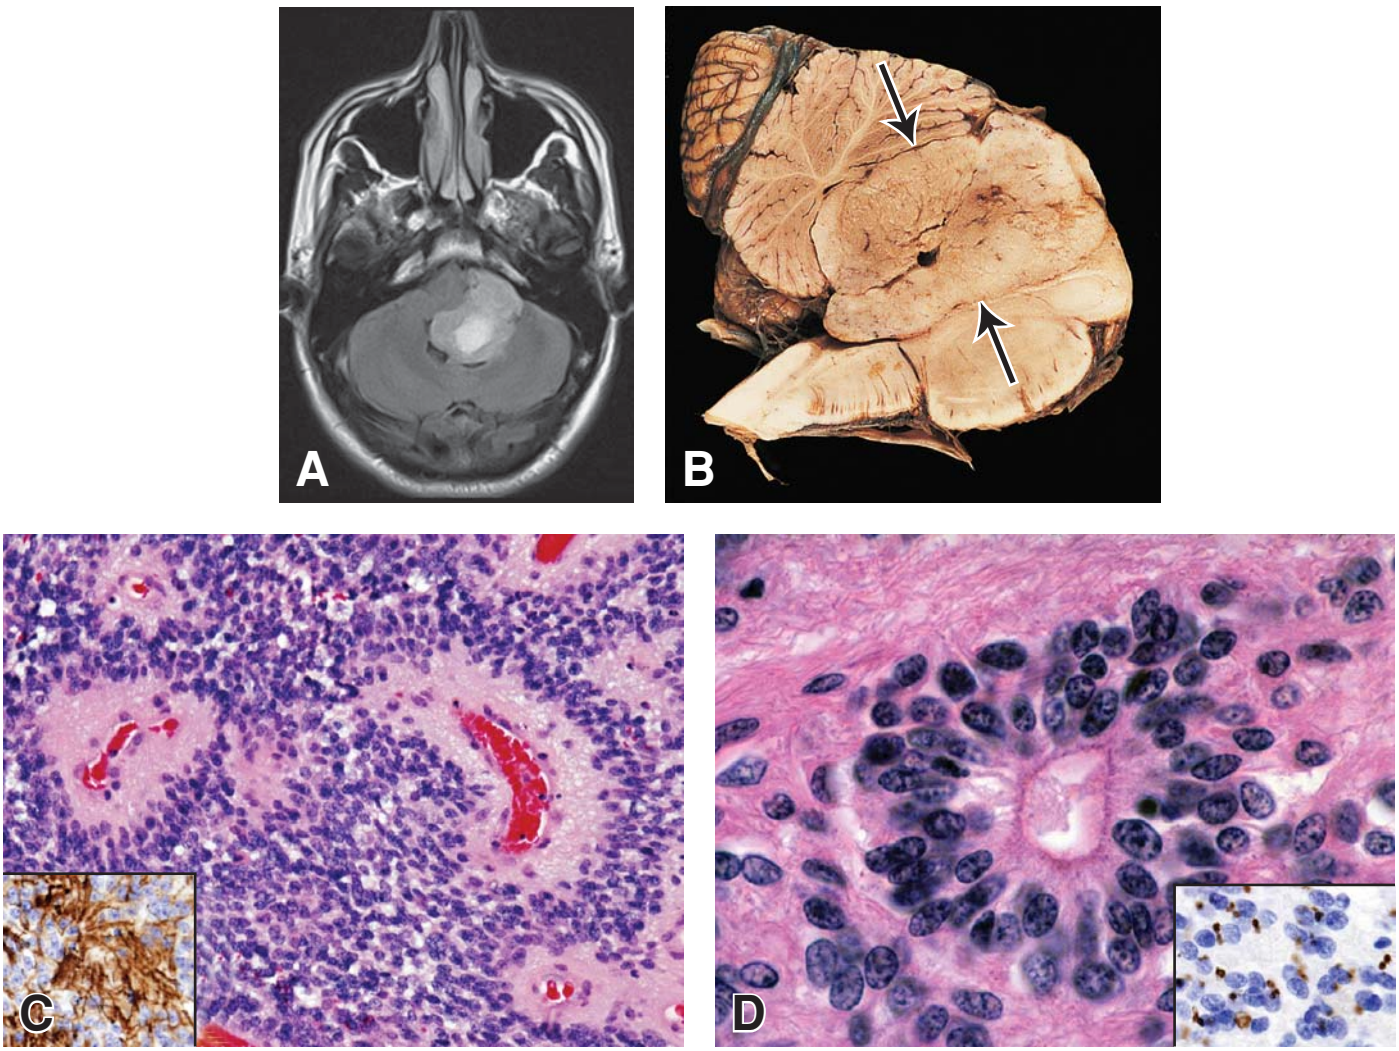

FIGURE 32-122. Ependymoma. A. Ependymomas can arise in the ventricles, the cerebral hemisphere or the spinal cord. Those located within the posterior fossa tend to grow through the ventricular outlet foramina (median foramen of Magendie and lateral foramina of Luschka) into the subarachnoid space, as seen in this magnetic resonance image. **B.** Autopsy gross specimen. Tumor is identified between the arrows. (Courtesy of Dr. F. Stephen Vogel, Duke University.) **C.** Microscopically, the hallmark of ependymomas is the perivascular pseudorosette. The immunophenotype of ependymoma includes dot-like and ring-like positivity for epithelial membrane antigen (*inset*). **D.** Well-formed true ependymal rosette with immunoreactivity of the glial marker glial fibrillary acidic protein (*inset*).

CPPs are benign and, given their location within ventricles, are potentially curable by surgery; however, CSF dissemination can occur, significantly worsening the prognosis in such cases.

PATHOLOGY: CPP closely recapitulates the papillary architecture of normal choroid plexus, but the tumor cells tend to be more crowded together and commonly assume a columnar rather than cuboidal architecture (Fig. 32-125B). Their immunophenotype includes reactivity for glial markers (S-100, GFAP) and transthyretin (prealbumin). There are two higher-grade choroid plexus tumors: **atypical CPP (WHO grade II),** which has increased mitotic activity compared to grade I tumors, and **choroid plexus carcinoma (WHO grade III),** which show increased mitotic activity, loss of papillary architecture with a solid growth pattern and often marked nuclear atypia and cellular pleomorphism (Fig. 32-125C). The latter tumors can invade adjacent brain parenchyma and can also disseminate via the CSF.

The choroid plexus may also host several other types of neoplastic and nonneoplastic mass lesions, including "intraventricular" meningioma, metastatic carcinoma (especially renal cell carcinoma) and **xanthogranuloma** (a reactive mass lesion probably related to microhemorrhage, and showing prominent cholesterol clefts and multinucleated giant cell reaction).

Medulloblastoma and Other Primitive Neuroectodermal Tumors (WHO Grade IV) Are Largely Tumors of Children

Of the several different types of primitive neuroectodermal tumors (PNETs) recognized in the WHO classification, medulloblastoma (MB) is by far the most common. By definition, MBs arise in the cerebellum. Their peak incidence is at 7 years, but they also occur in 20–45-year-old adults. Childhood MBs commonly arise in the midline vermis, often expanding to fill the fourth ventricle (Fig. 32-126A).

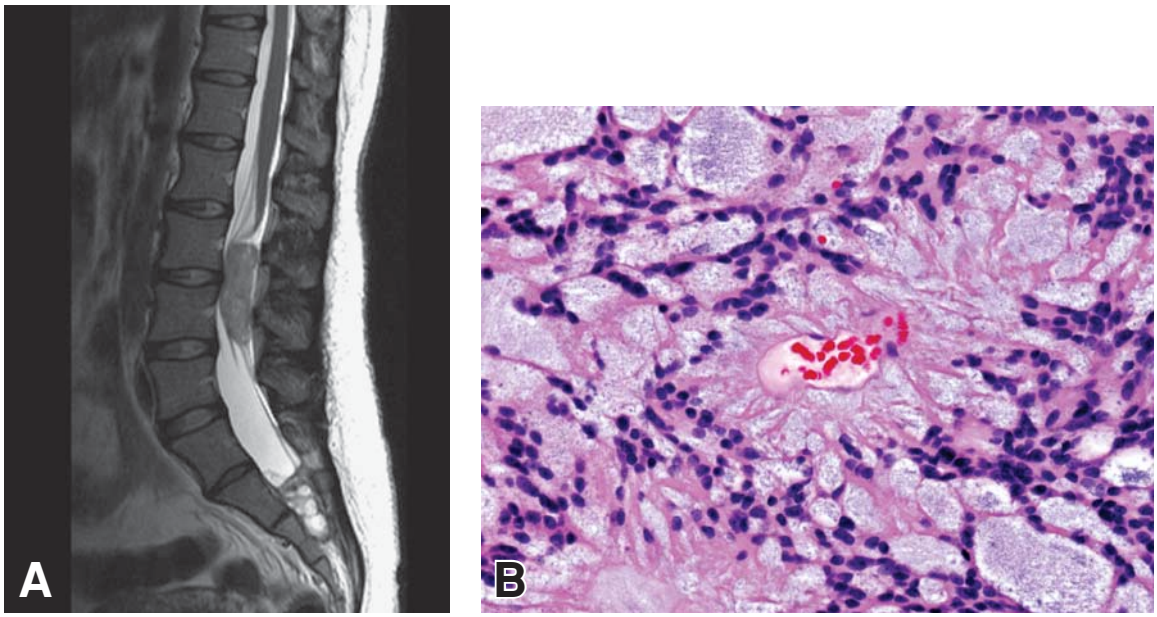

FIGURE 32-123. Myxopapillary ependymoma (MPE). A. MPEs are very low-grade (World Health Organization grade I) ependymal tumors that arise from remnants of the central canal in the spinal cord conus medullaris and filum terminale within the lumbar cistern. **B.** Histologically, prominent myxoid microcysts and perivascular myxoid cuffs separate nests and cords of ependymal cells.

The adult versions prefer the cerebellar hemispheres. There are, however, many exceptions in both children and adults. About 1/3 of patients have leptomeningeal spread, a negative prognostic factor, at the time of presentation. Only partial surgical resection, large cell or anaplastic morphology and amplification of the *MYCN* oncogene all portend poor prognosis.

CLINICAL FEATURES: In addition to the common classic subtype, there are 4 recognized MB variants. Two of these, desmoplastic/nodular MB and MB with extensive nodularity, have better prognoses than does the classic subtype; the remaining two variants, anaplastic and large cell, are the most aggressive varieties and have a worse prognosis. CSF dissemination is common and may be a presenting feature of the tumor. MBs sometimes metastasize to regional lymph nodes, lungs or bone and may disseminate, if provided the opportunity, via ventriculoperitoneal shunts.

PATHOLOGY: MBs are composed of sheets of densely packed malignant small cells with a high nucleus:cytoplasm ratio (Fig. 32-126B). Neuroblastic (Homer Wright–type) rosettes are present in 40% of cases. Mitotic activity is high. Desmoplastic/nodular MB superficially resembles lymph node tissue, with reticulin-free

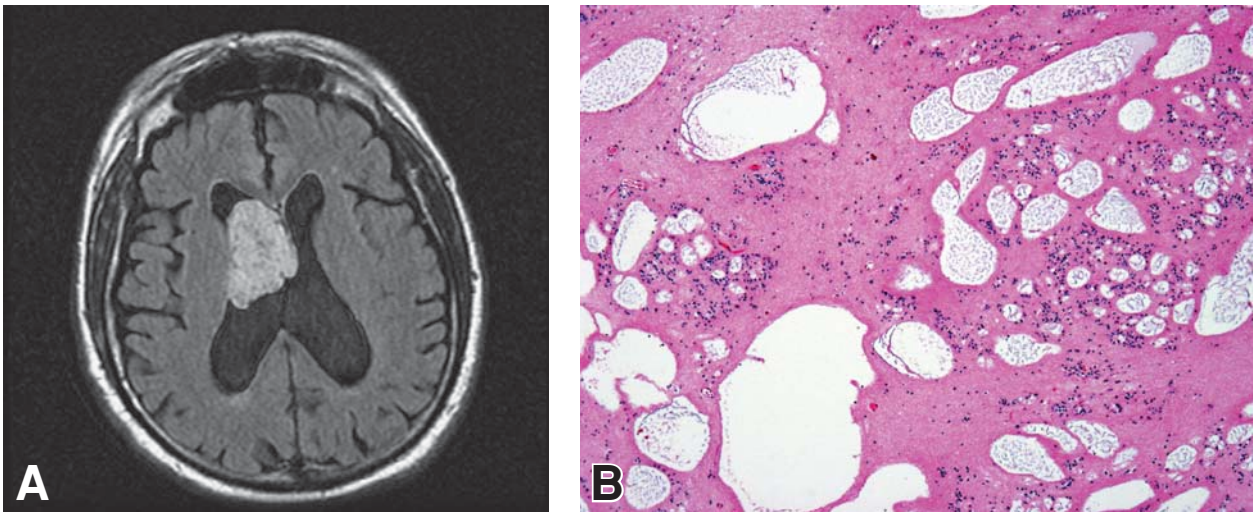

FIGURE 32-124. Subependymoma (SE). A. SE is another very low-grade (World Health Organization grade I) ependymal tumor that arises within the cerebral ventricle (shown in this magnetic resonance imaging scan) or very rarely within the spinal cord (not shown). **B.** Microscopically, SE consists of clusters of small, bland glial nuclei embedded within an abundant finely fibrillar matrix composed of tumor cell processes. Those examples located in the lateral ventricles tend to undergo microcystic degeneration as they enlarge.

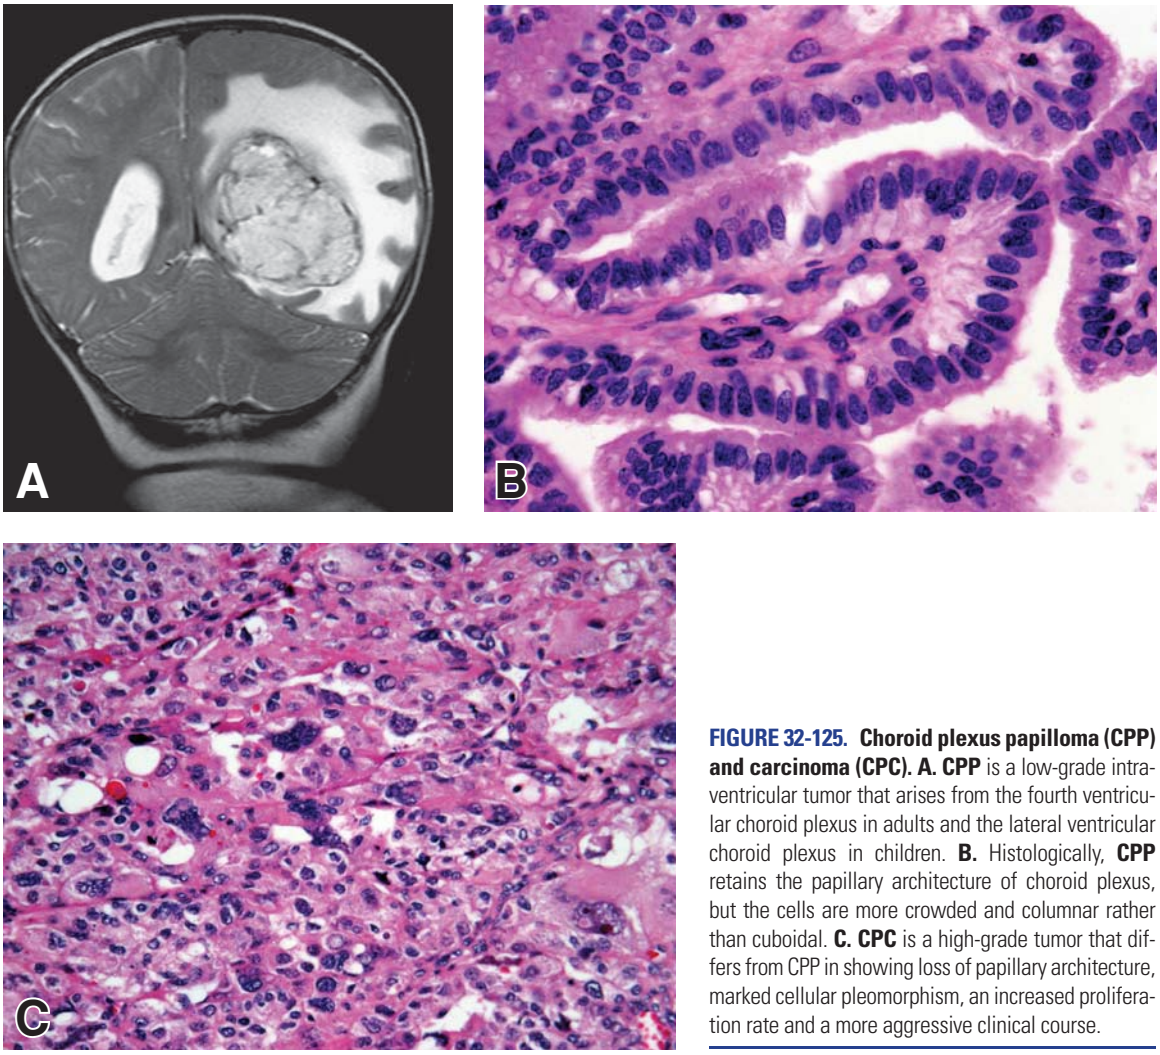

FIGURE 32-125. Choroid plexus papilloma (CPP) and carcinoma (CPC). A. CPP is a low-grade intraventricular tumor that arises from the fourth ventricular choroid plexus in adults and the lateral ventricular choroid plexus in children. **B.** Histologically, **CPP** retains the papillary architecture of choroid plexus, but the cells are more crowded and columnar rather than cuboidal. **C. CPC** is a high-grade tumor that differs from CPP in showing loss of papillary architecture, marked cellular pleomorphism, an increased proliferation rate and a more aggressive clinical course.

neurocytic islands ("pale islands") looking like germinal centers (Fig. 32-126C,D). This variant arises mainly in the cerebellar hemispheres of adults. The closely related MB with extensive nodularity is a tumor of infancy and has a distinctive multinodular appearance on imaging, as well as histologically.

Anaplastic MB and large cell MB are aggressive variants with overlapping morphologies (Fig. 32-126E). The former shows marked nuclear pleomorphism, nuclear molding and cell–cell wrapping. In contrast, the large cell variant has a monomorphous population of large cells whose nuclei have prominent nucleoli. Both variants have high proliferative rates and abundant apoptosis. Most MBs show neuronal differentiation, in the form of immunoreactivity for synaptophysin; some also express GFAP, like glial cells. Rare cases show differentiation toward myocytes or melanocytes.

MOLECULAR PATHOGENESIS: MB is thought to arise from stem cells of the fetal external granular layer and/or the periventricular germinal matrix. Molecular studies have implicated the *Wnt* and *sonic hedgehog (SHH)* signaling in tumor genesis. Differential activation of these pathways likely determines the MB subclass: the SHH pathway underlies desmoplastic/nodular MB and MB with extensive nodularity variants. The Wnt pathway favors the classic and anaplastic/large cell variants.

Atypical Teratoid/Rhabdoid Tumor (WHO Grade IV) Shows Multilineage Differentiation

Atypical teratoid/rhabdoid tumor (ATRT) is a malignant tumor of early childhood with divergent differentiation along rhabdoid, epithelial, mesenchymal, neuronal and glial lines. The posterior fossa is most affected (75%), followed by the supratentorial compartment (25%). Rhabdoid cells, with eccentrically located nuclei and eosinophilic globular cytoplasm, rarely may compose the entire tumor (referred to as "CNS rhabdoid tumor") but most often are one component of a heterogeneous malignancy (Fig. 32-127). ***Inactivation of the INI-1 (hSNF5/SMARCB1) tumor suppressor gene through mutation or deletion is the molecular hallmark of ATRT*** and is detected as loss of immunostaining for INI1 protein (Fig. 32-127). Renal rhabdoid tumors (see Chapter 22) share the same genetic alteration as ATRT. Germline *INI1* mutations result in **rhabdoid tumor predisposition syndrome,** with CNS and systemic rhabdoid tumors in infancy.

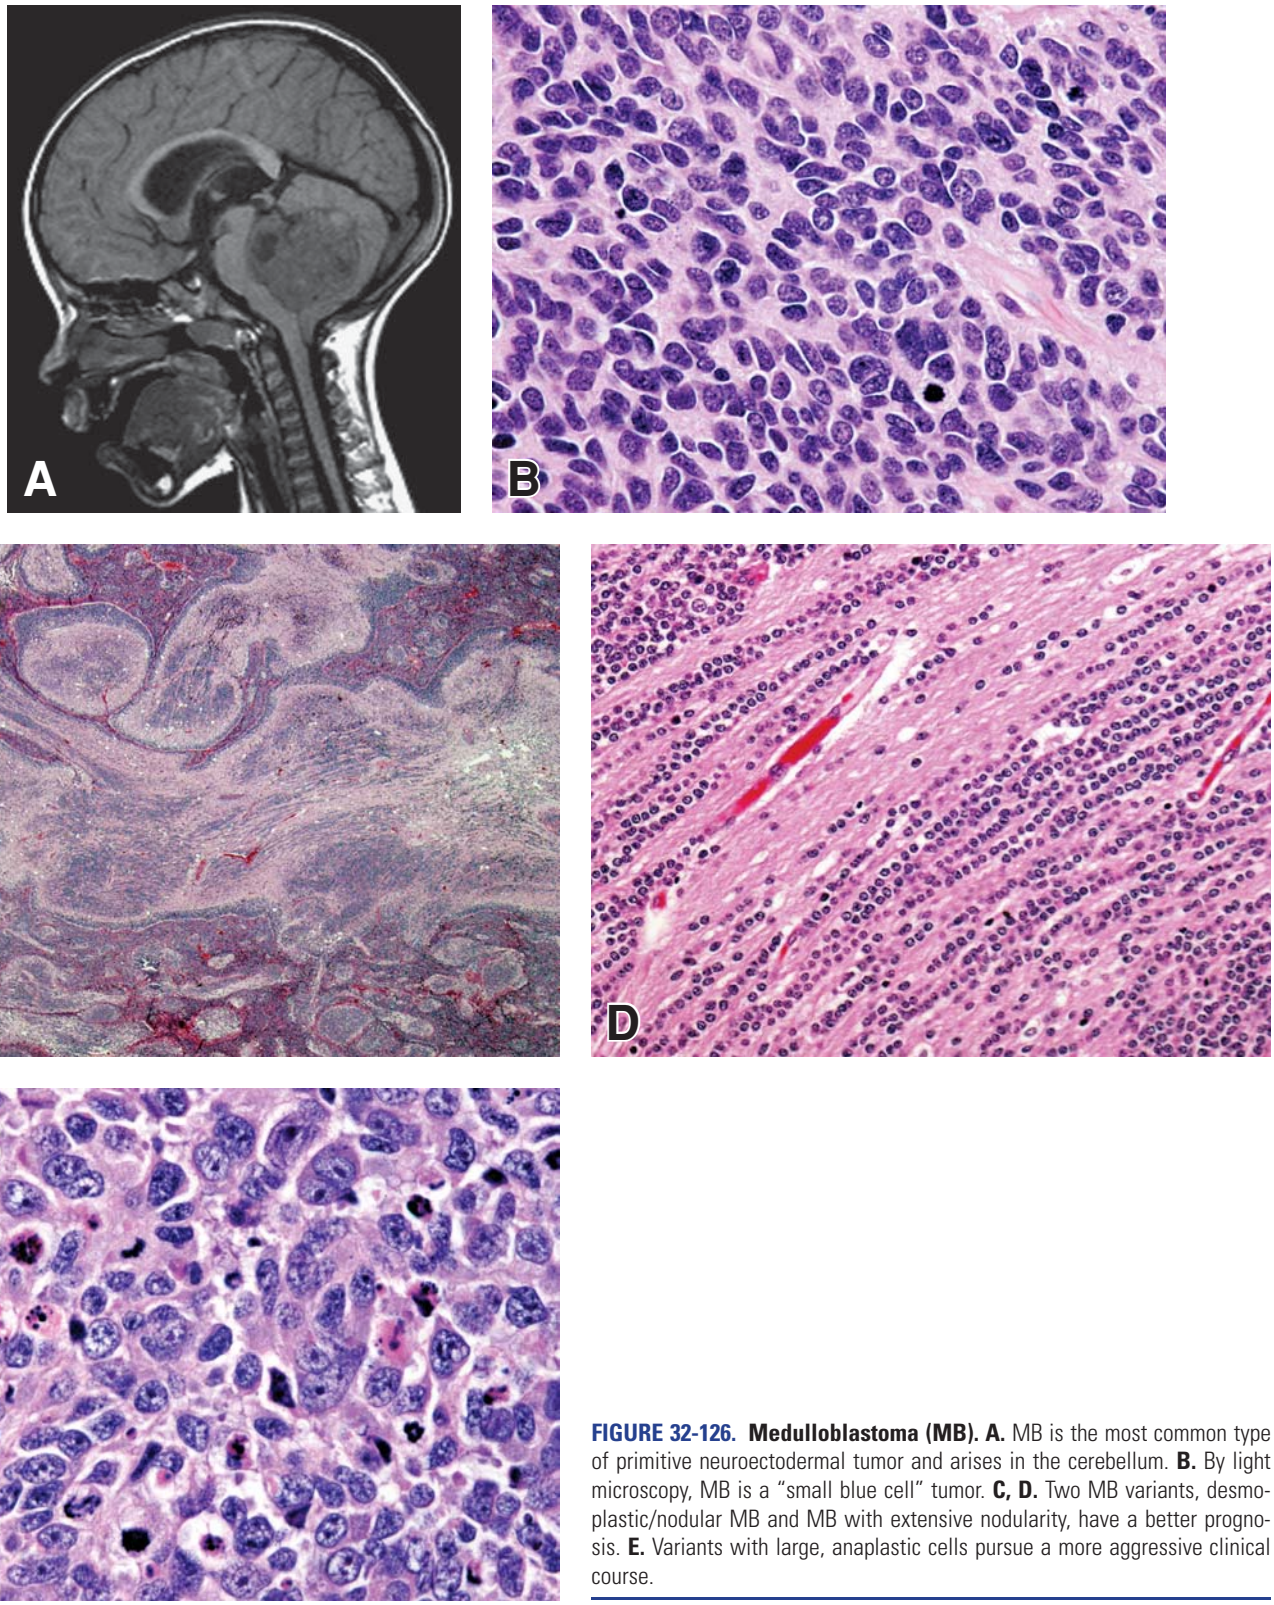

FIGURE 32-126. Medulloblastoma (MB). A. MB is the most common type of primitive neuroectodermal tumor and arises in the cerebellum. **B.** By light microscopy, MB is a "small blue cell" tumor. **C, D.** Two MB variants, desmoplastic/nodular MB and MB with extensive nodularity, have a better prognosis. **E.** Variants with large, anaplastic cells pursue a more aggressive clinical course.

Craniopharyngiomas (WHO Grade I) Arise in the Sella Turcica and Suprasellar Region

Craniopharyngioma (CP) is a circumscribed epithelial tumor, presumptively derived from Rathke cleft remnants. It arises mainly in children but also occurs in adults. These tumors typically show complex heterogeneous solid and cystic areas on imaging (Fig. 32-128A). Given the origin and expansile growth in the sellar/suprasellar region, CPs typically present with mixed endocrine and visual disturbances, due to compression of the pituitary below and optic chiasm above. Surgical resection is the preferred

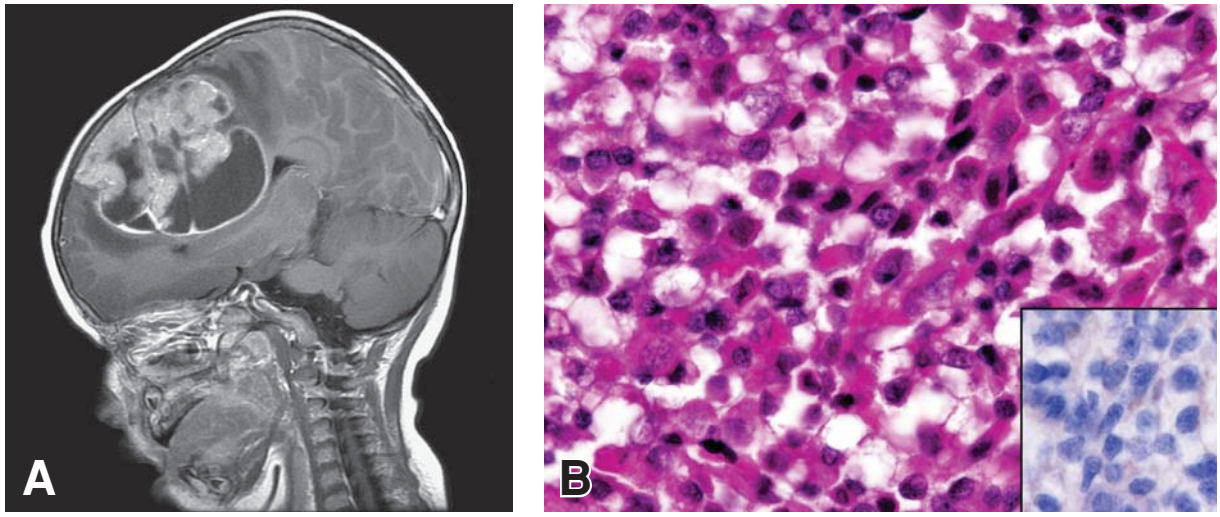

FIGURE 32-127. Atypical teratoid/rhabdoid tumor (ATRT). A. ATRT is a highly malignant neoplasm (World Health Organization grade IV) of early childhood that can arise in the cerebellum or, as illustrated here, in the cerebrum. **B.** The histologic features vary but usually include a rhabdoid cell component featuring plump hypereosinophilic cytoplasm. The molecular signature of ATRT is mutation or deletion of the *INI-1* gene, which can be detected as loss of immunostaining in tumor cell nuclei (*inset*); normal host cells, such as vascular endothelium, serve as positive internal control in this immunostain.

treatment; however, encroachment on the many vital structures in this area, including cranial nerves and blood vessels, often limits resectability, and residual tumor will recur inexorably.

PATHOLOGY: There are two morphologic subtypes: **adamantinomatous** (by far the more common), which arises in children and adults, and the rarer **papillary,** which occurs almost exclusively

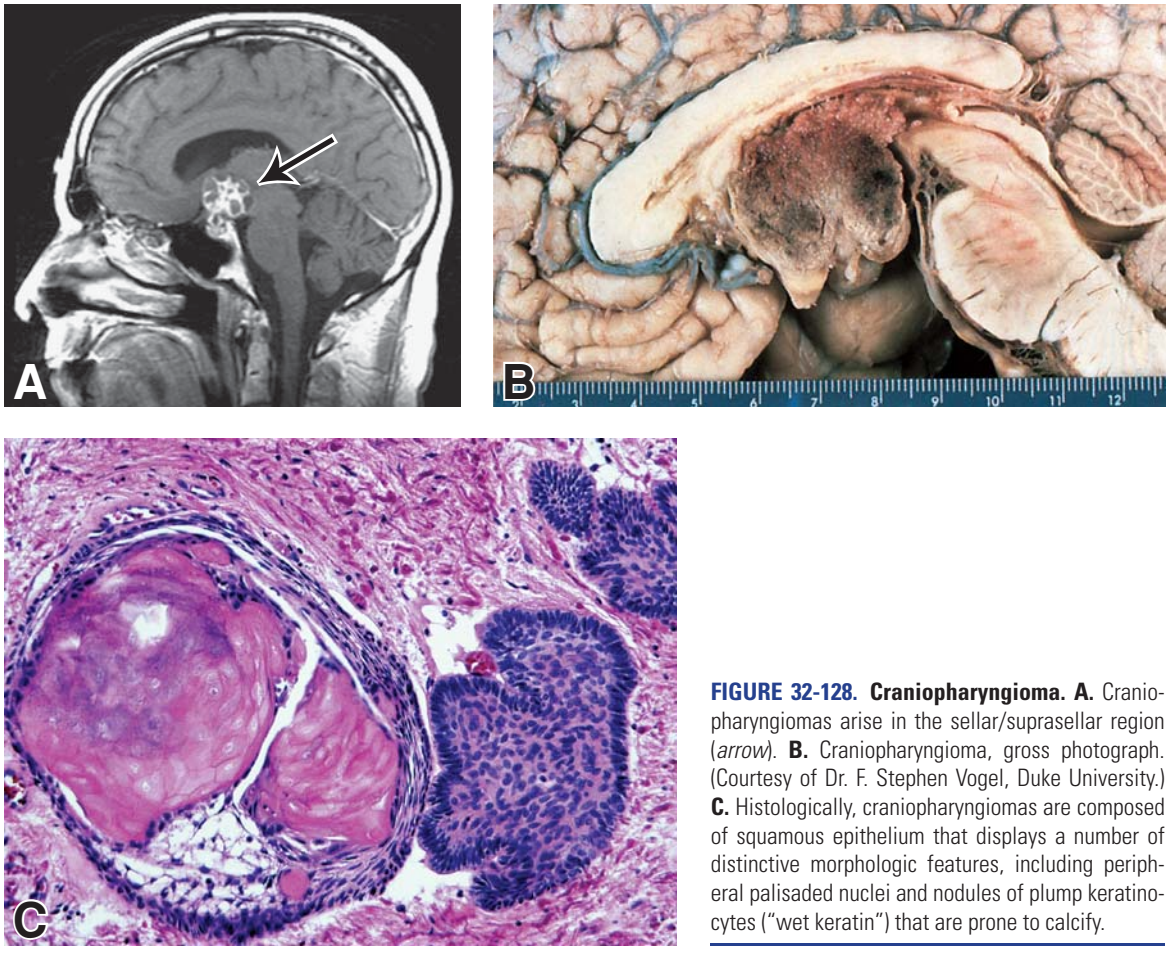

FIGURE 32-128. Craniopharyngioma. A. Craniopharyngiomas arise in the sellar/suprasellar region (*arrow*). **B.** Craniopharyngioma, gross photograph. (Courtesy of Dr. F. Stephen Vogel, Duke University.) **C.** Histologically, craniopharyngiomas are composed of squamous epithelium that displays a number of distinctive morphologic features, including peripheral palisaded nuclei and nodules of plump keratinocytes ("wet keratin") that are prone to calcify.

in adults. The former has distinctive morphology, including sheets of squamous epithelium with prominent peripheral palisading, hydropic degeneration of central areas of the epithelium ("stellate reticulum") and nodular aggregates of plump keratinocytes ("wet keratin") that tend to calcify (Fig. 32-128B). Long-standing compression of surrounding brain parenchyma may cause reactive piloid astrocytosis with prominent Rosenthal fibers. Papillary CP contains exclusively nonkeratinizing squamous epithelium. Its histologic appearance is very bland compared to the variegated morphology of the adamantinomatous subtype.

Germinoma (WHO Grade III) and Other CNS Germ Cell Tumors Often Involve the Pineal Gland

Germ cell tumors (GCTs) of the CNS most often arise in midline structures, especially the pineal gland and third ventricular region (Fig. 32-129A). **Germinomas** tend to have biphasic cell composition: large malignant cells are interspersed with swarms of small reactive lymphocytes (Fig. 32-129B). In some cases, a granulomatous response may predominate and obscure the neoplastic germ cell component. The tumors are characterized by strong immunoreactivity for OCT3/4 and c-kit, with focal positivity for placental alkaline phosphatase (PLAP) (Fig. 32-129C). In some cases, β-human chorionic gonadotropin (β-HCG) expression identifies isolated syncytiotrophoblastic cells. Pure germinomas are highly radiosensitive, and patients may receive radiation therapy, chemotherapy or a combination of both. Other germ cell tumors from the pineal region and at other CNS sites include **teratoma** (mature and immature), **yolk sac tumor, embryonal carcinoma** and **choriocarcinoma**.

After germinomas, teratomas are the most common of this group to occur as pure (nonmixed) tumors. The remaining GCTs are mostly **mixed germ cell tumors**. The prognosis for nongerminomatous GCTs is less favorable than for pure germinoma and largely depends on the extent of surgical resection.

Hemangioblastomas (WHO Grade I) Occur Most Often in the Cerebellum

Hemangioblastomas (HBs) are very vascular tumors that mainly arise in the cerebellum but may also occur in the spinal cord and brainstem, especially in von Hippel-Lindau disease. They are among a number of low-grade circumscribed CNS tumors that appear on preoperative imaging studies as cysts with enhancing mural nodules (Fig. 32-130A). They

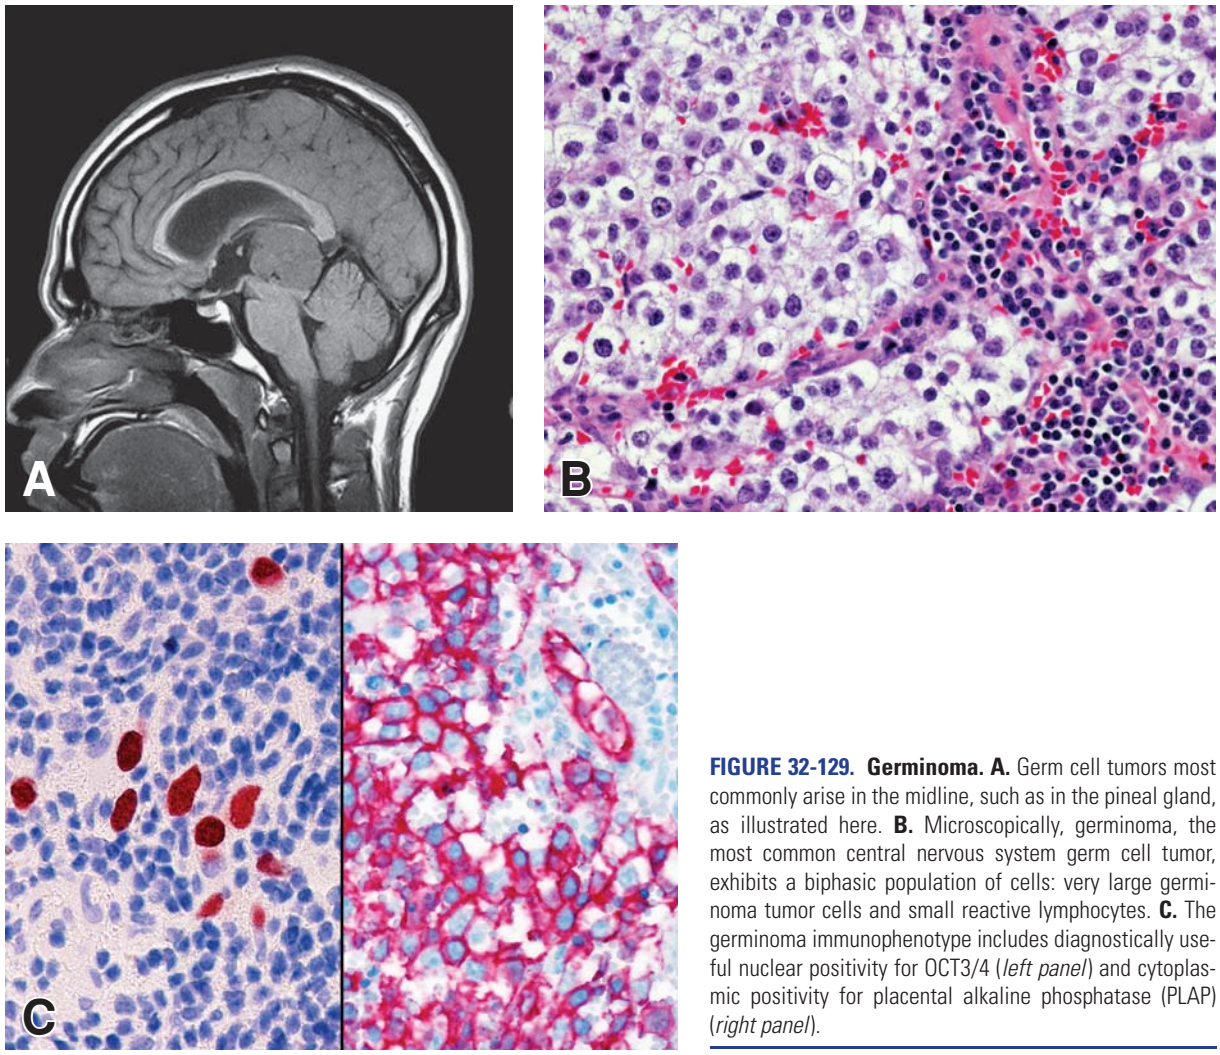

FIGURE 32-129. Germinoma. A. Germ cell tumors most commonly arise in the midline, such as in the pineal gland, as illustrated here. **B.** Microscopically, germinoma, the most common central nervous system germ cell tumor, exhibits a biphasic population of cells: very large germinoma tumor cells and small reactive lymphocytes. **C.** The germinoma immunophenotype includes diagnostically useful nuclear positivity for OCT3/4 (*left panel*) and cytoplasmic positivity for placental alkaline phosphatase (PLAP) (*right panel*).

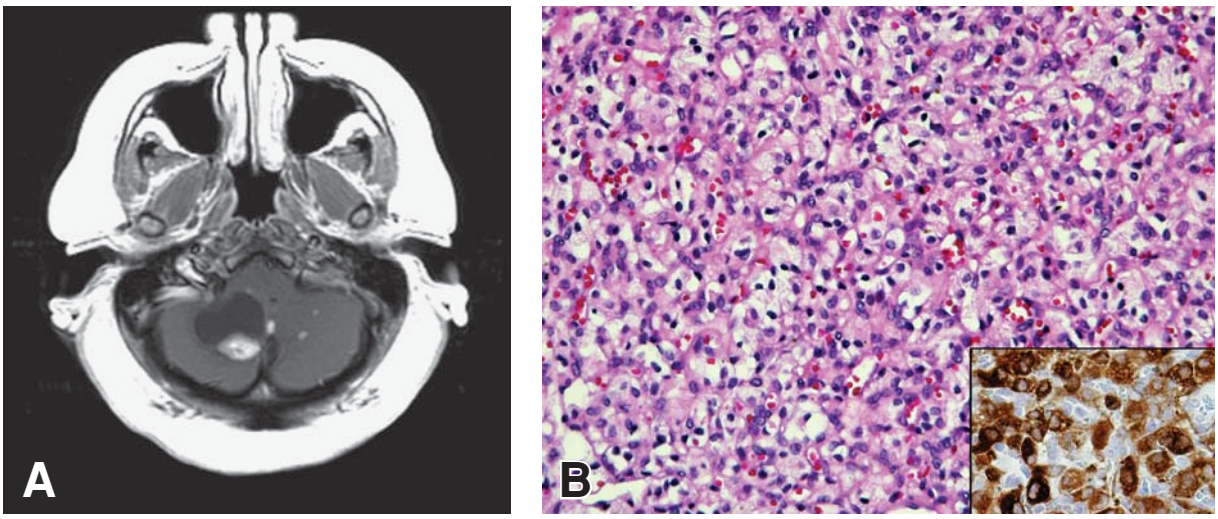

FIGURE 32-130. Hemangioblastoma (HB). A. HB most commonly arises in the cerebellum either sporadically or as part of von Hippel-Lindau disease. A common imaging presentation is as a cyst with a mural nodule. **B.** Microscopically, HB is a highly vascular neoplasm, with the neoplastic stromal cells enmeshed in a dense capillary network. The tumor cells of HB display strong cytoplasmic positivity for inhibin-α (*inset*).

usually present clinically as expanding masses in patients 20–40 years old. In 20% of cases, HBs secrete erythropoietin and induce secondary polycythemia. They can often be cured by surgical resection alone.

PATHOLOGY: HBs have vacuolated stromal cells amid a dense capillary vasculature (Fig. 32-130B). The stromal cells are the neoplastic element and are immunoreactive for inhibin-α.

Tumors That Show Only Neuronal Differentiation Are Rare

All such tumors are low grade (WHO grade I or II). **Gangliocytoma (WHO grade I)** is a very well-differentiated, circumscribed tumor composed entirely of dysmorphic mature ganglion cells. The temporal lobe is a favored location. **Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease; WHO grade I)** is a distinctive entity of the cerebellum, presenting with gross enlargement of the folia as easily seen on MRI and disorganized cerebellar cortical histology with large ganglion cells (derived from granular cell neurons). A layer of myelinated axons in the outermost molecular layer just beneath the pia is another distinctive feature. Half of patients have **Cowden syndrome** (see Chapter 5). Complete surgical resection is curative.

Central neurocytoma (CN; WHO grade II) and **extraventricular neurocytoma (WHO grade II)** are low-grade tumors of young adults that arise from the septum pellucidum, grow into the lateral ventricles and often extend into the third ventricle (Fig. 32-131A). CNs contain monomorphous round cells that look like oligodendrocytes (Fig. 32-131B) but, like neurons, strongly express synaptophysin. Extraventricular neurocytomas look and behave similarly but occur in the brain parenchyma rather than the ventricles. Surgery can be curative for small tumors, but partially resected tumors may recur, and central neurocytomas also have the potential for CSF dissemination.

Paraganglioma of the filum terminale (PFT; WHO grade I) is an uncommon neuroendocrine tumor that, like myxopapillary ependymoma, arises in the lumbar cistern from the conus medullaris or filum terminale of the spinal cord (Fig. 32-131C). Like paragangliomas elsewhere in the body, PFTs show compact acinar ("zellballen") architecture (Fig. 32-131D) and express such neuronal markers as synaptophysin and chromogranin. They often show ganglion cell differentiation. Most are "encapsulated" by an investing layer of leptomeninges and are cured by surgical excision.

Mixed Glioneuronal Tumors

Gangliogliomas (GGs; WHO grades I and III) are well-differentiated, circumscribed tumors of neoplastic ganglion cells, with a glioma component. The temporal lobe is its favored location. GGs are the most common tumors associated with chronic temporal lobe epilepsy (40% of tumor-associated temporal lobe epilepsy cases). Atypical ganglion cells are intermixed with the glioma element, usually astrocytoma. Although low grade (WHO grade I), GG can progress to **anaplastic ganglioglioma (WHO grade III)**. For either grade, prognosis depends on the extent of surgical resection.

Dysembryoplastic neuroepithelial tumors (DNETs; WHO grade I) are low-grade glioneuronal tumors arising superficially within the cerebral cortex of children (Fig. 32-132A). Their intracortical location correlates with the typical clinical history of long-standing seizures. They may also occur anteriorly in the frontal horn of the lateral ventricle, in association with the caudate nucleus and septum pellucidum. DNETs have multinodular architecture, with prominent nodular aggregates of small rounded oligodendroglial-like cells with interspersed neurons that appear to "float" within cystic spaces in the cortical parenchyma (Fig. 32-132B). These tumors resemble low-grade oligodendrogliomas but lack the latter's characteristic translocation. Foci of cortical dysplasia may occur in adjacent peritumoral cortex. Resection is curative.

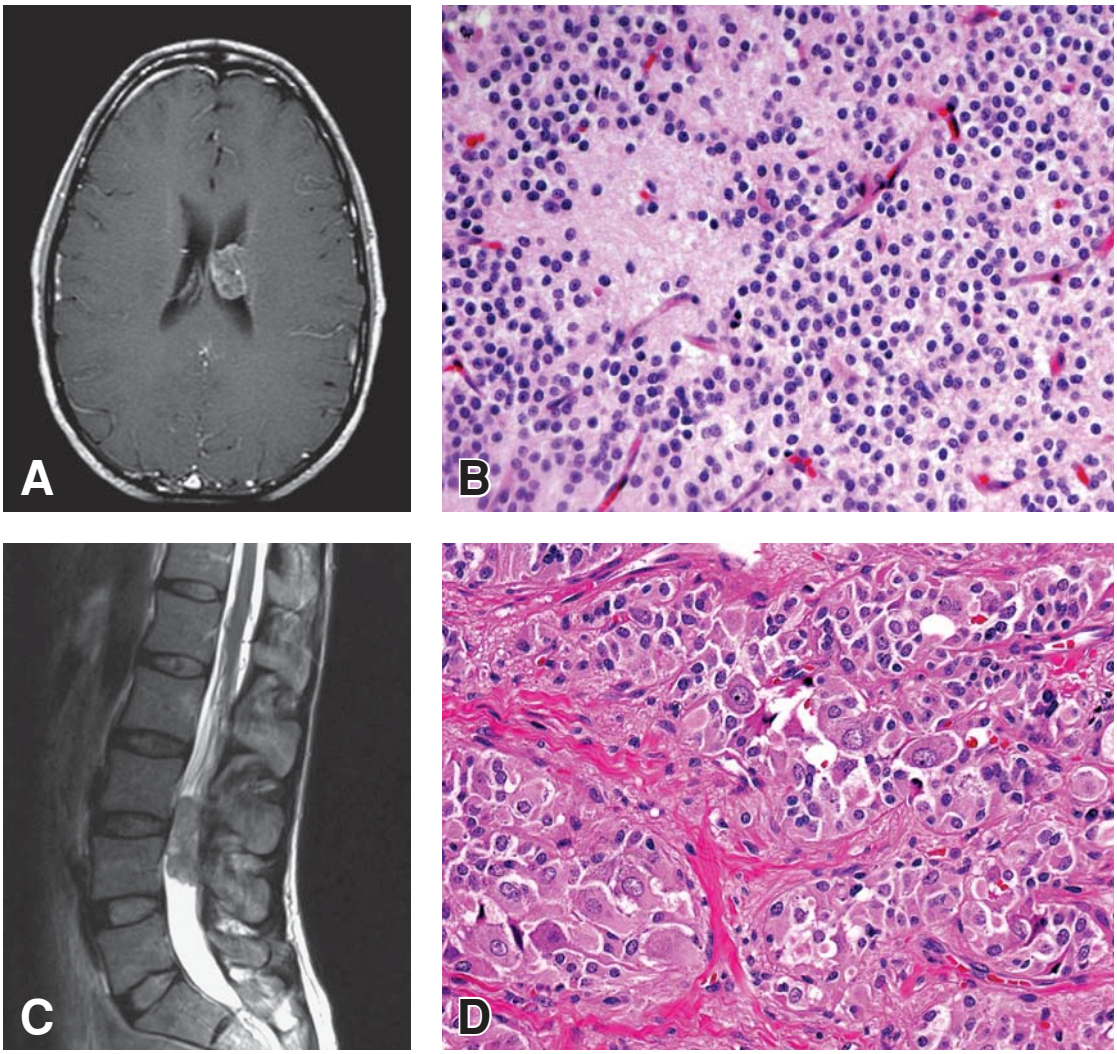

FIGURE 32-131. Neuronal and neuroendocrine tumors. A. Central nervous system neoplasms that exhibit purely neuronal/neuroendocrine differentiation are rare, and the vast majority are low grade. **Central neurocytoma** (CN) is a low-grade neuronal tumor of young adulthood that arises within the lateral ventricle. **B.** CN cells closely mimic oligodendroglioma (compare to Fig. 32-121A) but exhibit a neuronal immunophenotype, including immunoreactivity for synaptophysin. **C. Paraganglioma of the filum terminale** arises, as the name implies, from the distal spinal cord terminus within the lumbar cistern. **D.** Paraganglioma tumor cells exhibit a neuroendocrine phenotype, with strong reactivity for synaptophysin and chromogranin, and frank ganglion cell differentiation is seen in about 25% of cases.

Pineal Parenchymal Tumors Encompass a Spectrum of Clinical Behavior

Pineal parenchymal tumors (PPTs) range from the very low-grade **pineocytoma (WHO grade I)** to **pineoblastoma,** a highly malignant PNET **(WHO grade IV)**. Between these two extremes are **pineal parenchymal tumors of intermediate differentiation (PPTIDs; WHO grade II or III)**. These are discussed in Chapter 27.

Primary CNS Lymphomas Are Usually B-Cell Tumors

Systemic lymphomas often spread to the CNS, but lymphomas may also originate in the CNS. PCNSLs are tumors of adults and have increased in incidence in the last several decades in both immunocompromised and elderly immunocompetent patients. They may present with a wide variety of MRI patterns, including in superficial cortical, deep periventricular or cerebellar location, and may be solitary or multiple (Fig. 32-133A).

Definitive pathologic diagnosis is usually made by stereotactic biopsy; surgical resection does not aid survival or response to treatment. PCNSLs are composed of highly infiltrative neoplastic lymphocytes that show prominent invasion and expansion of blood vessel walls (Fig. 32-133B). The vast majority are large cell B-cell tumors and express CD20 and other B-cell markers (Fig. 32-133B). In immunocompromised individuals, PCNSL may be driven by Epstein-Barr virus, which can be detected by immunohistochemistry. They are highly sensitive to steroids, often shrinking dramatically after glucocorticoid treatment, but this response is temporary. In addition, steroid therapy can make histologic diagnosis of PCNSL extremely difficult because posttreatment biopsies may show only gliosis and reactive changes. Radiation and/or chemotherapy give a median survival of

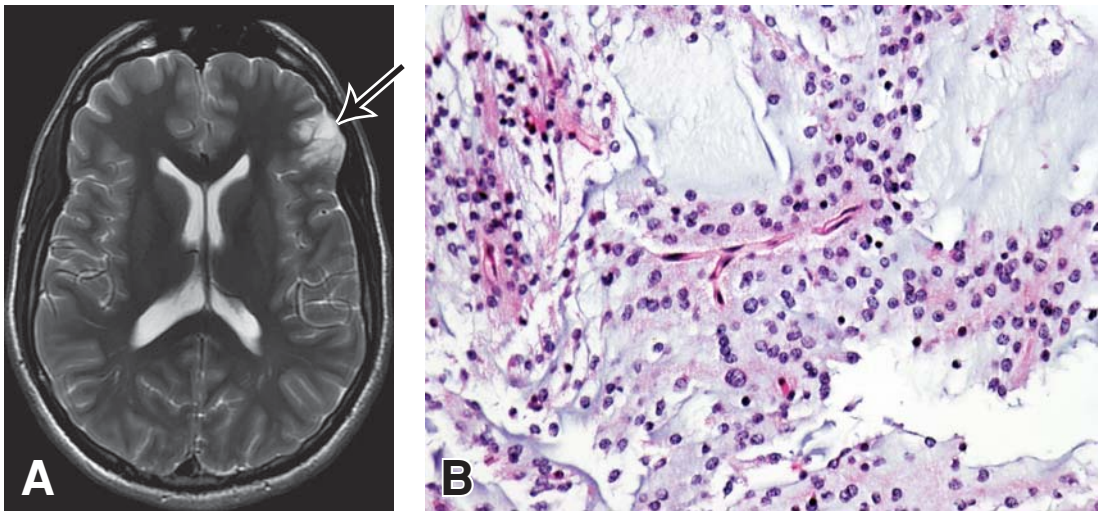

FIGURE 32-132. Dysembryoplastic neuroepithelial tumor (DNET). A. DNET is a very low-grade seizure-inducing neuronal tumor of childhood that arises superficially within the cerebral cortex. **B.** DNET is composed of monotonous round cells that resemble oligodendroglia (*B*) but is not infiltrative and is potentially curable through surgical resection.

70% at 2 years and up to 45% at 5 years in immunocompetent patients.

Many Different Benign (Nonneoplastic) Cysts Occur in the CNS

These are listed in Table 32-10. Some are degenerative in nature and are usually incidental findings on neuroimaging studies done for other reasons, or at autopsy. Only very rarely do they cause clinical symptoms, such as **choroid plexus cysts** and **pineal gland cysts**. Others, such as **arachnoid cysts** and **ependymal cysts,** are largely asymptomatic but may occasionally require surgical fenestration of the cyst wall to release pressure and relieve mass effects on surrounding structures. The remaining group are primarily of developmental origin and relatively often may cause mass effects that require simple surgery as definitive treatment.

Diagnosis of specific cyst types depends on a combination of anatomic location and histology of the cyst wall lining. For example, three CNS cysts, **Rathke cyst, colloid cyst** and **neurenteric cyst,** share virtually identical epithelial linings (i.e., ciliated pseudostratified columnar epithelium with goblet cells) but are easily and confidently diagnosed based on anatomic location: Rathke cysts arise in the sellar/suprasellar region, colloid cysts in the roof of the third ventricle near the foramen of Monro and neurenteric cysts in the subarachnoid space anterior to the brainstem medulla or cervical spinal cord (Fig. 32-134). **Epithelial inclusion cysts** (epidermoid and dermoid cysts) are distinguished by their lining and cyst contents, with epidermoids showing only keratinizing stratified squamous epithelium and sheets of anucleate flattened squames for contents, and dermoids displaying a wall that includes dermal appendages, such as sebaceous glands and hair follicles, and contents that include not only anucleate squames but also matted hair (Fig. 32-134).

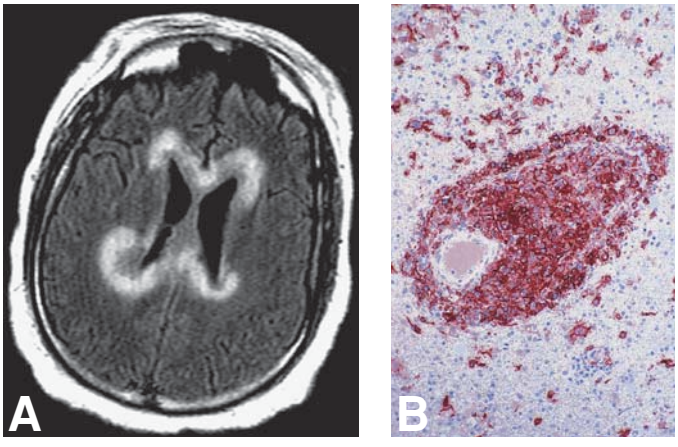

FIGURE 32-133. Primary central nervous system lymphoma (PCNSL). A. One common clinical presentation of PCNSL is as a diffuse periventricular tumor lining the lateral ventricles. **B.** The vast majority of PCNSLs are of diffuse large B-cell phenotype and thus strongly express B-cell markers such as CD20. (Courtesy of Dr. F. Stephen Vogel, Duke University.)

TABLE 32-10
CENTRAL NERVOUS SYSTEM CYSTS

Choroid plexus cyst
Pineal cyst
Epidermoid cyst
Dermoid cyst
Arachnoid cyst
Ependymal cyst
Neurenteric (enterogenous) cyst
Rathke cyst
Colloid cyst

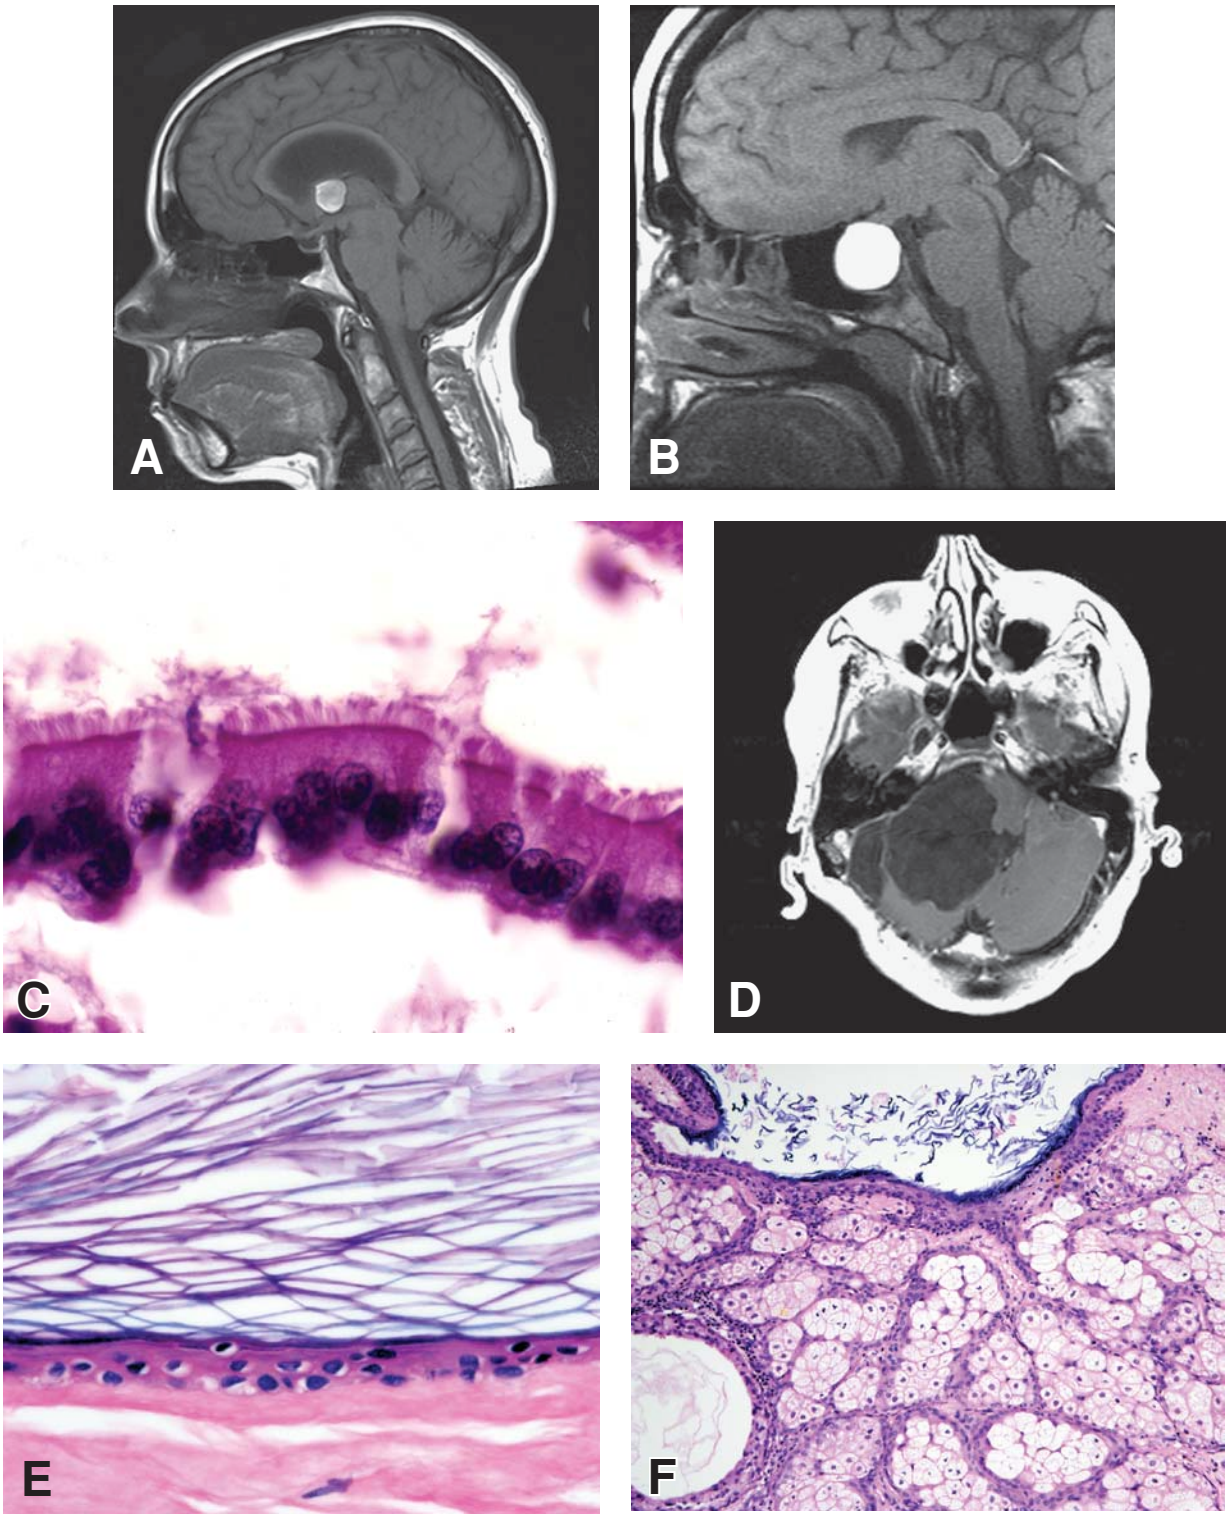

FIGURE 32-134. Cysts of the central nervous system. A. Colloid cysts arise in the rostral roof of the third ventricle. **B. Rathke cysts** are located in the sellar/suprasellar region. **C.** Both of these cysts exhibit a very similar epithelial lining, consisting of ciliated pseudostratified columnar epithelium with goblet cells. **D.** A favored anatomic site for **epidermoid cysts** is the cerebellopontine angle. **E.** Epidermoid cysts differ from dermoid cysts in that the lining of epidermoids is composed of only keratinizing squamous epithelium. **F.** Dermoids also include skin adnexal appendage structures, such as sebaceous glands and hair follicles.

The Most Common CNS Tumors Are Metastases from Elsewhere

Metastatic tumors far surpass primary CNS tumors in numbers, and malignancies metastatic to the CNS are major clinical problems. Autopsy series show that up to 25% of patients with systemic cancers have CNS metastases. The most common site for brain metastasis is at the gray–white junction of the cerebral cortex, but any CNS region may be affected, including the choroid plexus, pineal gland and pituitary gland.

The most common primary tumors to involve the CNS are lung (most frequent for both men and women), breast, melanoma, kidney and gastrointestinal tract. Over half of all metastatic disease cases involve multiple metastases (Fig. 32-135A), and metastatic patterns may reflect tumor type. For example, CNS metastases from cancers of gastrointestinal, breast, prostate and uterine origin are frequently solitary, but those from lung carcinomas and melanomas are usually multiple. A rare extreme form of multiple metastasis, called military metastasis ("carcinomatous encephalitis"), in which innumerable minute metastases shower the brain, is most common with lung adenocarcinomas. Metastases to cranial bones and vertebrae usually originate in the prostate, breast, kidney, thyroid, lung or lymphoma/leukemia (acronym: "Pb KTL"—"lead kettle") (Fig. 32-135B). Isolated dural metastases most often represent spread from breast cancers, and single metastases to the leptomeninges and subarachnoid space usually occur with lung, breast and gastric adenocarcinomas; hematopoietic tumors; and melanomas. Prostate carcinomas frequently metastasize to the skull and spine but only rarely involve the brain parenchyma. For some very common cancers, such as carcinoma of the uterine cervix, CNS metastases are extremely rare.

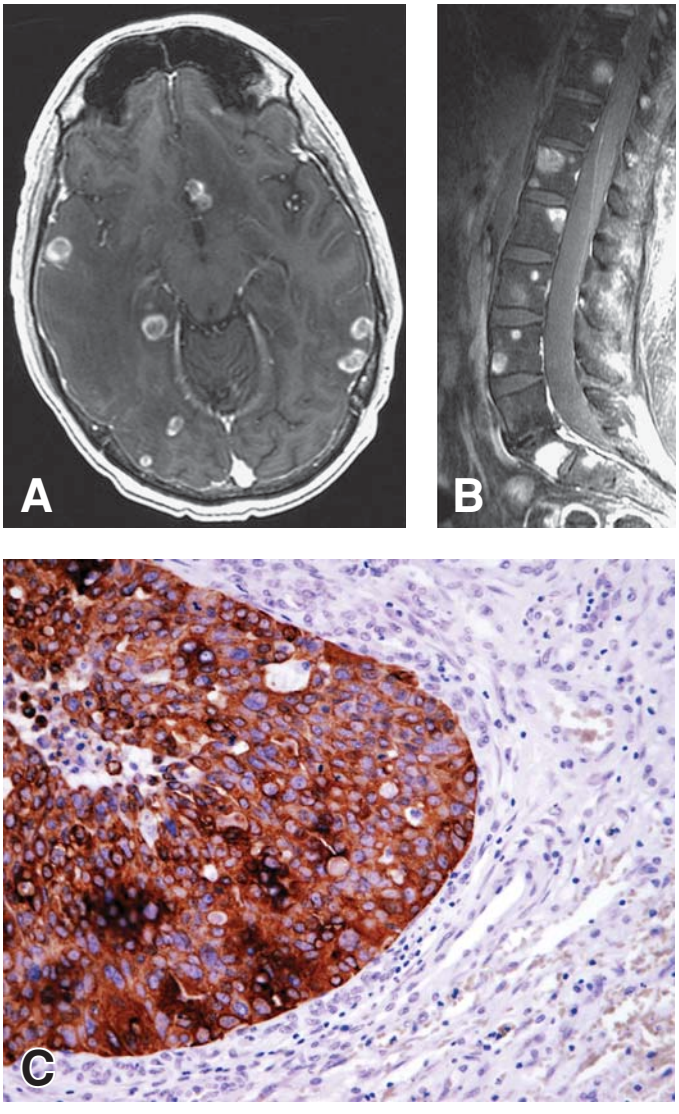

FIGURE 32-135. Metastatic disease. Metastases to the central nervous system commonly produce multiple lesions in both the brain **(A)** and spine **(B). C.** Metastatic tumor masses typically show very sharp "pushing" borders with the adjacent brain tissue, as illustrated here with metastatic carcinoma immunostained for keratin.

Injury to surrounding CNS parenchyma due to metastatic tumors entails (1) tumor growth itself; (2) attendant elicited vasogenic edema in surrounding brain tissue; (3) hemorrhage in the tumor, which can be substantial (especially with melanomas, renal cell carcinomas and choriocarcinomas); and (4) depending on the location of metastasis, obstructive hydrocephalus (e.g., when metastases to the midbrain cause occlusion of the cerebral aqueduct).

Hereditary Intracranial Neoplasms Are Often Associated with Extracranial Tumors

Several hereditary disorders associated with CNS tumors and the genetic bases of the major syndromes are listed in Table 32-8. In some, neoplasms of systemic organs are most prominent, but nervous system tumors also occur. Thus, malignant gliomas occur in Li-Fraumeni syndrome, and medulloblastomas are associated with gastrointestinal tumors in Turcot syndrome.

Tuberous Sclerosis (Bourneville Disease)

Tuberous sclerosis is an autosomal dominant disease characterized by hamartomas (tubers) of the brain, retina and viscera, as well as various neoplasms. It reflects disordered migration and arrested maturation of neuroectoderm, leading to formation of "tubers" in the cerebral cortex and of subependymal giant cell astrocytomas (Fig. 32-120). The tubers are discrete cortical areas with bizarre cells with neuronal and glial features. The subependymal giant cell astrocytomas resemble "candle drippings."

In addition to intracranial lesions, tuberous sclerosis includes (1) facial angiofibromas (adenoma sebaceum), (2) cardiac rhabdomyomas and (3) mesenchymal tumors of the kidney (angiomyolipomas). Most patients have seizures and are mentally retarded. Mutations in *TSC1* and *TSC2* are responsible: *TSC1* (9q34) encodes a protein called hamartin, and *TSC2* (16p13) encodes tuberin, which is homologous to a GTPase-activating protein. Both are tumor suppressors (see Chapter 5).

Sturge-Weber Syndrome (Encephalofacial Angiomatosis)

Sturge-Weber syndrome is a rare, nonfamilial congenital disorder characterized by angiomas of the brain and face.

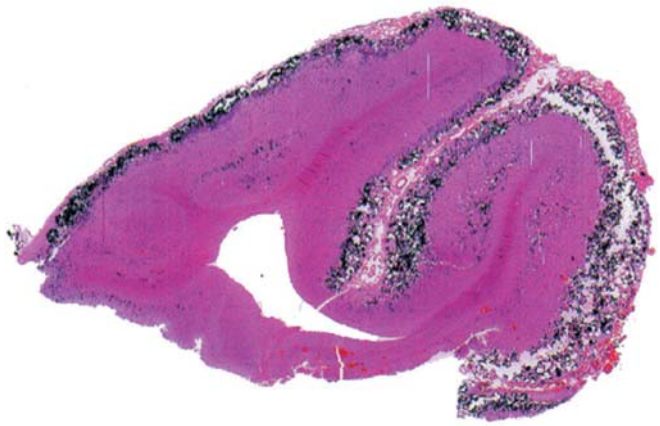

FIGURE 32-136. Sturge-Weber syndrome. Portion of cerebral cortex with overlying capillary angioma involving the leptomeninges and underlying cortical calcification (*purple*).

The facial lesion is usually unilateral and is called a **port wine stain (nevus flammeus)**. The leptomeninges contain large angiomas, which in severe cases may occupy an entire hemisphere. Cerebral calcification and atrophy often underlie the intracranial angiomas (Fig. 32-136). The link between angiomas of the face and brain may reflect the continuity of the embryologic vascular supply to the telencephalon, the eye and the overlying skin. In most instances, Sturge-Weber syndrome is associated with mental deficiency.

Paraneoplastic Syndromes Involving the Central Nervous System

AUTOIMMUNE TUMOR-ASSOCIATED SYNDROMES

Systemic benign or malignant tumors may occasionally elicit autoimmune attack on the nervous system. Paraneoplastic neurologic disorders occur when an immune response against a tumor antigen recognizes an antigen, usually a protein, on a nervous system cell **(onconeural antigens)**. Antionconeural antibodies can often be identified in a patient's serum or CSF. ***Paraneoplastic manifestations may precede clinical signs of the primary tumor,*** sometimes by years, and successful treatment of the cancer often results in resolution of the paraneoplastic syndrome associated with it.

The clinical signs and symptoms of a given syndrome depend on where the neurons that express the particular onconeural antigen are. In some cases, it is broadly expressed in neuron populations throughout the brain and spinal cord, and so results in a **diffuse encephalomyelitis**. A prominent example is the Hu antigen (see below), for which the most commonly associated cancer is small cell lung carcinoma (SCLC). In other cases, the antigen is more restricted, as in **cerebellar degeneration** resulting from immune attack against cerebellar Yo or Ri antigens, typically associated with breast or ovarian cancer, or **limbic encephalitis** targeting the Ma or Ma2 antigen, which is often associated with SCLC or testicular cancer.

Two major classes of neuron proteins are targets of paraneoplastic autoimmune attack: (1) **intracellular antigens,** such as Hu, Yo, Ri and Ma; and (2) **neuron cell surface antigens,** such as potassium channel proteins, and AMPA, GABA(B), glycine, glutamate and *N*-methyl-D-aspartic acid (NMDA) receptors. The latter exemplify the importance of clinical recognition and accurate diagnosis of paraneoplastic syndromes. Limbic encephalitis due to anti-NMDA receptor autoantibodies is potentially a lethal disease that can be completely cured by simple surgical resection of a triggering benign ovarian teratoma!

Manifestations of CNS-Directed Paraneoplastic Diseases

Limbic Encephalitis

This condition may mimic herpes encephalitis, with seizures, memory deficits and a predilection for temporal lobe involvement. Anti-Hu antibodies in SCLC are often the culprits, although other autoantibodies causing this syndrome may be associated with other tumors (e.g., testicular cancer). There are some forms involving antibodies to voltage-gated potassium channels, in which immune suppression, in addition to antineoplastic chemotherapy, may treat the CNS symptoms.

Progressive Cerebellar Degeneration

This paraneoplastic syndrome may be the presenting feature of an underlying malignancy and can be devastating. It occurs most often in association with breast cancer and, less often, Hodgkin lymphoma. Progressive cerebellar degeneration (PCD) often is caused by an antibody against a leucine zipper protein, Yo, although a number of other autoantibodies have been implicated. People afflicted with paraneoplastic PCD vary greatly in their responses to therapeutics, in part as a function of the particular autoantibody involved.

Vision Loss

Loss of sight may occur as an unusual paraneoplastic syndrome, most often caused by loss of retinal photoreceptors. SCLC is the tumor most often responsible, by virtue of eliciting an antibody against a photoreceptor antigen, recoverin.

PHYSICAL AND CHEMICAL INJURIES

Physical trauma to the eye commonly causes ecchymosis of the highly vascular eyelids (black eye); when this occurs, other parts of the eye also may be injured. Superficial disruptions of the corneal epithelium follow traumatic abrasions, prolonged wearing of a contact lens, foreign bodies on the eye and exposure to ultraviolet light. The eye is commonly injured by a variety of household and industrial caustic chemicals. The damage created depends on the nature of the chemical.

Blunt trauma increases intraorbital pressure momentarily and may cause the bones in the floor of the orbit to fracture into the maxillary sinus **(blowout fracture)**. The inferior rectus muscle may become entrapped in such a fracture, thereby causing the eye to sink into the orbit **(enophthalmos)**.

An array of foreign materials can injure the eye. Whereas small particles often lodge in superficial ocular tissues, some penetrate into or through the eye. A foreign particle may damage the eye during entry or because of secondary infection after the introduction of microorganisms. Some foreign bodies provoke a prominent acute inflammatory or granulomatous reaction. Others, such as those containing iron, cause retinal degeneration and even discoloration of ocular tissues **(siderosis bulbi)**, effects that may not be evident for several years. Other complications of ocular injuries include cataracts, retinal detachment and glaucoma.

THE EYELIDS

The important conditions affecting the eyelids include:

- **Blepharitis** is inflammation of the eyelids. It is common and sometimes produces an acute, red, tender, inflammatory mass.
- **Hordeolum (or sty)** refers to an acute, inflammatory, focal lesion of the eyelid. Acute inflammation involving the meibomian glands is termed an **internal hordeolum,** whereas acute folliculitis of the glands of Zeis is an **external hordeolum**.
- **Chalazion** is a granulomatous inflammation centered around the meibomian glands or the glands of Zeis. It is thought to represent a reaction to extruded lipid secretions and usually produces a painless swelling in the eyelid.
- **Xanthelasma** is a yellow plaque of lipid-containing macrophages, usually involving the nasal aspect of the

eyelids. It is often seen in older persons and patients with disorders of lipid metabolism (e.g., familial hypercholesterolemia, primary biliary cirrhosis).

THE ORBIT

Exophthalmos or Proptosis Is Abnormal Forward Protrusion of the Eyeball

The term **exophthalmos** is used mainly when the condition is bilateral; **proptosis** refers to a unilateral protrusion of the eye. Numerous conditions cause forward protrusion of the eye. The most common cause is thyroid disease, followed by orbital dermoid cysts and hemangiomas. Other orbital conditions can cause proptosis: various inflammatory lesions, lymphomas, developmental anomalies, vascular problems and neoplasms. Proptosis also results from lesions of the paranasal sinuses and intracranial cavity.

Exophthalmos of Hyperthyroidism Continues Despite Treatment

Exophthalmos caused by Graves disease may precede or follow other manifestations of thyroid dysfunction. Exophthalmos resulting from thyroid disease usually occurs in early adult life, especially in women (female-to-male ratio, 4:1). It may be severe and progressive, particularly in middle life, when exophthalmos no longer correlates well with the state of thyroid function. Dysthyroid exophthalmos may be associated with edema of the eyelids, chemosis (conjunctival edema) and limitation of ocular motion. Theories of the pathogenesis of hyperthyroidism-related exophthalmos are discussed in Chapter 27.

CLINICAL FEATURES: Although exophthalmos of hyperthyroidism is usually bilateral, one eye may be involved earlier or more extensively than the other. Other ocular manifestations of hyperthyroidism include upper eyelid retraction (due to increased sympathetic tone) and a characteristic stare or apparent proptosis resulting from exposure of the conjunctiva above the corneoscleral limbus.

Complications of severe exophthalmos include several potentially blinding complications: corneal exposure with subsequent ulceration, and optic nerve compression. Paradoxically, thyroidectomy may increase the incidence and severity of exophthalmos associated with hyperthyroidism.

Inflammatory Pseudotumor Is a Chronic Idiopathic Inflammatory Condition

Inflammatory pseudotumor is associated with a variable degree of fibrosis. It is a common cause of proptosis and partial immobility of the eyeball.

THE CONJUNCTIVA

Conjunctival Hemorrhage May Follow Blunt Trauma, Anoxia or Severe Coughing

Conjunctival hemorrhages also occur spontaneously, often first noted on arising after sleep. They do not extend into the cornea because of the barrier imposed by the close apposition of corneal epithelium to the underlying substantia propria.

Conjunctivitis May Be Infectious or Allergic

Microorganisms lodging on the surface of the eye frequently cause conjunctivitis, keratitis (corneal inflammation) or a corneal ulcer. The conjunctiva, as well as other parts of the eye, may also become infected by hematogenous spread from a focus of infection elsewhere. Iatrogenic eye infections (e.g., with adenovirus) may follow ophthalmic manipulations, such as corneal grafts, intraocular implantation of lens prostheses or use of infected eyedrops or diagnostic instruments.

At some stage in life, virtually everyone has viral or bacterial conjunctivitis. This extremely common eye disease is characterized by hyperemic conjunctival blood vessels (pink eye). The inflammatory exudate that accumulates in the conjunctival sac commonly crusts, causing the eyelids to stick together in the morning. The conjunctival discharge may be purulent, fibrinous, serous or hemorrhagic. Participating inflammatory cells vary with the etiologic agent. As many allergens are seasonal, the allergic conjunctivitis they elicit tends to occur only at particular times of the year.

Trachoma

Trachoma is a chronic, contagious conjunctivitis caused by *Chlamydia trachomatis.* Various serotypes of *C. trachomatis* cause ocular, genital and systemic infections (trachoma, inclusion conjunctivitis and lymphogranuloma venereum; see Chapter 9).

EPIDEMIOLOGY: About 500 million people are afflicted by trachoma, an acute, infectious, fibrosing keratoconjunctivitis caused by *C. trachomatis* (serotypes A, B and C). ***This infection is the most common cause of blindness in the world and is especially prevalent in Asia, the Middle East and parts of Africa.*** The disease has been eradicated in the United States and other developed countries. Trachoma is not very contagious, but overcrowding and poor hygienic conditions favor its transmission by fingers, fomites and flies. Spontaneous healing is common in children, but in adults, the disease progresses more rapidly and rarely heals without treatment.

ETIOLOGIC FACTORS: An inflammatory reaction is generated by the immune system in response to *C. trachomatis.* Serial persistent or repetitive inflammatory reactions to different strains of the pathogen are believed to cause the serious cicatricial complications.

PATHOLOGY: Trachoma is virtually always bilateral and involves the upper half of the conjunctiva more than the lower (Fig. 33-1). The cellular infiltrate is predominantly lymphocytic, and conjunctival lymph follicles with necrotic germinal centers are characteristic. Eventually lymphocytes and blood vessels invade the superior portion of the cornea between the epithelium and Bowman zone **(trachomatous pannus)**. Scarring of the conjunctiva and eyelids distorts the eyelids. On microscopic examination, the desquamated conjunctival epithelium

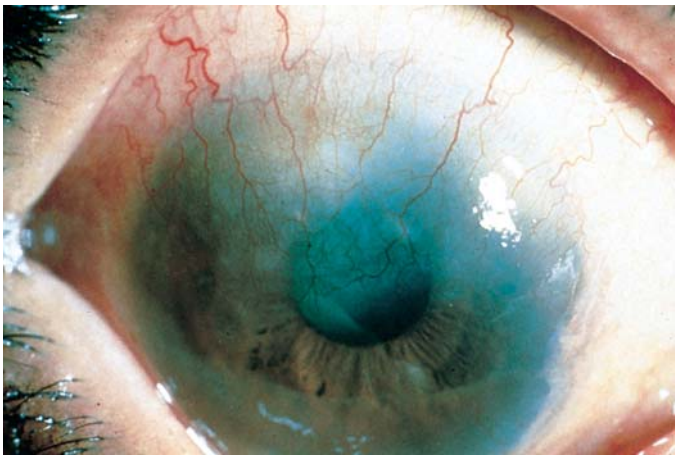

FIGURE 33-1. Trachoma. The cornea of a patient with severe trachoma shows extensive fibrovascular opacity **(pannus)** in the superior cornea.

exhibits glycogen-rich intracytoplasmic inclusion bodies and large macrophages containing nuclear fragments (Leber cells). Secondary bacterial infections occur commonly.

Other Chlamydial Infections

Chlamydia is responsible for a purulent conjunctivitis **(inclusion blennorrhea)** that develops in newborns, who become infected during passage through the birth canal. The infection is also acquired by swimming in nonchlorinated pools (swimming pool conjunctivitis) or from contact with discharges of infected urethra or cervix.

In adults and older children, *Chlamydia* causes a chronic follicular conjunctivitis with focal lymphoid hyperplasia **(inclusion conjunctivitis)**. In contrast to trachoma, the lower tarsal conjunctiva is involved. Scarring and necrosis do not develop, and keratitis is rare and mild.

Ophthalmia Neonatorum

***Ophthalmia neonatorum is a severe, acute conjunctivitis with a copious purulent discharge, especially in the newborn, caused by* Neisseria gonorrhoeae.** The infection, which is a common cause of blindness in some parts of the world, is complicated by corneal ulceration, perforation, scarring and panophthalmitis. Infants usually become infected while passing through the birth canal of an infected mother. Other causative organisms for ophthalmia neonatorum include other pyogenic bacteria and *C. trachomatis.* Today, newborns are usually routinely treated with 5% Betadine eye drops.

Pinguecula and Pterygium

Pinguecula is a yellowish conjunctival lump usually located nasal to the corneoscleral limbus. It is the most common conjunctival lump. It consists of sun-damaged connective tissue identical to that in similarly injured skin (actinic elastosis; see Chapter 28).

Pterygium is a fold of vascularized conjunctiva that grows horizontally onto the cornea in the shape of an insect wing (hence the name). It is often associated with a pinguecula and frequently recurs after excision.

THE CORNEA

Herpes Simplex Virus Causes Corneal Ulcerations

Herpes simplex virus (HSV) has a predilection for corneal epithelium, where it causes keratitis, but it can invade corneal stroma and occasionally other ocular tissues.

PRIMARY INFECTION BY HERPES SIMPLEX VIRUS TYPE 1: Subclinical or undiagnosed localized ocular lesions are caused by HSV type 1 in childhood. These infections are accompanied by regional lymphadenopathy, systemic infection and fever. Except in newborns infected during passage through an infected mother's birth canal, HSV type 2 rarely causes ocular infection. When it does, it may produce widespread lesions of the cornea and retina. Most corneal lesions due to HSV are asymptomatic plaques of diseased epithelial cells that contain replicating virus. These usually heal without ulceration, but an acute unilateral follicular conjunctivitis may occur. Corneal ulcers appear after serum antibody levels increase.

REACTIVATION OF HERPES SIMPLEX VIRUS INFECTION: Latent in the trigeminal ganglion, HSV may pass down the nerves and reactivate the infection. Unlike primary HSV infection, reactivation disease is characterized by corneal ulceration and a more severe inflammatory reaction. Recurrence of corneal ulcers due to HSV may be precipitated by ultraviolet light, trauma, menstruation, emotional and physical stress, exposure to light or sunlight, vaccination and other factors.

PATHOLOGY: HSV causes multiple, minute, discrete, intraepithelial corneal ulcers (superficial punctate keratopathy). Although some of these lesions heal, others enlarge and eventually coalesce to form linear or branching fissures (dendritic ulcers, from the Greek *dendron,* "tree"). The epithelium between the fissures desquamates, leading to sharply demarcated, irregular geographical ulcers. The corneal ulcers are readily visualized after the cornea is stained with fluorescein. Affected epithelial cells, which may become multinucleated, contain eosinophilic, intranuclear inclusion bodies (Lipschütz bodies).

The lesions of the corneal stroma vary in reactivated HSV infection. Typically, a central disc-shaped corneal opacity develops beneath the epithelium, owing to edema and minimal inflammation **(disciform keratitis)**. The corneal stroma may become markedly thinned, and the Descemet membrane may bulge into it (descemetocele). Corneal perforation can also occur.

Onchocerciasis Leads to Blindness in Tropical Regions

The nematode *Onchocerca volvulus,* which is transmitted by bites of infected blackflies, is by far the most important helminthic infection of the eye (see Chapter 9). ***This parasite accounts for blindness in at least half a million people in regions of Africa and Latin America in which it is endemic.*** Microfilariae released from fertilized adult female worms migrate into the superficial cornea, bulbar conjunctiva, aqueous humor and other ocular tissues. The intracorneal microfilariae die and elicit an inflammatory response that leads to corneal opacification and visual impairment **(river blindness)**. Less frequently, endophthalmitis, retinal lesions and optic atrophy occur. Treatment with ivermectin is highly effective.

Arcus Lipoides Is a White Arc Due to Lipid Deposition in the Peripheral Cornea

Formerly called **arcus senilis** because of its frequency in the elderly, arcus lipoides may also form an entire ring, in which case the term **annulus lipoides** is more appropriate. Although not necessarily associated with increased serum lipid levels, arcus lipoides accompanies certain disorders of lipid metabolism, and its presence alerts the perceptive clinician to the systemic disorder.

Band Keratopathy Is an Opaque Horizontal Band across the Cornea

The opacification in band keratopathy may contain calcium phosphate (**calcific band keratopathy**) or noncalcified protein (**chronic actinic keratopathy**).

In **calcific band keratopathy,** calcium phosphate deposits in a horizontal band across the superficial central cornea in conditions associated with hypercalcemia. However, the disorder most often occurs in the absence of hypercalcemia, as in chronic uveitis.

Chronic actinic keratopathy occurs worldwide but is most severe in regions in which people spend a considerable amount of time outdoors. Their unprotected eyes are exposed to excessive ultraviolet light, such as that reflected from desert, water or snow.

Noninflammatory Genetic Corneal Disorders Are Diverse

Most corneal dystrophies have an autosomal dominant or recessive mode of inheritance, but rare cases are X-linked recessive. Some of these diseases affect other parts of the body (e.g., Fabry disease, cystinosis, certain types of mucopolysaccharidosis and ichthyosis). Other conditions that primarily affect the cornea were traditionally called corneal dystrophies before the era of molecular genetics and were classified according to the primary corneal layer that is involved: (1) the outer layer composed of epithelium, basement membrane and Bowman layer; (2) the stroma; and (3) the endothelium and Descemet membrane, the basement membrane of the corneal endothelium. However, this classification is now considered somewhat artificial because many corneal dystrophies involve more than one layer.

EPITHELIAL DYSTROPHIES: The different epithelial dystrophies are characterized by a variety of distinct abnormalities, which include microcysts or accumulations of anomalous material within the cytoplasm of the corneal epithelium, defects in the epithelial basement membrane and deposition of a finely fibrillar substance in the Bowman layer. In some epithelial dystrophies, faulty desmosomes may permit adjacent epithelial cells to separate, leading to accumulation of fluid-filled microcysts. Loss of hemidesmosomes between the epithelium and Bowman layer leads to painful, recurrent erosions that begin in early childhood. Although there may be a slow decrease in visual acuity, epithelial dystrophies do not ordinarily cause blindness.

MOLECULAR PATHOGENESIS: Patients with one disorder of the corneal epithelium (*Meesmann dystrophy*) have dominant mutations in the *KRT3* or *KRT12* genes, which encode keratin 3 and keratin 12, respectively. The mutations result in aggregations of abnormal cytokeratin filaments and severely impair cytoskeletal function in the affected cells. In the rare bilateral, autosomal recessive corneal disorder *familial subepithelial corneal dystrophy,* wherein the *TACSTD2* gene is mutated, amyloid is found beneath the corneal epithelium in gelatinous drop-like deposits.

STROMAL DYSTROPHIES: The stromal corneal dystrophies are clear-cut entities in which different substances (amyloid, glycosaminoglycans, proteins or a variety of lipids) accumulate within corneal stroma because of inherited metabolic disorders. Each stromal dystrophy causes a characteristic form of corneal opacification. The age of onset and rate of progression vary with the particular disorder. Although clinical manifestations may be limited to the cornea, other tissues are involved in some of these disorders.

MOLECULAR PATHOGENESIS: Several clinically and histopathologically different inherited corneal disorders, including the granular corneal dystrophies and most lattice corneal dystrophies, result from distinctly different mutations in the same gene, namely, the *TFGBI* gene. Another predominantly stromal corneal dystrophy (macular corneal dystrophy) results from a defect in the *CHST6* gene, which encodes a sulfotransferase that catalyzes sulfation of *N*-acetyl glucosamine and galactose in keratan sulfate. Other corneal stromal diseases are caused by mutations in the genes *PIP5K3* (fleck corneal dystrophy), *DCN* (congenital stromal corneal dystrophy) and *UBIAD1* (Schnyder corneal dystrophy).

MOLECULAR PATHOGENESIS:
ENDOTHELIAL DYSTROPHIES: Several different endothelial dystrophies are recognized, usually accompanied by abnormalities in the Descemet membrane. In *Fuchs endothelial corneal dystrophy,* wart-like excrescences form on the Descemet membrane (guttae), and progressive visual loss follows corneal edema and endothelial cell degeneration. Missense mutations in *COL8A2,* the gene encoding the α_2-chain of type VIII collagen, have been identified in some patients with early-onset Fuchs dystrophy and in ***posterior polymorphous corneal dystrophy,*** both of which affect the corneal endothelium and Descemet membrane.

THE LENS

Cataracts Are Opacifications in the Crystalline Lens

Cataracts are a major cause of visual impairment and blindness throughout the world and are the outcome of numerous conditions.

ETIOLOGIC FACTORS: The most common cause of cataracts in the United States is advancing age (age-related cataract). Other cataracts are caused by diabetes, nutritional deficiencies (e.g., deficiencies in riboflavin or tryptophan), toxins (e.g., dinitrophenol, naphthalene, ergot), drugs (e.g., corticosteroids, topical phospholine iodide, phenothiazines) or physical agents (e.g., heat, ultraviolet light, trauma, intraocular surgery and ultrasound).

Cataracts may develop in ocular diseases such as uveitis, intraocular neoplasms, glaucoma, retinitis pigmentosa and retinal detachment. Cataracts also are associated with

congenital rubella virus infection, some skin diseases (e.g., atopic dermatitis, scleroderma) and various systemic diseases.

MOLECULAR PATHOGENESIS: A wide variety of cataracts result from genetic disorders, and some of them are associated with other ocular or systemic abnormalities. Cataracts can result from mutations in the heat shock transcription factor-4 (*HSF4*) gene and genes that encode specific lens proteins such as connexins (*GJA3, GJA8*), crystallins (a family of *CRY* genes), a beaded filament structural protein-2 (*BFSP2*), a putative cell-junction protein (*LIM2*) and aquaporin 0 (*MIP*). They also result from genetic mutations and chromosomal anomalies that cause numerous systemic diseases and syndromes.

PATHOLOGY: In the development of cataracts, clefts appear between the lens fibers, and degenerated lens material accumulates in these spaces (morgagnian corpuscles, incipient cataract). Degenerated lens material exerts osmotic pressure, causing the damaged lens to imbibe water and swell. The swollen lens may obstruct the pupil and cause glaucoma (phacomorphic glaucoma).

In a *mature cataract* (Fig. 33-2), the entire lens degenerates, and the lenticular debris escapes into the aqueous humor through the lens capsule, diminishing the volume of the lens (hypermature cataract). After becoming engulfed by macrophages, the extruded lenticular material may obstruct aqueous outflow and produce glaucoma (phacolytic glaucoma). The compressed lens fibers in the center of the lens normally harden with aging (simple nuclear sclerotic cataract) and may become brown or black. If the peripheral part of the lens (lens cortex) becomes liquefied (morgagnian cataract), the sclerotic nucleus may sink within the lens by gravity.

Fortunately, cataractous lenses can be surgically removed, and optical devices can be provided to permit focusing of light on the retina (spectacles, contact lenses, implantation of prosthetic lenses).

Presbyopia Is a Failure of Accommodation as a Result of Aging

With this impairment of vision, the near point of distinct vision becomes located farther from the eye. At the equator of the crystalline lens, the cuboidal subcapsular cells normally differentiate into elongated lens fibers throughout life. Once formed, these lens fibers persist indefinitely. Older fibers become displaced into the center of the lens, causing it to enlarge with age. After this process occurs over many years, the lens loses its elasticity. This effect interferes with the normal tendency of the lens to become spherical, and so diminishes the power of accommodation. As a result, most persons after age 40 years begin to have difficulty reading and require spectacles for near vision.

FIGURE 33-2. Cataract. The white appearance of the pupil in this eye is due to complete opacification of the lens ("mature cataract").

Phacoanaphylactic Endophthalmitis Is an Autoimmune Granulomatous Reaction to Lens Proteins

In this disorder, an inflammatory lesion occurs around or within the lens (or its remains) in an eye with a traumatized or cataractous lens and sometimes after surgical removal of a cataractous lens. A similar reaction may occur spontaneously in the contralateral eye months or years later. This autoimmune reaction to unique lens proteins, which are normally sequestered from the immune system, can be provoked experimentally by immunization with autologous lens material.

THE UVEA

A Variety of Inflammatory Conditions Affect the Uveal Tract

Inflammation of the uvea **(uveitis)** also encompasses inflammation of the iris **(iritis),** the ciliary body **(cyclitis)** and the iris plus the ciliary body **(iridocyclitis)**. Inflammation of the iris and ciliary body typically causes a red eye, photophobia, moderate ocular pain, blurred vision, a pericorneal halo, ciliary flush and slight miosis. A flare is common in the anterior chamber on slit-lamp biomicroscopy, and keratic precipitates or a **hypopyon** (leukocytic exudate in the anterior chamber) also develops.

Peripheral anterior synechiae are adhesions between the peripheral iris and the anterior chamber angle. **Posterior synechiae** are adhesions that develop between the iris and the lens. Both types of synechiae are complications of iritis, and both can cause glaucoma.

Sympathetic Ophthalmitis Is an Autoimmune Uveitis

In sympathetic ophthalmitis, the entire uvea develops granulomatous inflammation after a latent period, in response to an injury in the other eye. Perforating ocular injury and prolapse of uveal tissue often lead to a progressive, bilateral, diffuse, granulomatous inflammation of the uvea. This uveitis develops in the originally injured eye (exciting eye) after a latent period of 4–8 weeks. The latent period may, however, be as short as 10 days or as long as many years. The uninjured eye (sympathizing eye) becomes affected at the same time as the injured eye, or shortly thereafter. Vitiligo and graying of the eyelashes sometimes accompanies the uveitis. Nodules containing reactive retinal pigment epithelium, macrophages and epithelioid cells commonly appear between the Bruch membrane **(lamina vitrea)** and retinal pigment epithelium **(Dalen-Fuchs nodules)**.

Experimental studies suggest that the antigen responsible for sympathetic ophthalmitis resides in the photoreceptors of the retina **(arrestin)**.

Sarcoidosis Commonly Affects the Eye

Ocular involvement occurs in one fourth to one third of patients with sarcoidosis and is often the initial clinical manifestation. Both eyes are usually affected, most often with a granulomatous uveitis. Although any ocular and orbital tissues may be involved, this granulomatous disease has a predilection for the anterior segment of the eye. Other ocular manifestations of sarcoidosis include calcific band keratopathy, cataracts, retinal vascularization, vitreous hemorrhage and bilateral enlargement of the lacrimal and salivary glands (**Mikulicz syndrome**).

THE RETINA

Retinal Hemorrhage May Occur in Both Local and Systemic Diseases

The important causes of retinal hemorrhages are hypertension, diabetes mellitus, central retinal vein occlusion, bleeding diatheses and trauma, including the "shaken baby

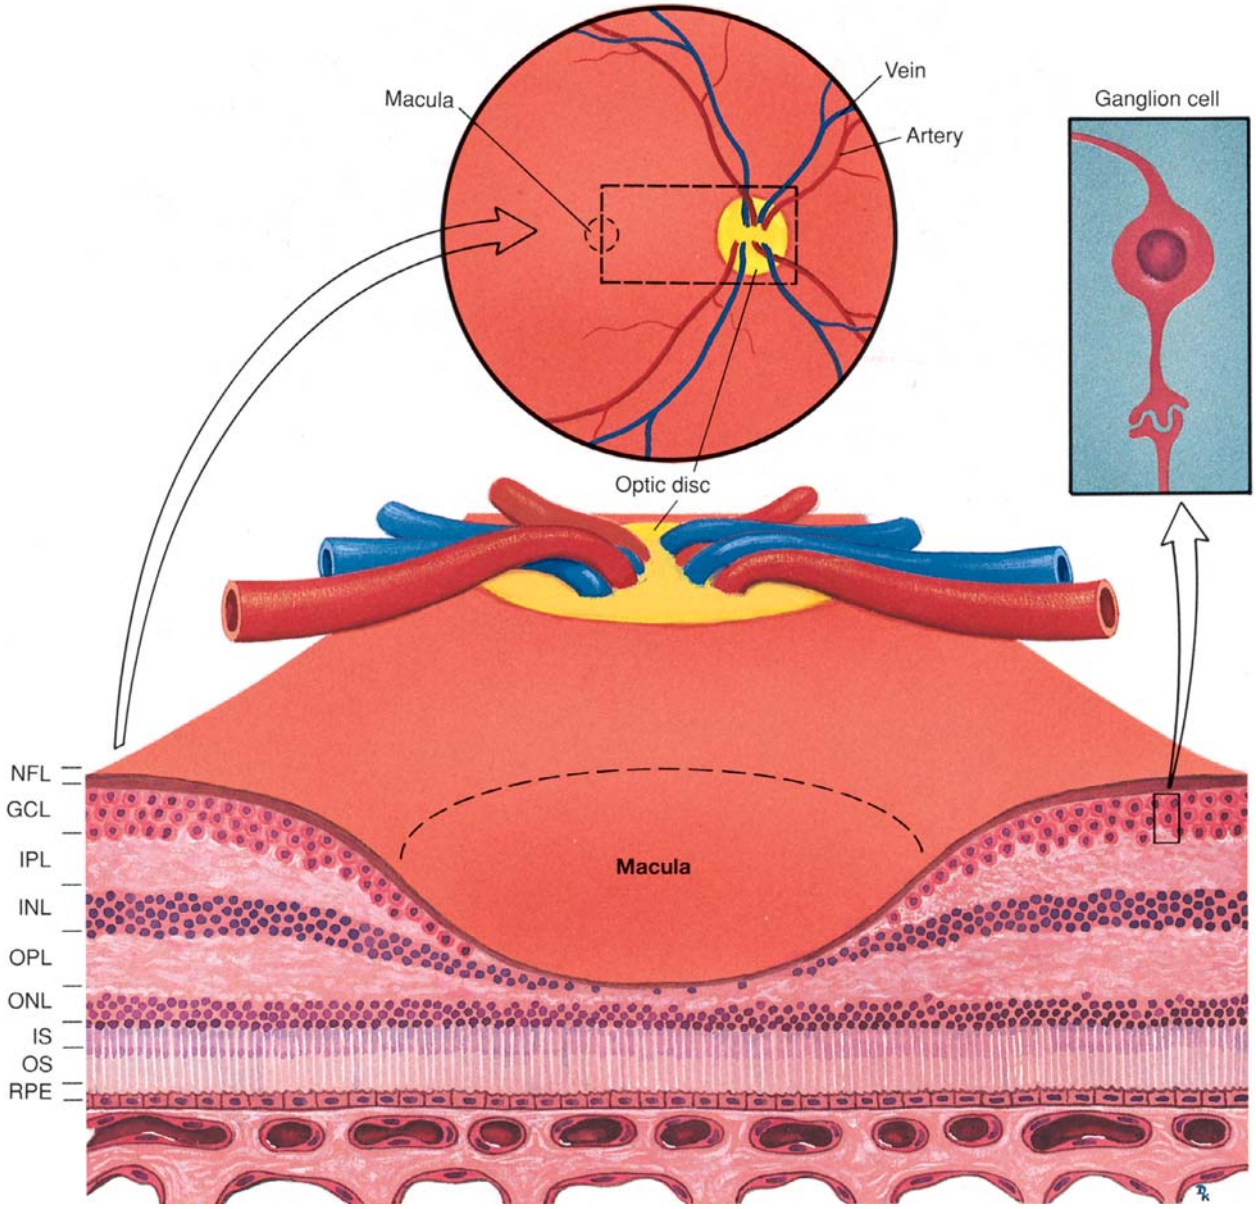

FIGURE 33-3. The normal retina. Constituents of the normal retina are arranged in distinct layers. These include the nerve fiber layer (*NFL*), ganglion cell layer (*GCL*), inner plexiform layer (*IPL*), inner nuclear layer (*INL*), outer plexiform layer (*OPL*), outer nuclear layer (*ONL*), inner segments (*IS*) and outer segments (*OS*) of the photoreceptors and the retinal pigment epithelium (*RPE*). The axons from the ganglion cells enter the nerve fiber layer and converge toward the optic nerve head. The inner retina contains arteries and veins. The retina is thinnest at the center of the macula, where bare photoreceptors rest on the retinal pigment epithelium. Only one cell thick in most of the retina, the ganglion cell layer is multilayered at the macula.

syndrome." Appearance varies with cause and location. Hemorrhages in the nerve fiber layer spread between axons and causes a flame-shaped appearance on funduscopy, whereas deep retinal hemorrhages tend to be round. When located between the retinal pigment epithelium and Bruch membrane, blood appears as a dark mass, which may resemble a melanoma.

After accidental or surgical perforation of the globe, choroidal hemorrhages may detach the choroid and displace the retina, vitreous body and lens through the wound.

Retinal Occlusive Vascular Disease Is an Important Cause of Blindness

Vascular occlusion results from thrombosis, embolism, stenosis (as in atherosclerosis), vascular compression, intravascular sludging or coagulation and vasoconstriction (e.g., in hypertensive retinopathy or migraine). Thrombosis of ocular vessels may accompany primary disease of these vessels, as in giant cell arteritis.

Certain disorders of the heart and major vessels, such as the carotid arteries, predispose to emboli that may lodge in the retina and are evident on funduscopic examination at points of vascular bifurcation. Within the optic nerve, emboli in the central retinal artery frequently lodge in the vessel where it passes though the scleral perforations **(lamina cribrosa)**.

PATHOLOGY: The effect of vascular occlusion depends on the size of the vessel involved, the degree of resultant ischemia and the nature of the embolus. Small emboli often do not interfere with retinal function, whereas septic emboli may cause foci of ocular infection. Retinal ischemia due to any cause frequently leads to white fluffy patches that resemble cotton on ophthalmoscopic examination **(cotton-wool spots)**. These round spots, which are seldom wider than the optic nerve head, consist of aggregates of swollen axons in the nerve fiber layer of the retina. Affected axons contain numerous degenerated mitochondria and dense bodies related to the lysosomal system, which accumulate because of impaired axoplasmic flow. Histologically, in cross-section, individual swollen axons resemble cells (cytoid bodies). Cotton-wool spots are reversible if circulation is restored in time.

Central Retinal Artery Occlusion

Like neurons in the rest of the nervous system, those in the retina (Fig. 33-3) are extremely susceptible to hypoxia. Central retinal artery occlusion (Figs. 33-4 and 33-5) may follow thrombosis of the retinal artery, as in atherosclerosis or giant cell arteritis, or embolization to that blood vessel. Intracellular edema, manifested by retinal pallor, is prominent, especially in the macula, where ganglion cells are most numerous. The foveola, the center of the macula, stands out in sharp contrast as a prominent **cherry-red spot,** because of the underlying vascularized choroid. The lack of retinal circulation reduces retinal arterioles to delicate threads (Fig. 33-5).

Permanent blindness follows central retinal artery obstruction, unless the ischemia is of short duration. Unilateral blurred vision, lasting a few minutes **(amaurosis fugax),** occurs with small retinal emboli.

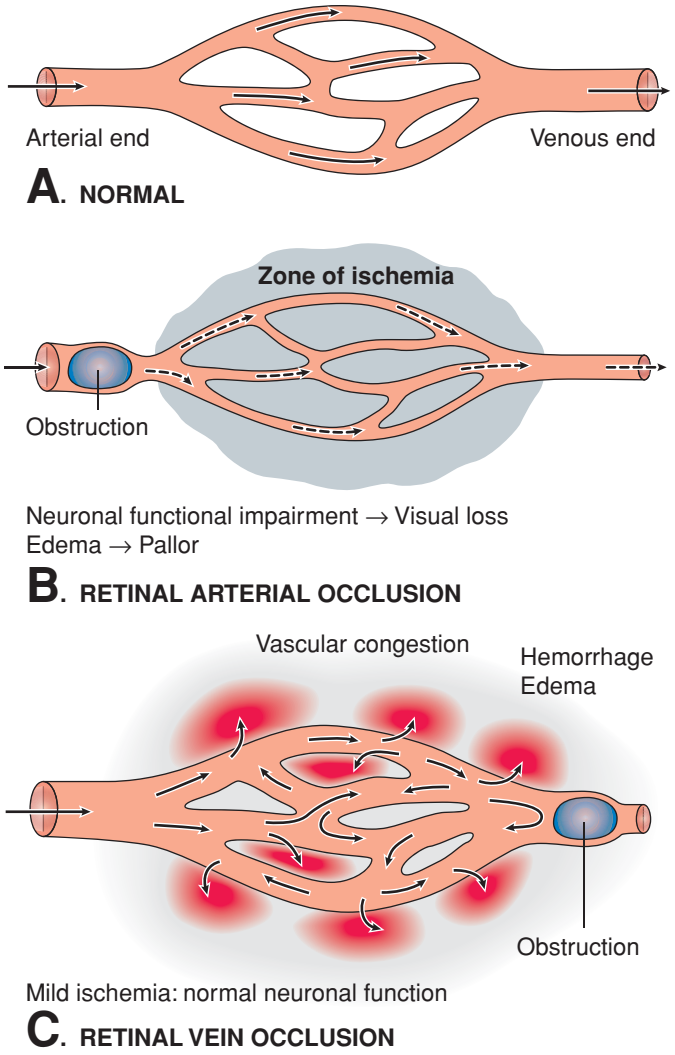

FIGURE 33-4. Occlusion of the retinal artery and vein. A. In the retina, as in other parts of the body, blood normally flows through a capillary network. **B.** When the retinal arteries become occluded (e.g., with an embolus), a zone of retinal ischemia ensues. This is accompanied by impaired neuronal function and visual loss, and the ischemic retina becomes pale. Because the intravascular pressure within the ischemic tissue is low, hemorrhage is inconspicuous. **C.** With retinal vein occlusion, vascular congestion, hemorrhage and edema are prominent, whereas ischemia is mild and neuronal function remains intact.

Central Retinal Vein Occlusion

Central retinal vein occlusion results in flame-shaped hemorrhages in the nerve fiber layer of the retina, especially around the optic nerve head. The hemorrhages reflect the high intravascular pressure that dilates and ruptures the veins and collateral vessels (Fig. 33-6). Edema of the optic nerve head and retina occurs because absorption of interstitial fluid is impaired.

Vision is disturbed but may recover surprisingly well, considering the severity of the funduscopic changes. An intractable, closed-angle glaucoma, with severe pain and repeated hemorrhages, commonly ensues 2–3 months after central retinal vein occlusion (so-called 100-day glaucoma, thrombotic glaucoma or neovascular glaucoma). This distressing complication is caused by neovascularization of the

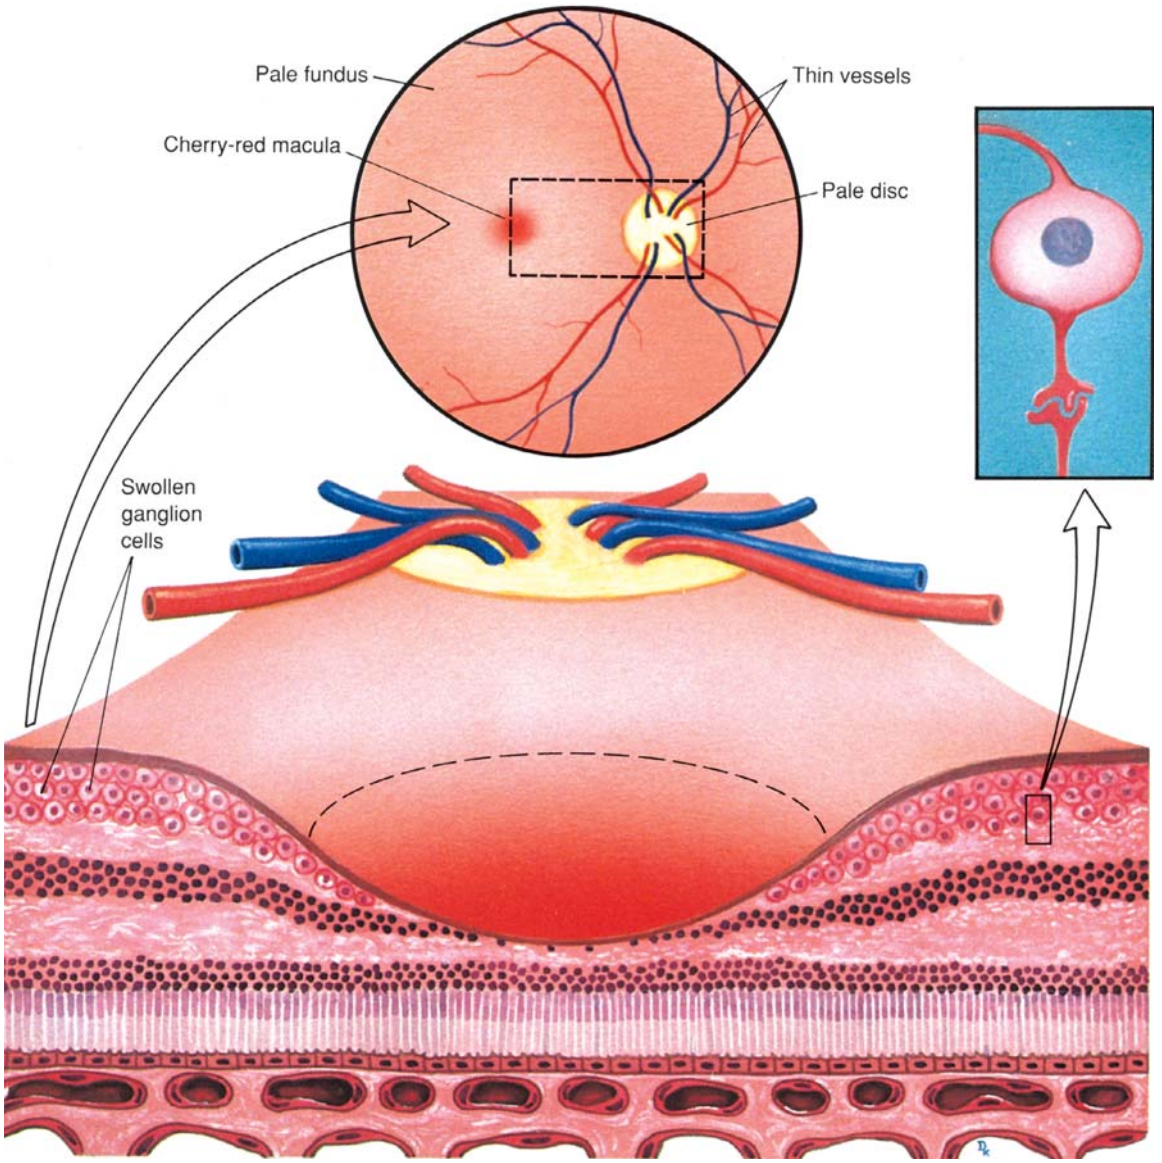

FIGURE 33-5. Central retinal artery occlusion. When the central retinal artery becomes occluded (e.g., with an embolus), the entire retina becomes edematous and pale. Decreased blood flow makes the retinal vessels less visible on funduscopic examination. The macula becomes cherry-red, owing to the prominent, but normal, underlying vasculature of the choroid.

iris and adhesions between the iris and the anterior chamber angle **(peripheral anterior synechiae)**.

Hypertensive Retinopathy Correlates with the Severity of Hypertension

Increased blood pressure commonly affects the retina, causing changes that can readily be seen with the ophthalmoscope (Figs. 33-7 and 33-8).

PATHOLOGY: Features of hypertensive retinopathy include:

- **Arteriolar narrowing**
- **Hemorrhages** in the retinal nerve fiber layer (flame-shaped hemorrhages)
- **Exudates,** including some that radiate from the center of the macula (macular star)
- Fluffy white bodies in the superficial retina **(cotton-wool spots)**
- **Microaneurysms**

In the eye, arteriolosclerosis accompanies long-standing hypertension and commonly affects the retinal and choroidal vessels. Lumina of the thickened retinal arterioles become narrowed, increasingly tortuous and of irregular caliber. At sites where arterioles cross veins, the latter appear kinked **(arteriovenous nicking)**. However, the venous diameter before the site of compression is not wider than that after it. The kinked appearance of the vein reflects sclerosis within the venous walls, because retinal arteries and veins share a common adventitia at sites of arteriovenous crossings, rather than compression by a taut sclerotic artery.

By funduscopy, abnormal retinal arterioles appear as parallel white lines at sites of vascular crossings **(arterial sheathing)**. Initially, the narrowed lumen of the retinal

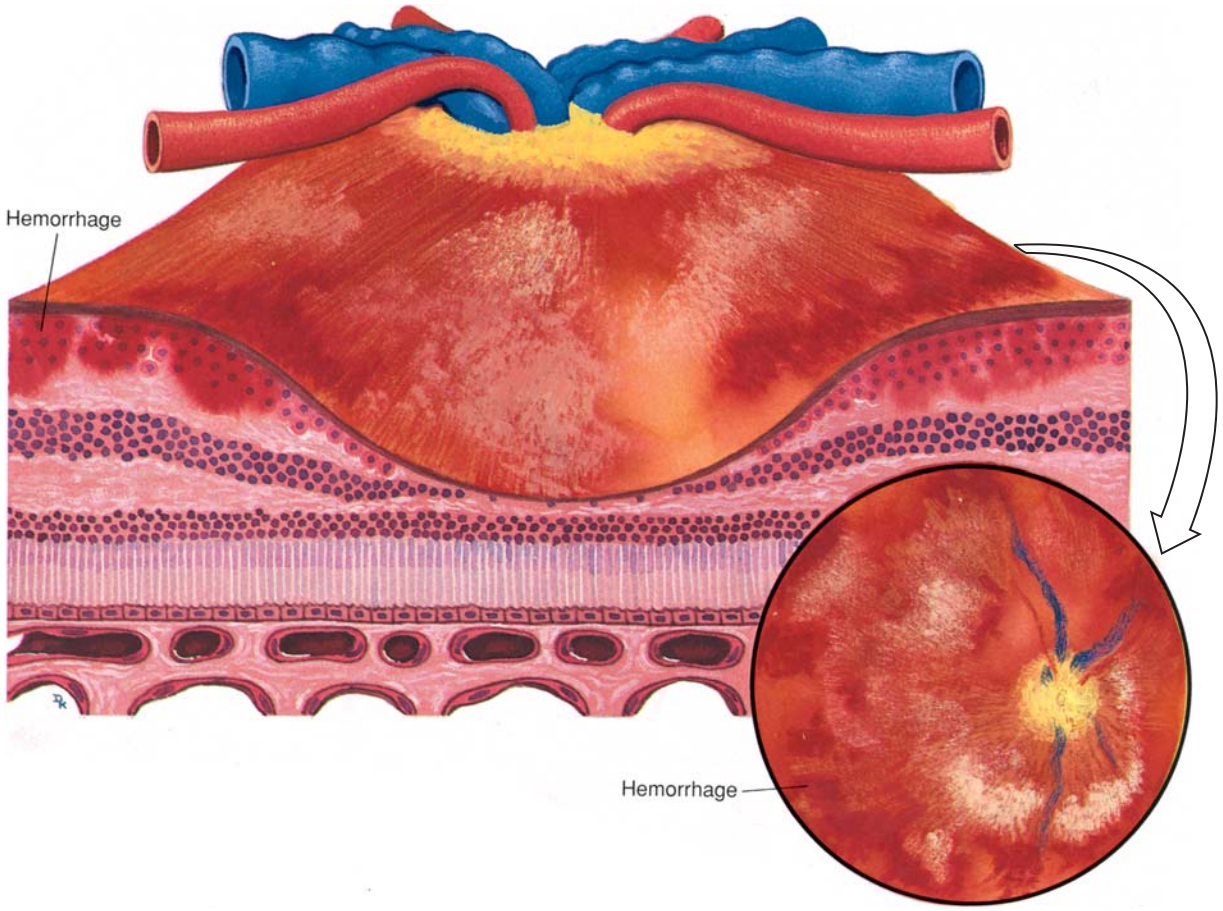

FIGURE 33-6. Central retinal vein occlusion. In contrast to central retinal artery occlusion, central retinal vein occlusion produces considerable vascular engorgement and retinal hemorrhage as a consequence of increased intravascular pressure.

vessels decreases the visibility of the blood column and makes it appear orange on ophthalmoscopic examination **(copper wiring)**. However, as the blood column eventually becomes completely obscured, light reflected from the sclerotic vessels appears as threads of silver wire **(silver wiring)**.

Small superficial or deep retinal hemorrhages often accompany retinal arteriolosclerosis. **Malignant hypertension** is characterized by necrotizing arteriolitis, with fibrinoid necrosis and thrombosis of precapillary retinal arterioles.

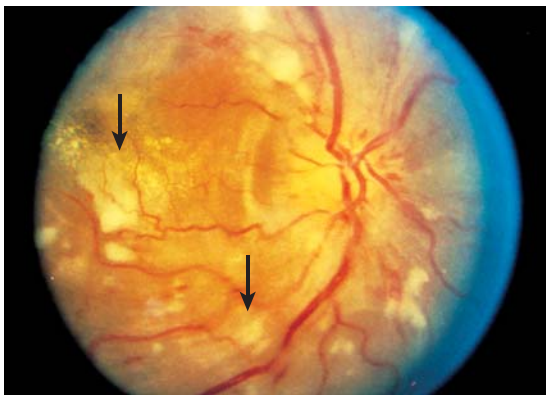

FIGURE 33-7. Hypertensive retinopathy. A photograph of the ocular fundus in a patient with extensive retinopathy. The optic nerve head is edematous; the retina contains numerous "cotton-wool spots" (*arrows*).

Diabetic Retinopathy Is Primarily a Vascular Disease

The eye is frequently involved in diabetes mellitus. Ocular symptoms occur in 20%–40% of diabetics and may even be evident at the time diabetes is diagnosed. Virtually all patients with type 1 (insulin-dependent) diabetes and many of those with type 2 (non–insulin-dependent) diabetes develop some background retinopathy (see below) within 5–15 years of the onset of diabetes (Figs. 33-9 to 33-11). The more dangerous **proliferative retinopathy** does not appear until at least 10 years of diabetes, after which its incidence increases rapidly and remains high for many years. ***In type 1 diabetes, the frequency of proliferative retinopathy correlates with the degree of glycemic control; patients whose diabetes is better controlled develop retinopathy less frequently.*** The relationship between retinal microvascular disease and blood glucose levels in type 2 diabetes is less clear, and other parameters (e.g., blood cholesterol levels, blood pressure) may play more of a role than blood glucose levels.

Retinal ischemia can account for most features of diabetic retinopathy, including the cotton-wool spots, capillary closure, microaneurysms and retinal neovascularization. Ischemia results from narrowing or occlusion of retinal arterioles (as from arteriolosclerosis or platelet and lipid thrombi) or from atherosclerosis of the central retinal or ophthalmic arteries.

FIGURE 33-8. Hypertensive retinopathy. Various abnormalities develop within the retina in hypertension. The commonly associated arteriolosclerosis affects the appearance of the retinal microvasculature. Light reflected from the thickened arteriolar walls mimics silver or copper wire. Blood flow through the retinal venules is not well visualized at the sites of arteriolar–venular crossings. This effect is due to a thickening of the venular wall rather than to an impediment to blood flow caused by compression; the column of blood proximal to the compression is not wider than the part distal to the crossing. Impaired axoplasmic flow within the nerve fiber layer, caused by ischemia, results in swollen axons with cytoplasmic bodies. Such structures resemble cotton on funduscopy ("cotton-wool spots"). Hemorrhages are common in the retina, and exudates frequently form a star around the macula.

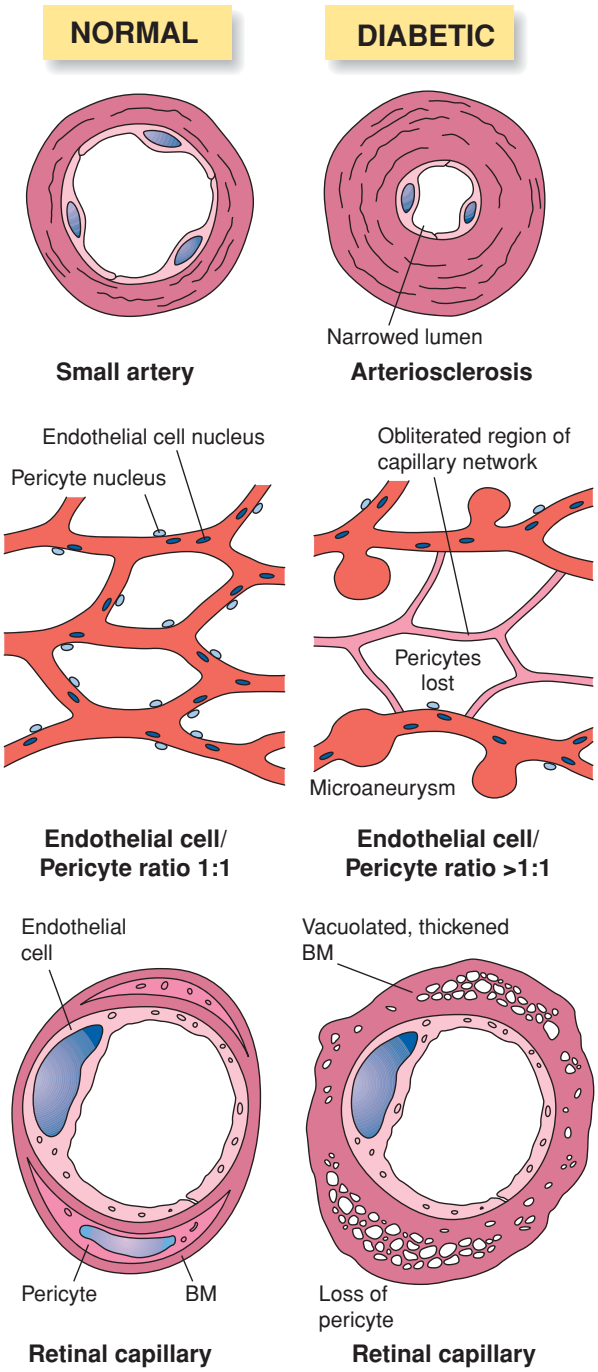

FIGURE 33-9. Diabetic retinopathy. In diabetic retinopathy, the microvasculature is abnormal. Arteriosclerosis narrows the lumen of the small arteries. Pericytes are lost, and the endothelial cell–to–pericyte ratio is greater than 1. Capillary microaneurysms are prominent, and portions of the capillary network become acellular and show no blood flow. The basement membrane (BM) of the retinal capillaries is thickened and vacuolated.

PATHOLOGY: The retinopathy of diabetes is characterized by background and proliferative stages.

BACKGROUND (NONPROLIFERATIVE) DIABETIC RETINOPATHY: This stage exhibits venous engorgement, small hemorrhages (dot and blot hemorrhages), capillary microaneurysms and exudates. These lesions usually do not impair vision unless associated with macular edema. The retinopathy begins at the posterior pole but eventually may involve the entire retina.

On funduscopy, the first discernible clinical abnormality in background diabetic retinopathy is engorged retinal veins, with localized sausage-shaped distentions, coils and loops. This is followed by small hemorrhages in the same areas, mostly in the inner nuclear and outer plexiform layers. With time, "waxy" exudates accumulate, chiefly in the vicinity of the microaneurysms. The retinopathy of elderly diabetic persons frequently displays numerous exudates **(exudative diabetic retinopathy),** which are not seen with type 1 diabetes. Because of the hyperlipoproteinemia of diabetics, the exudates are rich in lipid and thus appear yellowish **(waxy exudates)**.

PROLIFERATIVE RETINOPATHY: After many years, diabetic retinopathy becomes proliferative. Delicate new blood vessels grow along with fibrous and glial tissue toward the vitreous body. Retinal neovascularization is a prominent feature of diabetic retinopathy and of other conditions caused by retinal ischemia. Tortuous new vessels first appear on the surface of the retina and optic nerve head and then grow into the vitreous cavity. The newly formed friable vessels bleed easily, and resultant vitreal hemorrhages obscure vision. Neovascularization is associated with proliferation and immigration of astrocytes, which grow around the new vessels to form delicate white veils (gliosis). The proliferating fibrovascular and glial tissue contracts, often causing retinal detachment and blindness. Frequently, features of hypertensive and arteriolosclerotic retinopathy are associated with diabetic retinopathy.

Diabetic retinopathy, glaucoma and age-related maculopathy are the leading causes of irreversible blindness in the United States. Blindness in diabetic retinopathy results when the macula is involved, but it also follows vitreous hemorrhage, retinal detachment and glaucoma. Once blindness ensues, it heralds an ominous future for the patient, because death from ischemic heart disease or renal failure often follows. In fact, the mean life expectancy in such cases is less than 6 years, and only one fifth of blind diabetics survive 10 years. Laser phototherapy and strict glycemic control early in the course of proliferative retinopathy have proved effective in controlling this complication.

Diabetic Iridopathy

In diabetics with severe retinopathy, a fibrovascular layer frequently grows along the anterior surface of the iris and in the anterior chamber angle. Because such iris neovascularization **(rubeosis iridis)** occurs in several conditions associated with retinal ischemia, it is believed to be due to an angiogenic factor produced by the ischemic retina.

PATHOLOGY: A fibrovascular membrane leads to adhesions between the iris and the cornea **(peripheral anterior synechiae)** and between the iris and lens **(posterior synechiae),** while traction by the fibrovascular membrane pulls the iris pigment epithelium around the pupillary margin **(ectropion uveae)**. The friable new vessels on the iris bleed easily and cause **hyphema** (hemorrhage within the anterior chamber of the eye). Neovascularization of the iris is clinically important because it frequently culminates in a blind, painful eye, owing to secondary glaucoma **(neovascular glaucoma)**.

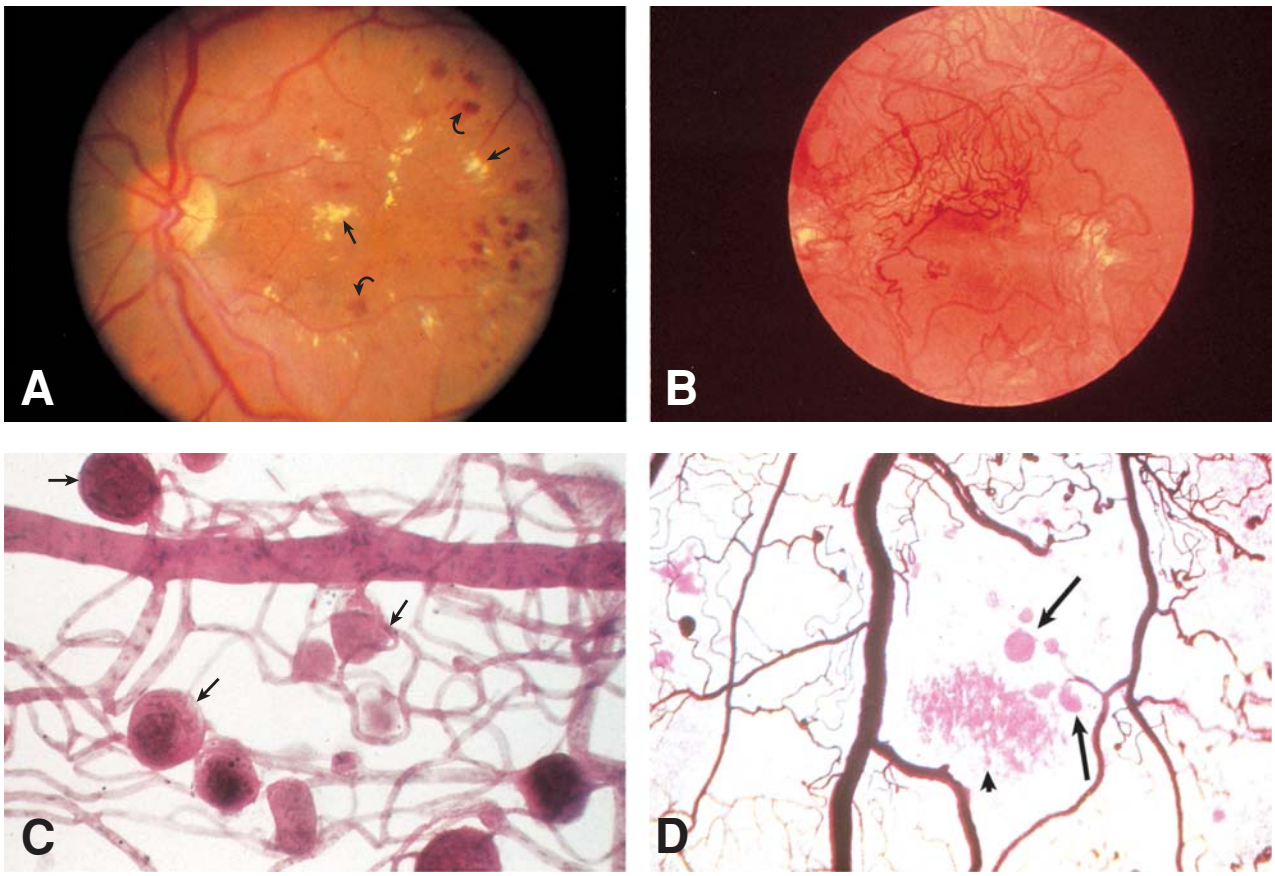

FIGURE 33-10. Diabetic retinopathy. A. The ocular fundus in a patient with background diabetic retinopathy. Several yellowish "hard" exudates (*straight arrows*), which are rich in lipids, are evident, together with several relatively small retinal hemorrhages (*curved arrows*). **B.** A vascular frond (*top half*) has extended anteriorly to the retina in the eye with proliferative diabetic retinopathy. **C.** Numerous microaneurysms (*arrows*) are present in this flat preparation of a diabetic retina. **D.** This flat preparation from a diabetic was stained with periodic acid–Schiff (PAS) after the retinal vessels had been perfused with India ink. Microaneurysms (*arrows*) and an exudate (*arrowhead*) are evident in a region of retinal nonperfusion.

Hyperglycemia leads to glycogen storage in the pigmented epithelium of the iris, a phenomenon analogous to that produced in the renal tubules by glycosuria. When tissue sections of diabetic eyes are processed in the usual manner, the pigment epithelium of the iris sometimes contains numerous vacuoles, which imparts a lacy appearance. The vacuoles result from loss of glycogen during preparation of tissue sections. Glycogen storage within the iris pigment epithelium is thought to account for the scattering of iris pigment observed clinically in diabetic patients.

Diabetic Cataracts

Patients with type 1 diabetes often develop bilateral "snowflake" cataracts, a blanket of white needle-shaped opacities in the lens immediately beneath the anterior and posterior lens capsule. The opacities coalesce within a few weeks in adolescents, and within days in children, until the whole lens becomes opaque. Snowflake cataracts can be produced experimentally in young animals and result from an osmotic effect caused by an accumulation of sorbitol, the alcohol derived from glucose (see Chapter 13). The increased sorbitol content of the lens causes imbibition of water and enlargement of the lens.

Age-related cataracts occur in diabetics at an earlier age than in the general population and progress more rapidly to maturity. A sudden temporary myopia, caused by an increase in the refractive power in the lens, may be the presenting manifestation of diabetes.

Other Ophthalmic Manifestations of Diabetes

People with diabetes are at increased risk for inflammation of the anterior segment of the eye, phycomycosis (mucormycosis) of the orbit and primary open-angle glaucoma. They are also prone to the **Argyll Robertson pupil** (unequal and irregularly shaped pupils that react to accommodation but not to light). Cranial nerve palsies occur, especially of the oculomotor nerve. Some patients with long-standing diabetes develop recurrent corneal erosions, which are thought to be due to impaired innervation of the cornea.

The effects of diabetes mellitus on the eye are reviewed in Fig. 33-11.

Retinal Detachment Separates the Sensory Retina from the Pigment Epithelium

During fetal development, the space between the sensory retina and the retinal pigment epithelium is obliterated

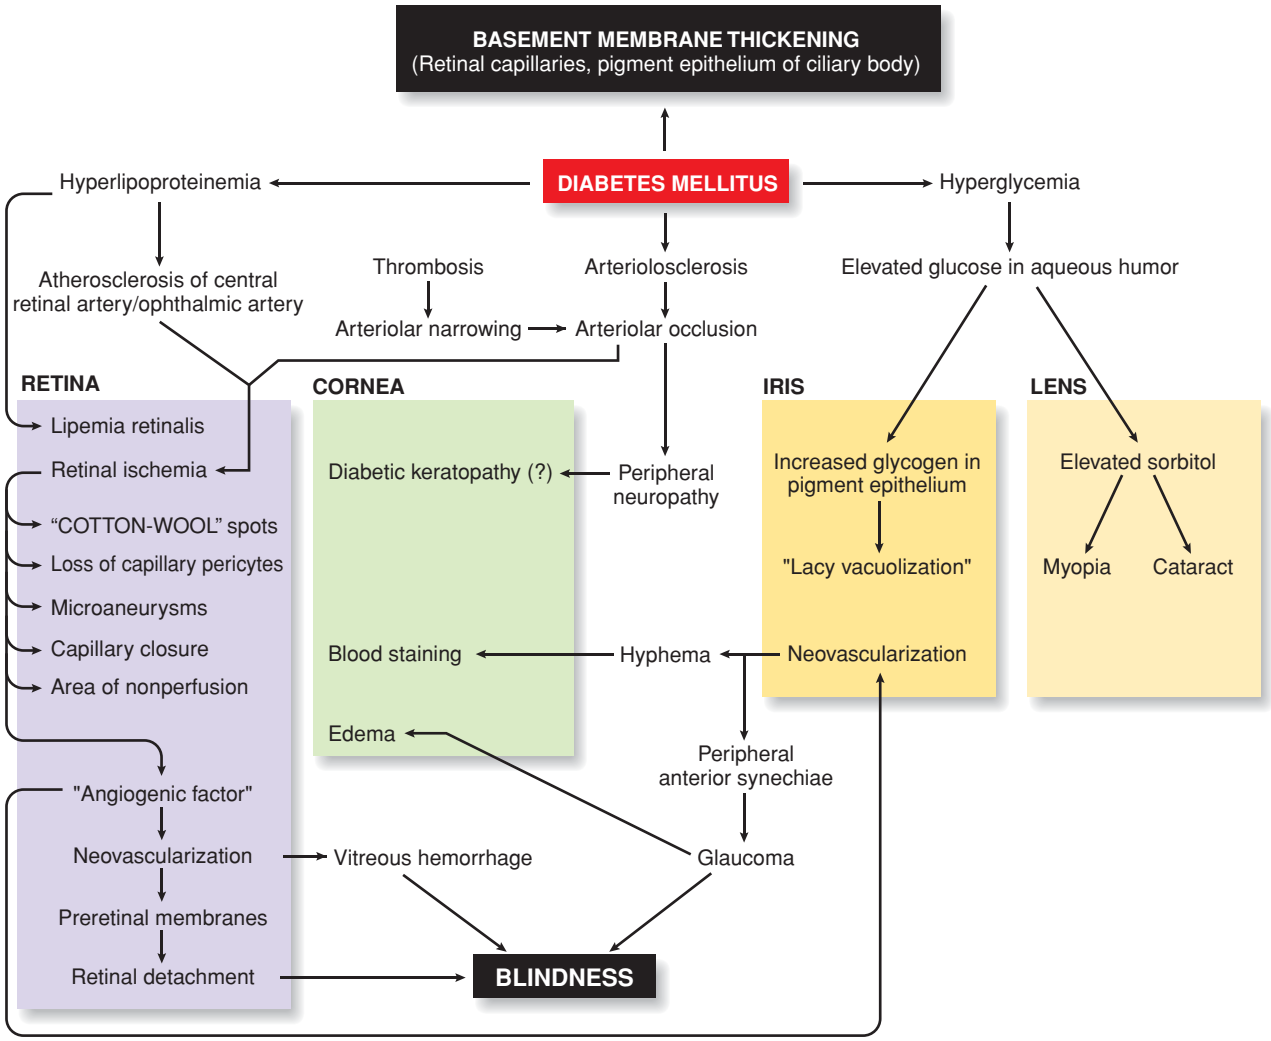

FIGURE 33-11. Effects of diabetes on the eye.

when these two layers become apposed. However, the sensory retina readily separates from the retinal pigment epithelium when fluid (liquid vitreous, hemorrhage or exudate) accumulates within the potential space between these structures. Such a separation is a common cause of visual impairment and blindness. Laser therapy and surgical approaches have greatly improved the prognosis for patients with detached retina.

ETIOLOGIC FACTORS: Retinal detachment follows intraocular hemorrhage (e.g., after trauma) and is a potential complication of cataract extractions and several other ocular operations. Factors predisposing to retinal detachment include retinal defects (due to trauma or certain retinal degenerations), vitreous traction, diminished pressure on the retina (e.g., after vitreous loss) and weakening of the fixation of the retina. Full-thickness holes in the retina are not complicated by retinal detachment unless liquid vitreous gains access to the potential space between the retina and the retinal pigment epithelium. Even then, some vitreoretinal traction seems to be necessary for retinal detachment to occur.

The photoreceptors and retinal pigment epithelium normally function as a unit. After they separate in a retinal detachment, oxygen and nutrients that normally reach the outer retina from the choroid must diffuse across a greater distance. This situation causes the photoreceptors to degenerate, after which cyst-like extracellular spaces appear within the retina.

PATHOLOGY: Three varieties of retinal detachment are recognized: rhegmatogenous, tractional and exudative.

RHEGMATOGENOUS RETINAL DETACHMENT: This type of retinal detachment is associated with a retinal tear and also often with degenerative changes in the vitreous body or peripheral retina.

TRACTIONAL RETINAL DETACHMENT: In some cases of retinal detachment, the retina is pulled toward the center of the eye by adherent vitreoretinal adhesions, as occurs in proliferative diabetic retinopathy, in retinopathy of prematurity and after intraocular infection.

EXUDATIVE RETINAL DETACHMENT: Accumulation of fluid in the potential space between the sensory retina and the retinal pigment epithelium causes a detached retina

in disorders such as choroiditis, choroidal hemangioma and choroidal melanoma.

Retinitis Pigmentosa Is a Heritable Cause of Blindness

Retinitis pigmentosa (pigmentary retinopathy) is a generic term that refers to a variety of bilateral, progressive, degenerative retinopathies characterized clinically by night blindness and constriction of peripheral visual fields and pathologically by loss of retinal photoreceptors (rods and cones) and pigment accumulation within the retina.

The term "retinitis" is a misnomer since inflammation of the retina is not a feature of this disease.

MOLECULAR PATHOGENESIS: A large number of retinal diseases, including retinitis pigmentosa, are caused by mutations in different genes (currently over 200; http://www.sph.uth.tmc.edu/retnet). Some are isolated ocular disorders, with autosomal dominant, autosomal recessive or X-linked recessive inheritance. Some pigmentary retinopathies are associated with neurologic and systemic disorders.

Mutations in at least 48 different genes and loci are associated with nonsyndromic retinitis pigmentosa. Some of the responsible mutated genes encode members of the rod phototransduction cascade, such as rhodopsin (*RHO*) and rod photoreceptor cyclic guanosine 3′,5′-monophosphate (cGMP), phosphodiesterase α and β subunits (*PDE6A*, *PDE6B*) and photoreceptor structures such as peripherin. How defective proteins in the rod photoreceptors lead to retinitis pigmentosa and the eventual loss of cones remains incompletely understood, but presumably all responsible mutations ultimately cause the death of photoreceptors because of a convergence at a final common point in key metabolic pathways.

PATHOLOGY: In retinitis pigmentosa, destruction of rods, and subsequently cones, is followed by migration of retinal pigment epithelial cells into the sensory retina (Fig. 33-12). Melanin appears within slender processes of spidery cells and accumulates mainly around small branching retinal blood vessels (especially in the equatorial portion of the retina), like spicules of bone. The retinal blood vessels then gradually attenuate, and the optic nerve head acquires a characteristic waxy pallor.

CLINICAL FEATURES: The clinical manifestations of retinitis pigmentosa, including the appearance and distribution of the retinal pigmentation, vary with the causes of the retinopathy. Half of these patients have a family history of the disease. Those with autosomal recessive and X-linked disease are more severely affected and develop night blindness and peripheral field defects in childhood. Autosomal dominant forms of retinitis pigmentosa tend to be less severe, with symptoms beginning later in life. As the condition progresses, contraction of visual fields eventually leads to tunnel vision. Central vision is usually preserved until late in the course of the disease. In some cases, blindness follows macular involvement.

Macular Degeneration Is a Common Cause of Blindness in the Elderly

The center of the macula, the foveola, is the point of greatest visual acuity. In this area, a high concentration of cones rests on the retinal pigment epithelium. Surrounding the macula, the retina has a multilayered concentration of ganglion cells. With aging, in certain drug toxicities (e.g., chloroquine) and in several inherited disorders, the macula degenerates, causing central vision to be impaired.

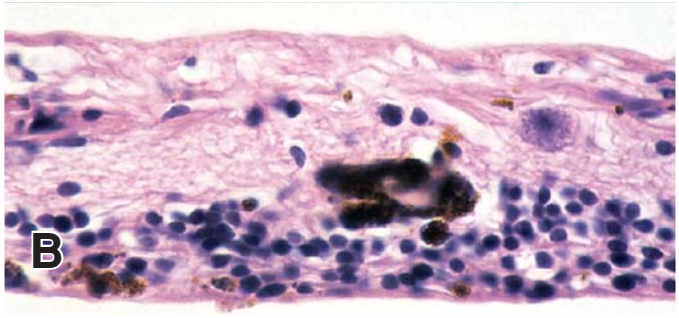

FIGURE 33-12. Retinitis pigmentosa. A. Fundus photograph of the retina of a patient with pigmentary retinopathy (retinitis pigmentosa) shows attenuated retinal vessels and foci of retinal pigmentation (*arrows*). **B.** Microscopic appearance of a severely degenerated retina in pigmentary retinopathy. Note the focal accumulations of pigmented, brown cells (derived from retinal pigmented epithelium) within the retina.

Age-related macular degeneration currently affects about 15 million people in the United States and is the most common cause of blindness among individuals of European descent older than age 65. Dry and wet forms of age-related macular degeneration are recognized. The wet variety of this disease accounts for 20% of cases and is associated with subretinal fibrovascular tissue and sometimes bleeding into the subretinal space. Laser photocoagulation and other intraocular antiangiogenic therapies are beneficial in this type of the disorder.

ETIOLOGIC FACTORS: There is general agreement that age-related maculopathy is a multifactorial disease to which environmental and genetic factors contribute. Risk factors include advancing age, smoking, carotid/cardiovascular disease and elevated serum cholesterol levels.

MOLECULAR PATHOGENESIS: A common missense variant of the *CFH* gene that encodes for complement factor H is a risk factor for about 50% of cases of age-related macular degeneration. A susceptibility to age-related macular degeneration has also been associated with mutations or single-nucleotide polymorphisms in *ABCA4* (formerly called *ABCR*), *FBLN5*,

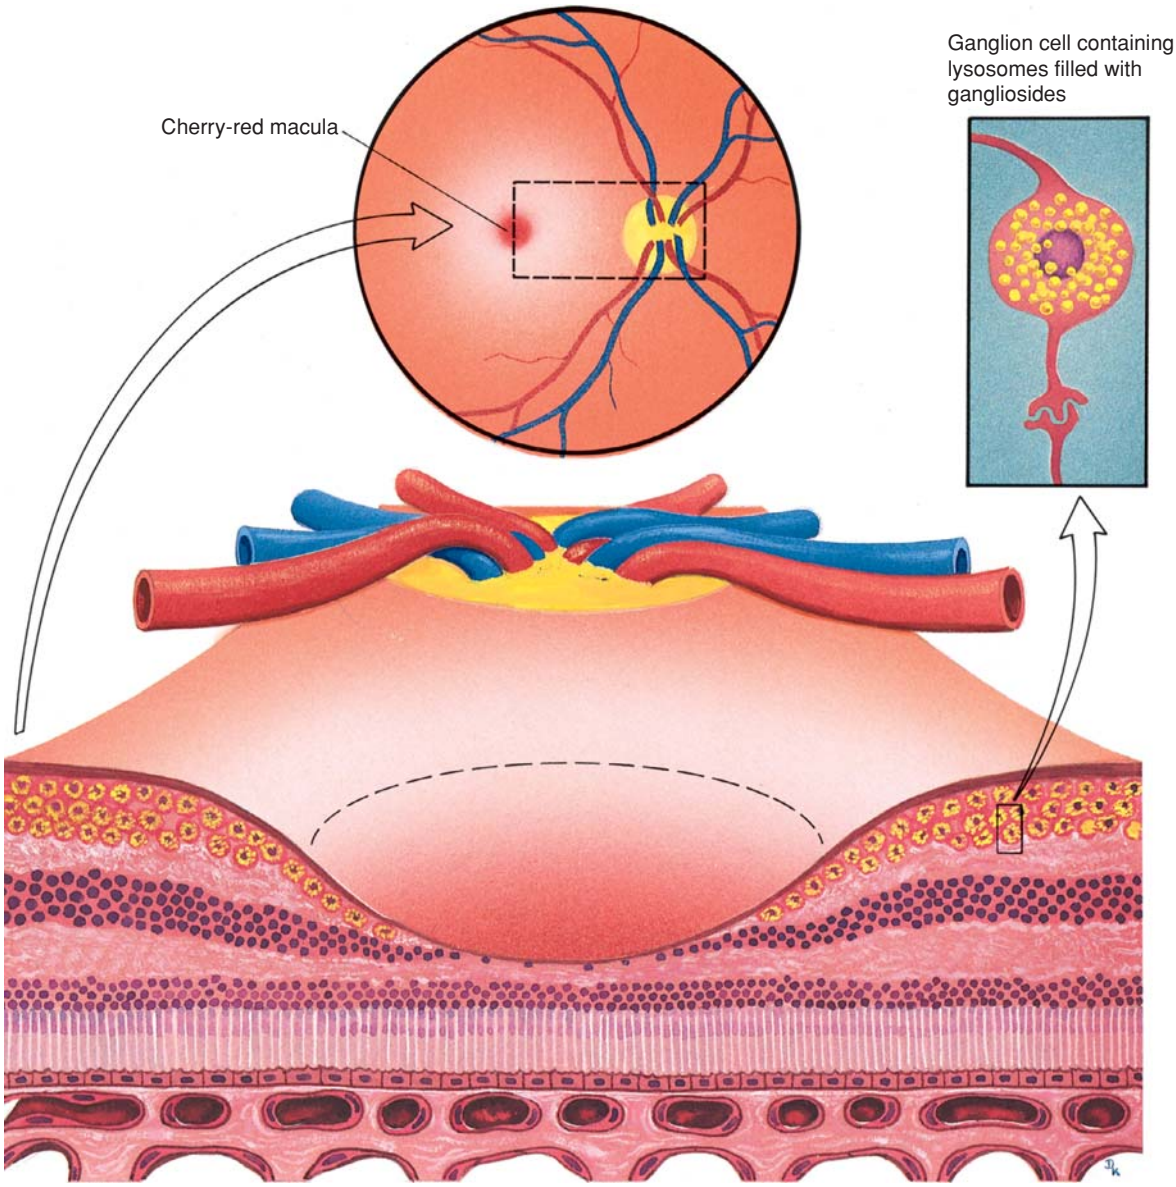

FIGURE 33-13. Cherry-red macula. A cherry-red spot appears at the macula in several lysosomal storage diseases that are characterized by intracytoplasmic accumulations within the retinal ganglion cells, such as Tay-Sachs disease, in which a particular ganglioside is stored (GM_2-ganglioside). The macula develops this appearance because the pallor created by the deposits within the multilayered ganglion cells enhances the visibility of the underlying normal choroidal vasculature.

FBLN6, C3, CST3, LOC387715, TLR4, ERCC6, RAXL1, HTRA1, CX3CR1 and *ESR1* genes and in a mitochondrial gene (*MTTL1*). *ABCA4* encodes a rod cell protein (rim protein) thought to be a transporter involved in molecular recycling. Mutations in this gene may allow degraded material **(drusen)** to accumulate and interfere with retinal function.

Lysosomal Storage Diseases Feature a Cherry-Red Spot at the Macula

In lysosomal storage diseases, including the gangliosidoses, myriad intracytoplasmic lysosomal inclusions within the multilayered ganglion cell layer of the macula impart a striking pallor to the affected retina. As a result, the central foveola appears bright red because of the underlying choroidal vasculature (Fig. 33-13). As mentioned above, a cherry-red spot also occurs at the macula after central retinal artery occlusion because the pale, edematous retina highlights the subfoveolar vascular choroid.

Angioid Streaks Are Vessel-Like Fractures in the Bruch Membrane

Angioid streaks are seen when the posterior segment of the eye is examined clinically. This occurs when the Bruch membrane fractures, causing characteristic irregular lines that radiate beneath the retina from the optic nerve head **(angioid streaks)**. This happens spontaneously in a variety of systemic disorders, most commonly pseudoxanthoma elasticum, sickle cell disease and Paget disease of bone.

FIGURE 33-14. Retinopathy of prematurity. Horizontal section through an eye with advanced retinopathy of prematurity (retrolental fibroplasia) shows a totally detached retina adherent to a fibrovascular mass behind the lens.

Retinopathy of Prematurity Results from Oxygen Toxicity

Retinopathy of prematurity is a bilateral, iatrogenic, retinal disorder that occurs predominantly in premature infants treated with high levels of inspired oxygen after birth. The entity was originally called **retrolental fibroplasia** because of a mass of scarred tissue behind the lens in advanced cases (Fig. 33-14). More than a half century ago, retinopathy of prematurity was the leading cause of blindness in infants in the United States and many other developed countries. Retinopathy of prematurity is almost always restricted to premature infants administered high concentrations of oxygen. In such infants, the developing retinal blood vessels become obliterated, and the peripheral retina, which is normally avascular until the end of fetal life, does not vascularize. The more mature the retina, the less the vaso-obliterative effect of hyperoxia. When the infant eventually returns to ambient air, intense proliferation of vascular endothelium and glial cells begins at the junction of the avascular and vascularized portions of the retina. This becomes apparent 5–10 weeks after removal of the infant from the incubator and, as in diabetic retinopathy, is thought to result from the liberation of an angiogenic factor produced by the avascular and ischemic peripheral retina. This angiogenic factor is also believed to account for the neovascularization of the iris that sometimes accompanies retinopathy of prematurity. In 25% of cases, the retinopathy progresses to a scarring phase, characterized by retinal detachment, a fibrovascular mass behind the lens (retrolental) and blindness.

THE OPTIC NERVE

Optic Nerve Head Edema Often Reflects Increased Intracranial Pressure

Optic nerve head (optic disc) edema refers to swelling of the optic nerve head where the retinal axons leave the globe.

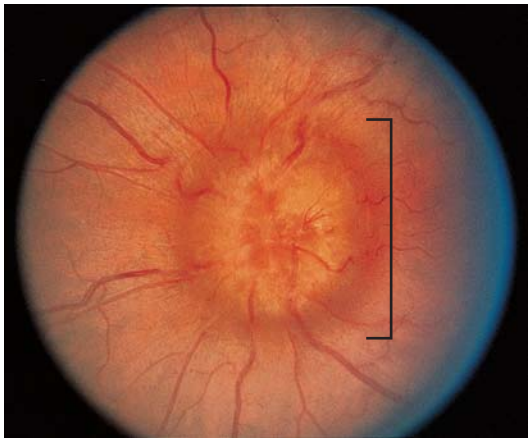

FIGURE 33-15. Chronic papilledema. The optic nerve head (*bracket*) is congested and protrudes anteriorly toward the interior of the eye. It has blurred margins, and the vessels within it are poorly seen. In contrast to acute papilledema, the veins are not so congested, and hemorrhage is not a feature.

It can result from various causes, the most important of which is increased intracranial pressure. The term **papilledema,** which is still widely used in that context, is imprecise because no optic papilla exists. Other important causes of optic nerve head edema are obstruction to the venous drainage of the eye (such as may occur with compressive lesions of the orbit), infarction of the optic nerve (ischemic optic neuropathy), inflammation of the optic nerve close to the eyeball (optic neuritis, papillitis) and multiple sclerosis.

Edema of the optic nerve head is characterized clinically by a swollen optic nerve head that displays blurred margins and dilated vessels (Fig. 33-15). Frequently, hemorrhages (Fig. 33-16), exudates and cotton-wool spots are seen, and concentric folds of the choroid and retina may surround the nerve head. Acutely, optic nerve head edema results in few, if any, visual symptoms. As the condition becomes established, swelling of the optic

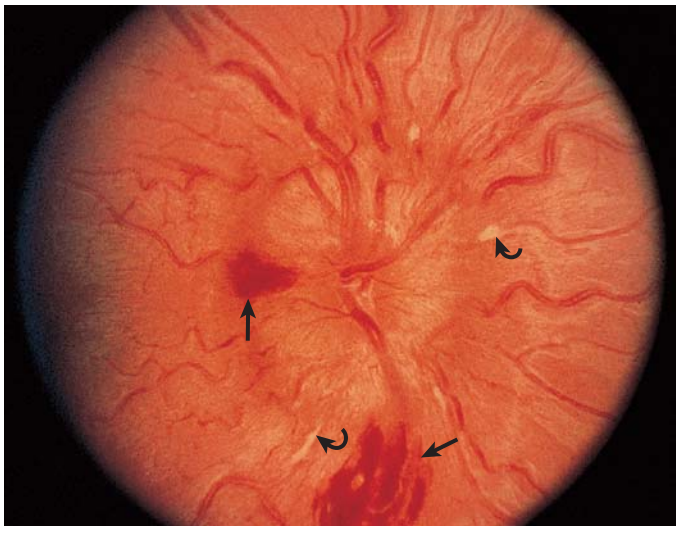

FIGURE 33-16. Hemorrhage in papilledema. The optic nerve head is markedly congested, with dilated veins and a blurred margin. A small hemorrhage is evident within the optic nerve head at its junction with the retina (*straight arrows*). Several small "cotton-wool spots" are present within the adjacent retina (*curved arrows*).

FIGURE 33-17. Optic atrophy. The margin of the optic nerve head is sharply demarcated from the adjacent retina. Because the myelinated axons in the optic nerve are markedly diminished, the optic nerve head appears much whiter than normal.

nerve head enlarges the normal blind spot. After many months, atrophic changes lead to loss of visual acuity.

Optic Atrophy Is a Thinning of the Optic Nerve Caused by Loss of Axons within Its Substance

The nerve axons within the optic nerve are lost in many conditions, including long-standing edema of the optic nerve head, optic neuritis, optic nerve compression, glaucoma and retinal degeneration.

ETIOLOGIC FACTORS: Optic atrophy can also be caused by some drugs, such as ethambutol and isoniazid. The optic nerve head is usually flat and pale in optic atrophy (Fig. 33-17), but when this disorder follows glaucoma, the optic nerve head is excavated **(glaucomatous cupping)**.

MOLECULAR PATHOGENESIS: Optic atrophy can follow mutations in *OPA1*, *OPA3* and *WFS1* genes. Multiple point mutations in the mitochondrial genome are associated with **Leber hereditary optic neuropathy,** and three of them account for more than 90% of cases (*MTND1-3460*, *MTND4-11778* and *MTND6-14484*).

GLAUCOMA

Glaucoma refers to a collection of disorders that feature an optic neuropathy accompanied by a characteristic progressive loss of visual field sensitivity and eventual excavation of the optic nerve head. In most cases, glaucoma is produced by increased intraocular pressure **(ocular hypertension);** however, increased intraocular pressure does not necessarily cause glaucoma, and not all patients with glaucoma have elevated intraocular pressure.

After being produced by the ciliary body, the aqueous humor enters the posterior chamber (the space between the iris and the zonules) before passing through the pupil to the anterior chamber (between the iris and the cornea). From that site, it drains into veins by way of the trabecular meshwork and the canal of Schlemm (Fig. 33-18). A delicate balance

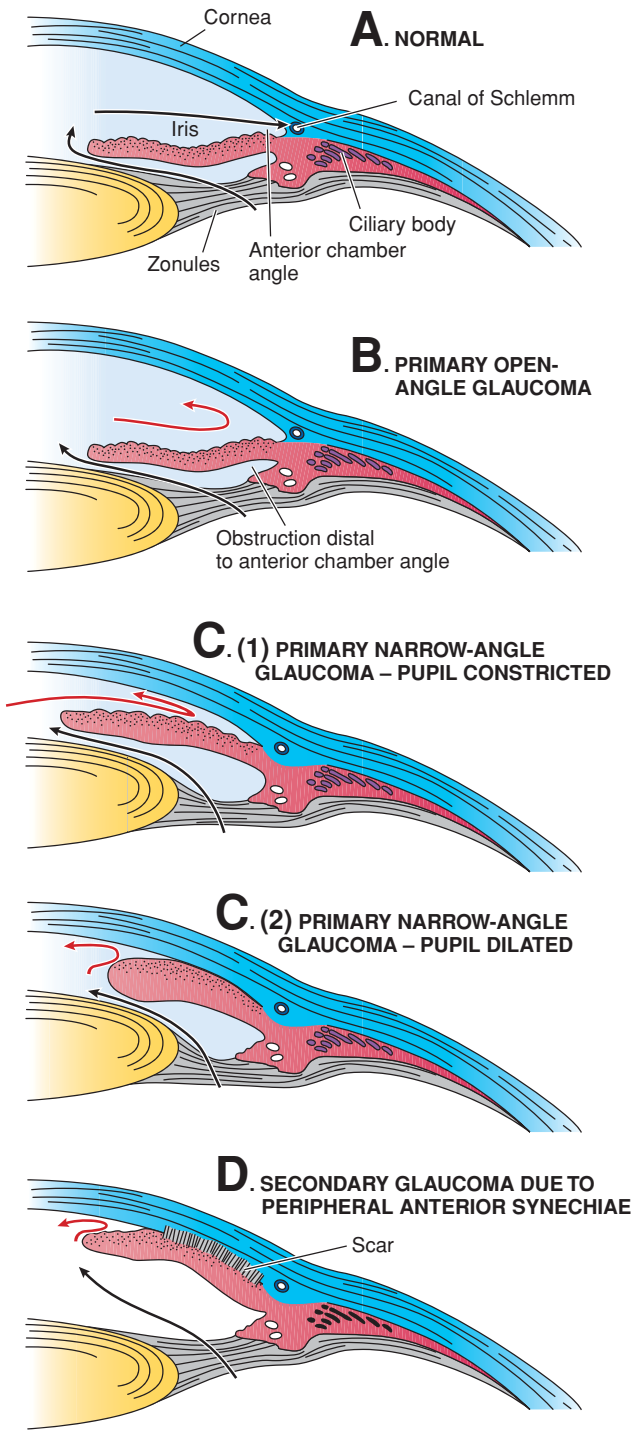

FIGURE 33-18. Pathogenesis of glaucoma. The anterior segment of the eye is affected differently in various forms of glaucoma. **A.** Structure of the normal eye. **B.** In primary open-angle glaucoma, the obstruction to the aqueous outflow is distal to the anterior chamber angle, and the anterior segment resembles that of the normal eye. **C.** In primary narrow-angle glaucoma, the anterior chamber angle is open, but narrower than normal when the pupil is constricted **(C1)**. When the pupil becomes dilated in such an eye, the thickened iris obstructs the anterior chamber angle **(C2)**, causing increased intraocular pressure. **D.** The anterior chamber angle can become obstructed by a variety of pathologic processes, including an adhesion between the iris and the posterior surface of the cornea **(peripheral anterior synechiae)**.

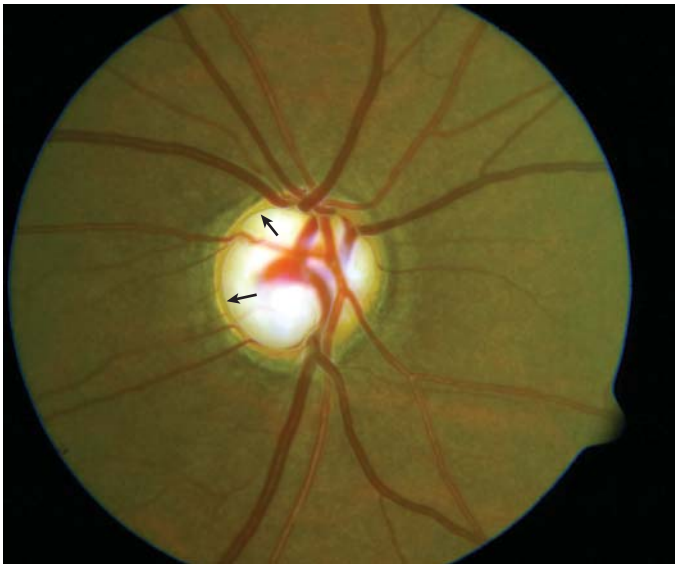

FIGURE 33-19. Optic nerve head in glaucoma. The anterior part of the optic nerve is depressed ("optic cupping"; *arrows*), and the blood vessels crossing the margin of the optic nerve head are displaced to the nasal side. The fundus appears dark because this eye of a black patient contains numerous pigmented melanocytes in the choroid.

between production and drainage of the aqueous humor maintains intraocular pressure within its physiologic range (10–20 mm Hg). In certain pathologic states, the drainage of aqueous humor from the eye becomes impaired, and intraocular pressure increases. Temporary or permanent impairment of vision results from pressure-induced degenerative changes in the retina and optic nerve head (Fig. 33-19) and from edema and opacification of the cornea.

Glaucoma Is Caused by Obstruction to the Drainage of Aqueous Humor

Glaucoma, one of the most common causes of preventable blindness in the United States, almost always follows a congenital or acquired lesion of the anterior segment of the eye that mechanically obstructs the aqueous drainage. The obstruction may be located between the iris and lens, in the angle of the anterior chamber, in the trabecular meshwork, in the canal of Schlemm or in the venous drainage of the eye.

There Are Several Types of Glaucoma

Congenital Glaucoma (Infantile Glaucoma, Buphthalmos)

Congenital glaucoma is caused by obstruction to aqueous drainage by developmental anomalies. This type of glaucoma develops even though intraocular pressure may not increase until early infancy or childhood. Most cases of congenital glaucoma occur in boys (65%), and an X-linked recessive mode of inheritance is common. The developmental anomaly usually involves both eyes and, although often limited to the angle of the anterior chamber, it may be accompanied by a variety of other ocular malformations. Congenital glaucoma is associated with a deep anterior chamber, corneal cloudiness, sensitivity to bright lights **(photophobia),** excessive tearing and buphthalmos. The term **buphthalmos** (from the Greek *bous,* "ox"; *ophthalmos,* "eye") describes the enlarged eyes of patients with congenital glaucoma that result from expansion caused by increased intraocular pressure beneath a pliable sclera.

MOLECULAR PATHOGENESIS: Several genes for primary congenital glaucoma have been identified. Homozygous mutations in the cytochrome P4501B1 gene (*CYP1B1*) account for some cases of autosomal recessive primary infantile glaucoma. Congenital glaucoma associated with developmental anomalies of the eye (secondary congenital glaucoma) results from mutations in the fork-head transcription factor gene (*FOXC1*), pituitary homeobox 2 gene (*PITX2*) or paired box 6 gene (*PAX6*).

Adult-Onset Primary Glaucoma

Adult-onset primary glaucoma develops in a person with no apparent underlying eye disease. It is subdivided into **primary open-angle glaucoma** (in which the anterior chamber angle is open and appears normal) and **primary closed-angle glaucoma** (in which the anterior chamber is shallower than normal, and the angle is abnormally narrow) (Fig. 33-18).

Primary Open-Angle Glaucoma

Primary open-angle glaucoma is the most frequent type of glaucoma and a major cause of blindness in the United States. It affects 1%–3% of the population older than 40 years and occurs principally in the sixth decade. The angle of the anterior chamber is open and appears normal, but there is increased resistance to the outflow of the aqueous humor in the vicinity of the canal of Schlemm. The intraocular pressure increases insidiously and asymptomatically, and although almost always bilateral, one eye may be affected more severely than the other. With time, damage to the retina and optic nerve causes irreversible loss of vision.

ETIOLOGIC FACTORS: Persons with diabetes mellitus and myopia have increased risk of primary open-angle glaucoma.

MOLECULAR PATHOGENESIS: Primary open-angle glaucoma has been mapped to at least 13 loci on chromosomes 1, 2, 3, 5, 6, 7, 8, 9, 10 and 20, and three genes have been identified. Some cases of primary open-angle glaucoma are due to numerous different mutations in the *MYOC* (*TGRR*) gene on chromosome 1 (1q21-q31). Primary open-angle glaucoma can occur as a manifestation of the nail–patella syndrome, in association with mutations in the Lim homeobox transcription factor-1 (*LMX1B*) gene. Juvenile-onset primary open-angle glaucoma may result from mutations in the *CRYP1B1, FKHL7, MYOC* and *OPTN* genes.

Primary Closed-Angle Glaucoma

Primary closed-angle glaucoma, differentiated from open-angle glaucoma above, occurs after age 40 years. ***It is the predominant form of primary glaucoma in adults living in Asia.***

ETIOLOGIC FACTORS: The disorder afflicts persons whose peripheral iris is displaced anteriorly toward the trabecular meshwork, thereby creating an abnormally narrow anterior chamber angle. When the pupil is constricted (miotic), the iris remains stretched so

that the chamber angle is not occluded. However, when the pupil dilates (mydriasis), the iris obstructs the drainage of aqueous humor from the eye, resulting in sudden episodes of intraocular hypertension. This is accompanied by ocular pain, and halos or rings are seen around lights. In such persons, intraocular pressure may also increase if the pupil becomes blocked (e.g., by a swollen lens) and aqueous humor accumulates in the posterior chamber.

MOLECULAR PATHOGENESIS: Primary closed-angle glaucoma has a familial predisposition, but in contrast to primary open-angle glaucoma, genetic loci have not yet been identified.

CLINICAL FEATURES: ***Acute closed-angle glaucoma is an ocular emergency, and it is essential to start ocular hypotensive treatment within the first 24–48 hours if vision is to be maintained.*** Primary closed-angle glaucoma affects both eyes, but it may become apparent in one eye 2–5 years before it is noted in the other. The intraocular pressure is normal between attacks, but after many episodes, adhesions form between the iris and the trabecular meshwork and cornea **(peripheral anterior synechiae)** and accentuate the block to the outflow of aqueous humor.

Low-Tension Glaucoma

In low-tension glaucoma, the characteristic visual field defect and all of the ophthalmoscopic features of chronic open-angle glaucoma occur, but without increased intraocular pressure. The characteristic visual field defect and all of the ophthalmoscopic features of chronic simple (open-angle) glaucoma often occur in elderly people who do not show increased intraocular pressure.

ETIOLOGIC FACTORS: Although some eyes may be hypersensitive to normal intraocular pressure, many cases of low-tension glaucoma probably represent an infarction of the optic nerve head. Susceptibility to normal tension glaucoma is associated with an intronic polymorphism of the *OPA1* gene, as well as with a mutation in the *OPTN* gene.

Secondary Glaucoma

In secondary glaucoma, anterior chamber angles may be open or closed. Because the underlying disorder is usually limited to one eye, secondary glaucoma tends to be unilateral. There are numerous causes of secondary glaucoma including inflammation, hemorrhage, neovascularization of the iris and adhesions.

Effects of Increased Intraocular Pressure

Prolonged ocular hypertension has several effects on the eye:

- In adults, increased intraocular pressure leads to a characteristic cupped excavation of the optic nerve head (glaucomatous cupping), accompanied by a nasal displacement of the retinal blood vessels. In infants, cupping of the optic nerve head tends to be less prominent (Fig. 33-19).
- The cornea or sclera bulges at weak points, such as sites of scars in the outer coat of the eye.
- Optic atrophy, with loss of axons, gliosis and thickening of the pial septa, follows the retinal degeneration and damage to the nerve fibers at the optic nerve head.
- The ganglion cell and nerve fiber layers of the retina degenerate, thereby impairing vision. The outer retina, which derives its nutrition from the underlying choroid, remains intact.
- When intraocular pressure is increased in a child younger than 3 years of age, the pliable eye sometimes enlarges extensively (buphthalmos). After the first few years of life, a rigid sclera prevents glaucomatous eyes from enlarging under the increased pressure.

MYOPIA

Myopia (also called "nearsightedness") is a refractive ocular abnormality in which light from the visualized object focuses at a point in front of the retina because of a longer than usual anteroposterior diameter of the eye. Myopia affects more than 70 million persons in the United States and is the most common clinically significant disorder of the eye. In Asia, it affects an even greater percentage of the population. Treatment requires refractive correction. In addition to glasses and contact lenses, refractive surgery using an excimer laser such as laser-assisted in situ keratomileusis (LASIK) and laser epithelial keratomileusis (LASEK) are popular. Myopia usually begins in young persons and varies in severity. A mild form (stationary or simple myopia) is generally nonprogressive after cessation of body growth, whereas a genetically determined "progressive myopia" is more severe.

ETIOLOGIC FACTORS AND MOLECULAR PATHOGENESIS: There is strong evidence to implicate excessive accommodation from reading and other near work in childhood in the pathogenesis of myopia. In childhood, the vast majority of human eyes with myopia adjust their axial length to the refraction by the anterior segment of the eye **(emmetropization),** and studies in animal models indicate that emmetropization mechanisms elongate the eye. Some nonsyndromic inherited types have been mapped to 14 different loci on various chromosomes. Myopia is also a feature of several systemic diseases, including some disorders of fibrillin (Marfan syndrome), collagen (Stickler syndrome, Knobloch syndrome) and perlecan (Schwartz-Jampel syndrome type I).

PHTHISIS BULBI

Phthisis bulbi refers to a nonspecific, end-stage eye that is disorganized and atrophic. This condition (Fig. 33-20) is most common after trauma to, or inflammation of, the eye. Eyes afflicted with phthisis bulbi are often enucleated. The eye is small and often extremely hard owing to intraocular ossification. The choroid and ciliary body are separated from the sclera, which is thickened, wrinkled and indented owing to loss of intraocular pressure. The cornea is flattened, shrunken and opaque. Intraocular contents are disorganized by diffuse scarring and detachment of the sensory retina is invariably encountered. If present, the lens is displaced and

FIGURE 33-20. Phthisis bulbi. Section through an eye with phthisis bulbi, exemplifying the markedly disorganized nature of the intraocular contents of such atrophic disordered globes.

often calcified. A typical finding in phthisis bulbi is intraocular bone formation, which may be derived from the hyperplastic pigment epithelium.

OCULAR NEOPLASMS

The eye and adjacent structures contain a large number of cell types, and as one might expect, benign and malignant neoplasms arise from them. ***Intraocular neoplasms arise mostly from immature retinal neurons (retinoblastoma) and uveal melanocytes (melanoma).*** Although the retinal pigment epithelium often undergoes reactive proliferation, it seldom becomes neoplastic.

Malignant Melanoma Arises from Melanocytes in the Uvea

Malignant melanoma is the most common primary intraocular malignancy. It may arise from melanocytes in any part of the eye, the choroid being the most common site.

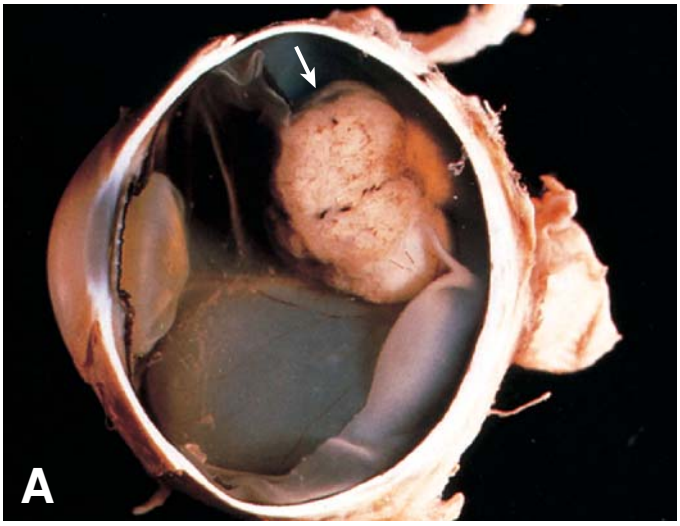
PATHOLOGY: Choroidal melanomas are mostly circumscribed and commonly invade the Bruch membrane, causing a mushroom-shaped mass (Fig. 33-21). By contrast, some tumors are flat (diffuse melanoma) and cause a gradual deterioration of vision over many years. Some do not become apparent until extraocular dissemination has occurred. Orange lipofuscin pigment is sometimes evident over the surface of some choroidal melanomas.

Microscopically, uveal melanomas may be composed mainly of variable numbers of spindle-shaped cells without nucleoli (spindle A cells), spindle-shaped cells with prominent nucleoli (spindle B cells), polygonal cells with distinct cell borders and prominent nucleoli (epithelioid cells) or a fourth cell type that is similar to epithelioid cells but smaller with indistinct cell borders.

Melanomas of the ciliary body and iris may extend circumferentially around the globe (ring melanoma). Melanomas in the iris are usually diagnosed clinically one to two decades earlier than those in the choroid and ciliary body, perhaps because they are more easily seen and are often first observed by the patient.

Lymphatic spread does not occur because the eye has no lymphatic vessels. Aside from hematogenous spread, uveal melanomas disseminate by traversing the sclera to enter the orbital tissues, usually at sites where blood vessels and nerves pass through the sclera. The liver is a common site of metastases, and anecdotally, the diagnosis of metastatic ocular melanoma can be made intuitively by astute clinicians who discover an enlarged liver in a patient with a "glass eye."

CLINICAL FEATURES: Intraocular melanomas may cause cataract, glaucoma, retinal detachment, inflammation and hemorrhage. The options for



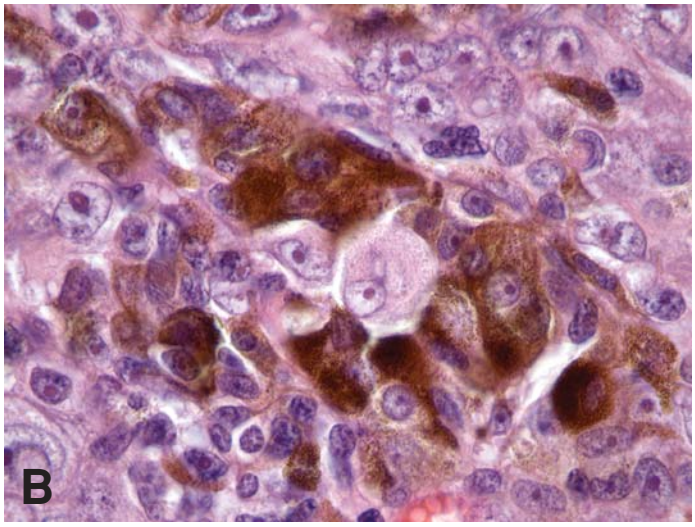


FIGURE 33-21. Malignant melanoma. A. A mushroom-shaped melanoma of the choroid is present in this eye (*arrow*). Choroidal melanomas commonly invade through the Bruch membrane and result in this appearance. **B.** Photomicrograph of a heavily pigmented melanoma of the choroid depicting epithelioid tumor cells with prominent nucleoli.

treating uveal melanomas include enucleation of the eye, radiotherapy and local excision. More than half of patients with uveal melanomas survive for 15 years after enucleation. Prognostic factors include tumor size, tumor location and cell type. Unfavorable indicators are tumor hyperploidy, high mitotic activity, high microvascular density, high tumor-infiltrating lymphocyte counts, chromosome 3 monosomy and high serum melanoma inhibitory activity protein. Deaths have been reported within 5 years from spindle A melanomas, but tumors composed purely of epithelioid cells have the worst prognosis.

Retinoblastomas Originate from Immature Neurons

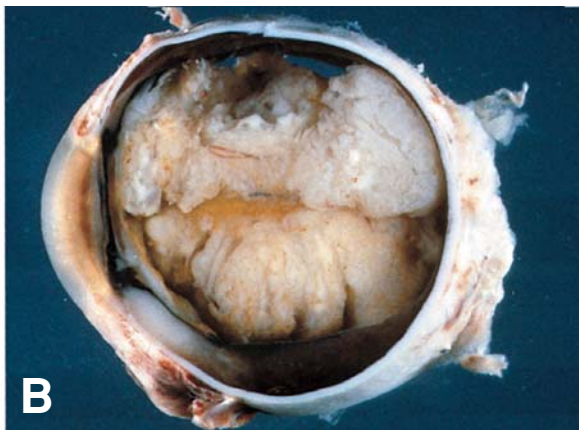
Retinoblastoma is the most common intraocular malignant neoplasm of childhood, affecting 1 in 20,000 to 1 in 34,000 children. It occurs most frequently within the first 2 years of life and may even be found at birth. Most retinoblastomas occur sporadically and are unilateral. Some 6%–8% of retinoblastomas are inherited. Up to 25% of sporadic retinoblastomas and most inherited retinoblastomas are bilateral.

MOLECULAR PATHOGENESIS: Retinoblastomas are related to inherited or acquired deletions of, or mutations in, the retinoblastoma (*Rb*) tumor suppressor gene, located on the long arm of chromosome 13 (13q14) (see Chapter 5). Some patients with retinoblastoma have homologous genomic mutations in the *Rb* gene. Others have a single genomic mutation but the tumors possess an additional one.

PATHOLOGY: Some retinoblastomas grow toward the vitreous body and can be seen with an ophthalmoscope **(endophytic retinoblastoma)**. Others extend between the sensory retina and the retinal pigment epithelium, thereby detaching the retina **(exophytic retinoblastoma)**. A few retinoblastomas are both endophytic and exophytic. Rarely, a retinoblastoma spreads diffusely within the retina without forming an obvious mass **(diffuse retinoblastoma)**. The retina often contains several distinct foci of tumor in the same eye, some of which represent a multifocal origin, whereas others are tumor implants from dissemination through the vitreous body.

Retinoblastoma is a cream-colored tumor that contains scattered, chalky white, calcified flecks within yellow necrotic zones (Fig. 33-22), which may be detected radiologically. The tumors are intensely cellular and display several morphologic patterns. In some instances, densely packed, round neoplastic cells with hyperchromatic nuclei, scant cytoplasm and abundant mitoses are randomly distributed. In other retinoblastomas, the cells are arranged radially around a central cavity **(Flexner-Wintersteiner rosettes),** as they differentiate toward photoreceptors. In some cases, the cellular arrangement resembles a fleur-de-lis **(fleurette)**. Viable tumor cells align themselves around blood vessels, and necrotic areas with calcification are seen a short distance from the vascularized regions.

Retinoblastomas disseminate by several routes. They commonly extend into the optic nerve, from where they spread intracranially. They also invade blood vessels, especially in the highly vascular choroid, before metastasizing



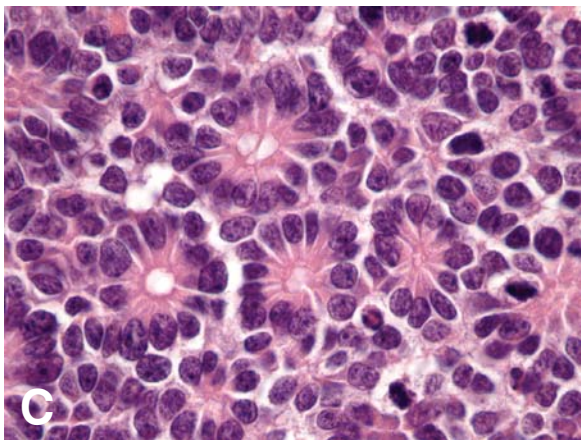


FIGURE 33-22. Retinoblastoma. A. The white pupil (leukocoria) in the left eye is the result of an intraocular retinoblastoma. **B.** This surgically excised eye is almost filled by a cream-colored intraocular retinoblastoma with calcified flecks. **C.** Light microscopic view of a retinoblastoma showing Flexner-Wintersteiner rosettes characterized by cells that are arranged around a central cavity.

hematogenously throughout the body. Bone marrow is a common site of blood-borne metastases, but surprisingly, the lung is rarely involved.

CLINICAL FEATURES: Presenting signs include a white pupil (leukocoria), squint (strabismus), poor vision, spontaneous hyphema or a red, painful eye. Secondary glaucoma is a frequent complication. Light entering the eye commonly reflects a yellowish color similar to that from the tapetum of a cat (cat's eye reflex).

Retinoblastomas are almost always fatal if left untreated. However, with early diagnosis and modern therapy, survival is high (about 90%). Rarely, spontaneous regression occurs for reasons that remain unknown. Patients with inherited retinoblastomas, presumably as a consequence of the loss of *Rb* gene function, show increased susceptibility to other malignant tumors, including osteogenic sarcoma, Ewing sarcoma and pinealoblastoma.

Metastatic Tumors to the Eye Are More Common Than Primary Ocular Neoplasms

Sometimes an ocular metastasis may be the initial clinical manifestation of a cancer, but most cases are diagnosed only after death. Leukemias and cancers of the breast and lung usually metastasize to the posterior choroid and account for most cases of intraocular metastases. Neuroblastoma frequently metastasizes to the orbit in infancy and childhood. The orbit may be invaded by malignant neoplasms of the eyelid, conjunctiva, paranasal sinuses, nose, nasopharynx and intracranial cavity.

Forensic pathology is the specialty in which pathological examinations and related investigations are conducted for the purposes of classifying the cause and manner of death. A related goal is the establishment of the time since death, which may range from minutes to days to years.

There are many observations of the deceased body that are made at the gross level and that cannot be documented by microscopic examination. Examples are the nature of traumatic injuries and the presence, location, size and extent of a pulmonary embolism. Whereas gross pathology is always part of the autopsy examination, the forensic pathologist may or may not pursue further microscopic examination, depending upon the nature of the case and the evidence. This chapter presents a summary of frequent problems in the practice of forensic pathology.

THE MANNER OF DEATH

The causes of death are multiple, but the manner is classified into only five categories: (1) accident, (2) homicide, (3) suicide, (4) natural and (5) undetermined/unclassified.

Most of the cases that fall under medical examiner jurisdiction actually support areas beyond or outside public safety. Only about 20% of cases are **homicides**. A rule of thumb is that the rate of **suicide** is double the rate of homicide (except in excessively violent, crime-ridden jurisdictions). In most locations, about 1/2 of **accidents** relate to motor vehicle accidents and traffic fatalities, whereas the other 1/2 are industrial accidents and those in the home or in recreational settings. In terms of **natural** causes of death occurring outside the presence of a treating physician, these investigations are often important in identifying acute or chronic threats to public health, such as infectious disease outbreaks, contaminated water supplies, accidental poisonings or other toxic exposures.

Cause of Death versus Mechanism of Death

Both resident and practicing physicians frequently complete a death certification incorrectly stating "cardiopulmonary" arrest as the cause of death. However, cardiopulmonary arrest is not a cause of death but a final common pathway whereby the underlying disease process finally leads to cessation of vital signs. The mechanism of cardiopulmonary arrest may be precipitated by (1) an event that causes respiratory arrest, evolving rapidly to cardiac arrest; (2) a fatal occurrence causing cardiac arrest, leading rapidly to respiratory arrest; or (3) a fatal central nervous system (CNS) injury that rapidly causes cessation of vital functions in both the heart and lungs. Through the intervention of respiratory ventilation therapy and cardiac electroversion, an otherwise fatal CNS event leading to "brain death" may not immediately cause physiologic death.

Causes of true sudden death, whereby an otherwise healthy ambulatory person suddenly "drops dead in his tracks," are relatively few. In the forensic context, a sudden gunshot wound (GSW) to the base of the brain will produce immediate cessation of vital functions; a similar wound to the heart can immobilize the organ. Medically, a pulmonary embolism may cause sudden death (see Chapter 7). A massive myocardial infarction brought about suddenly by coronary occlusion (see Chapter 7) may inactivate the conduction system and evoke an arrhythmia.

EVIDENCE ANALYZED BY THE FORENSIC PATHOLOGIST

Traumatic Injuries

Traumatic injuries result from incidents such as violent assaults upon one person by another, by encounters with

FIGURE 34-1. Entrance wounds **(A)** and exit wounds **(B)** on the right and left sides of the face, respectively, of this 39-year-old man with multiple gunshot wounds. The smaller entrances show a round to oval skin defect surrounded by abrasion rings. The exits are irregular lacerations, generally larger than the entrances, and lack a surrounding abrasion.

machinery at high velocity or by random physical forces and gravity. Fatal assaults are usually carried out with weapons such as (1) firearms, knives and other bladed weapons; (2) blunt objects of various kinds; and (3) occasionally only fists and other hard bodily surfaces such as feet, knees, elbows or even the forehead. Hard contact against a hard surface such as concrete is occasionally fatal.

Gunshot Wounds

GSWs actually represent only a small proportion of the work of a forensic pathologist. In densely populated areas, most fatal assaults with firearms involves handguns or small arms. Such weapons are really only useful at shorter ranges, and much of the forensic work involves identifying the distance between the muzzle of the firearm and the entrance wound.

There are basically two types of GSW, namely (1) penetrating wounds in which the projectile enters the body but does not exit and (2) perforating wounds in which the projectile passes through the body, creating both entrance and exit wounds (Fig. 34-1). Cases have been described in which a man supposedly died of natural causes and had been buried without an autopsy. An x-ray of the exhumed body later pointed out the presence of a projectile in the chest caviy.

Rifling

The barrels of modern firearms are rifled, and the markings or striations on the sides of the round projectile shaft can be compared to the weapon used in the assault. Test shots are fired into a tank of water and compared to the striations on a projectile recovered from the body. These markings can then be matched precisely.

Gunpowder residue may be recovered from the assailant if the hands are swabbed in a timely fashion. In the case of a suspected suicide by small firearm, one expects to find gunpowder remains on the dominant hand of the deceased.

Caliber

Small caliber wounds (e.g., a .22 caliber) can be fatal, especially in the case of head wounds. A small caliber projectile frequently penetrates the skull, but without the force to perforate the back of the skull, it may ricochet or "rattle around" within the skull, causing extensive brain damage. Likewise, the ability of a projectile to traverse and exit a body partially depends on whether or not it encounters bone, especially dense cortical bone, as in the mandible.

Notwithstanding the above considerations, the amount of damage caused by a projectile is directly related to its caliber (mass) and its velocity, thus momentum. The larger and heavier the projectile, the larger its momentum. Traveling at high velocity, a bullet transfers the force to the tissues of the body, causing tissue disruption. In the head, in addition to the focal injury in the path of the projectile, there is diffuse injury throughout the brain due to compression, stretching and tearing at the microscopic level, owing to the "shock wave" within an enclosed space. With penetrating wounds, exit wounds are larger and more irregular than the smaller and rounder entrance wounds.

Range

At extremely close range (contact wound), with the muzzle pressed against the skin, there may be stellate lesions, with star-shaped defects extending from the borders of the wound owing to expansion of hot gases from the barrel trapped in the enclosed space. There may also be a muzzle burn mark around the perimeter of the wound from heat of the metal (Fig. 34-2).

At close range, where the muzzle is separated from the surface of the skin, there tends to be stippling in a perimeter around the wound (Fig. 34-3). In this situation, the heated detritus that exits from the barrel along with the projectile reaches the surface of the skin. These particles expand out of the barrel of the firearm following the inverse square law for expanding particles from a point source; the perimeter of the stippling increases as the square of the distance from the

FIGURE 34-2. A muzzle imprint surrounds the entrance wound under the chin in a self-inflicted gunshot wound to the head.

gun barrel increases. Ultimately, there comes a point where the particles do not reach the surface of the skin at all in a long- or mid-range wound.

The wounds caused by a shotgun (especially with a "sawed-off" or intentionally shortened barrel) also follow a pattern dictated by the inverse square law. The shotgun pellets describe a larger perimeter of entrance wounds as the distance from the barrel increases, owing to the dispersal of the pellets from the barrel of the shotgun.

Gunshot Wounds to the Head

GSWs to the head present a special case because projectiles enter a closed space. Energy, heat and gases expand rapidly within the skull, causing extensive damage beyond the actual pathway of the projectile. The expansion causes ejection of blood and tissue through both entrance and exit wounds. Another force that also occurs with blunt trauma to the skull, or when there is no exit wound, is the "contra-coup" injury on the contralateral side of the "coup" (strike or hit). This results in damage to the brain against the skull

FIGURE 34-3. A close-range gunshot wound of entrance with surrounding stippling.

FIGURE 34-4. A single, deep-cutting wound using a samurai sword is on the right side of the face of this 34-year-old woman.

opposite to the site of the blow or entry. Within the closed space of the skull, bleeding may be intracranial, epidural or subdural. The spinal cord is also within the enclosed space of the CNS and is enclosed by the bony vertebrae of the spine.

Sharp Force and Incised Wounds

Incised wounds are caused by bladed objects such as knives (Fig. 34-4). Features of entry wounds made by a knife are distinguished by whether there is a single- or double-edged blade. The former is distinguished by a sharp incision at one border of the wound and a blunt border at the opposite edge. If the knife enters the body up to the hilt, a mark may be left behind on the skin where the hilt impacted the skin. When a blade is inserted at an oblique angle, it causes a wound whose dimensions are wider than the maximum width of the blade.

A sharp force wound also includes incised wounds that result from sharp, round, pointed objects, such as an ice pick, knitting needle, sharp stick or bone, or even an icicle (which has the feature of making the evidence rapidly disappear). Although small in diameter, such wounds can be deadly.

Blunt Force Trauma

Blunt force trauma can be inflicted by any object with enough hardness, mass and momentum to damage tissues. Such assaults cause blunt force injuries, which may or may not break the surface of the skin, and which may cause external or internal bleeding. Because of the strength and resilience of the skin, sufficient force may be transmitted to the underlying tissues and organs to cause extensive injury, even when the skin remains unbroken.

When the skin surface is broken by blunt trauma, it may manifest as a puncture, abrasion, laceration, maceration or avulsion. If the surface of the skin is not broken, internal bleeding may still be extensive. Exsanguination can be caused either by bleeding out from the body or into internal body cavities.

Pattern Injury

Sometimes distinctive patterns on the skin can be matched to the surface of a blunt object ("pattern injuries"). Such

FIGURE 34-5. Four patterned punctures are present in this 35-year-old man stabbed with a Phillips-head screwdriver.

patterns include the shape of a waffle iron, the tread of a shoe and even uniquely distinguishing marks that match the weapon ("tool mark") to the type of hardware used (Fig. 34-5). Although the surface of a blunt object is firm and hard, the skin is elastic and may well be stretched out of shape owing to the application of force that leaves a "distorted" pattern, which may nonetheless still be matched properly. The scalp holds a pattern injury relatively well, as its skin covers a firm surface of bone.

Abrasions, Avulsions, Contusions, Incisions, Lacerations, Punctures

Other blunt force injuries may result from the encounter of the body with hard surfaces of machinery, with surfaces of a motor vehicle (Fig. 34-6) or with the ground.

When they break the surface of the skin, such wounds may include punctures, avulsions, abrasions and incisions.

Contusions

Whether or not the skin is broken from blunt force contact, a contusion (bruise) may develop in the underlying tissues. Contusions result from bleeding into the surrounding tissues by ruptured blood vessels. As the bleeding occurs into any enclosed space (e.g., a muscle or joint compartment, or connective tissues), swelling occurs, pressure increases and the back pressure helps to staunch further blood flow while clotting takes place. Since hemoglobin in red blood cells breaks down over time, contusions manifest various pigment colorations of black-blue, purple, green and yellow (Fig. 34-7). These variations assist in the timing of the bruise in a victim who survives injury.

Exsanguination

Where the surface of the skin and the underlying blood vessels are broken, the body may exsanguinate quickly because the heart continues to pump large quantities of blood through the wounds. Deeper injuries involving the arteries at high blood pressure are also capable of causing exsanguination. More superficial injuries involving only veins at lower blood

FIGURE 34-6. This individual was extricated from the truck that he was driving after hitting a tree. He was found lying on the floor of the truck with his feet facing the driver seat and his head against one of the pedals. The right side of the face is diffusely congested with a contusion over the cheek and a pattern abrasion (truck pedal imprint) on the lower side of the face.

pressure are not likely to cause exsanguination unless the injury covers extensive surfaces or blood loss is prolonged.

Internal Bleeding

If the skin surface is not broken, internal bleeding may still occur. Even at a relatively "bloodless" scene of the death,

FIGURE 34-7. A sutured laceration present on the orbital ridge is surrounded by a healing contusion (with red, blue, yellow and green hues) in a patient with multiple sclerosis who suffered a fall 10 days before being pronounced dead.

body cavities may contain copious quantities of blood, resulting in exsanguination.

Death Occurring before a "Fatal" Accident

When a victim succumbs to sudden death prior to the time of blunt force injuries, bleeding will be minimal because the heart has stopped pumping prior to the occurrence of the wounds. For example, when a vehicle driver succumbs to sudden death from a heart attack or pulmonary embolism behind the wheel and then experiences a motor vehicle crash, multiple blunt injuries affect what is essentially a dead body. This may result in a bloodless scene despite extensive injuries.

Determination of Timing and Order of Receiving Wounds

A major issue is determining whether wounds contributed to death (homicide) or whether they were inflicted on the body after death (mayhem). Postmortem wounds are associated with minimal bleeding, as the heart has stopped pumping blood. In a deceased body, blood does not clot normally and the "dead" blood remains liquid. The appearance of postmortem injury itself is also relatively dry, tough and leathery compared to wounds inflicted on a still living body. Being able to determine the order and fatality of wounds is important when there are multiple assailants and when it can be determined that the first assailant committed homicide to a living victim whereas a subsequent one only committed mayhem on a deceased body.

Asphyxiation

Death by asphyxiation is a relatively slow process. During asphyxiation, the brain maintains consciousness for 2–3 minutes, at which point the victim may be expected to cease struggling. After an additional 2–3 minutes of asphyxiation, the brain dies from anoxia.

Strangulation: Ligature and Manual

The neck is a narrow structure that carries about 1/3 of the total blood volume at any given time to meet the high metabolic demands of the brain. Thus, it represents a convenient and efficient location for inducing asphyxiation by strangulation, either forcefully using the hands (manual) or by a ligature around the neck. In a homicidal assault by strangulation, there may be ligature marks around the neck; the hyoid bone, thyroid cartilage, cricoid cartilage and tracheal rings may (or may not) be broken. Petechial hemorrhages may occur in the eyes and elsewhere.

In addition to closing off the airway and causing asphyxiation, strangulation may compress the carotid arteries, directly cutting off blood flow to the brain. Extensive stress and stimulation to the carotid artery may also result in a reflex that induces cardiac arrhythmia.

To strangulate the neck structures, about 7 lb (3.2 kg) of pressure is required. Against a normal blood pressure of 120/80 mm Hg, the carotid artery is compressed by about 11–13 lb (5.0–5.9 kg) of pressure. The larynx is crushed by about 30 lb (13.6 kg) of pressure. These forces can be delivered by the hands (to a lean person) or by the elbow, knee or foot.

If a single blunt injury is applied by striking the neck with sufficient power to crush and collapse the larynx, suffocation and asphyxia will inexorably progress, whether or not any continued force is applied, because the airway has been cut off.

Asphyxiation by strangulation of the neck also occurs in judicial, suicidal and accidental hangings in autoerotic asphyxia. In a judicial hanging, the neck may be broken, causing instantaneous death due to injury to the cervical spine and CNS. If the hanging is not carried out "humanely," the neck may remain intact, and death eventually ensues from asphyxiation.

Petechial Hemorrhages

With asphyxiation (strangulation, drowning, fire/smoke inhalation), although the lungs continue to "breathe" or move, no oxygen enters the lungs. Thus, the heart continues to beat for several minutes and circulates unoxygenated blood. Sensitive cells in the peripheral blood vessels begin to die due to lack of oxygen, but the pumping heart pressures blood to rupture from the damaged capillaries for a short time, until the heart itself stops beating. The bleeding from the damaged blood vessels causes petechial hemorrhages. In the case of manual strangulation or suffocation, back pressure from cutting off circulation in the neck also contributes to petechiae. Such hemorrhages are typically observed in the conjunctivae of the eyes and in the pericardium.

Drownings: Asphyxiation and Hypothermia

Despite widespread aquatic safety measures in the United States, hundreds of drownings still occur each year in swimming pools and bathtubs. The fishing industry has the highest occupational death rates overall, often from drowning or hypothermia. In water, the body rapidly loses heat, causing death from hypothermia in minutes in freezing water and in up to a few hours in water at 40°–50°F (4°–10°C). Death may also result in water as warm as 70°–80°F (21°–27°C) when exposure is sufficiently prolonged.

A normal human body immersed in cold water will go through the following stages of reaction:

- **0–2 minutes:**
  Cold shock: Initial reaction, most likely to recover rapidly
- **5–15 minutes:**
  Motor incapacitation: Normal muscle movements maintained
- **Greater than 30 minutes:**
  Onset of hypothermia: Perceptions and sensations remain
- **Greater than 1 hour; up to 2 hours or more:** Loss of consciousness

Rates and Effects of Immersion Hypothermia

The ability to maintain consciousness, to survive and to maintain body functions in hypothermia is related to the time of immersion and the temperature of the water.

In cases of fatal drowning, water is usually present in the lungs. However, there are a minority of cases in which "dry drowning" occurs, owing to laryngeal spasm that closes off the lower respiratory system, causing asphyxiation with dry

TABLE 34-1
EFFECTS OF CARBON MONOXIDE POISONING

Carbon monoxide (CO) binds preferentially to hemoglobin, displacing oxygen and causing chemical asphyxia.

Blood Level of CO (hemoglobin concentrations)	Exposure	Effects
<10%	Tobacco smoking	None
10%–30%	Smoke/exhaust	Headache, dyspnea
30%–50%		Confusion, lethargy
50%–60%		Convulsions, coma
>60%		Death

lungs. Water enters the sinuses, and the presence of water in the sphenoid sinus is a typical sign of drowning.

Fires

Asphyxiation is a frequent cause of death in fire victims due to inhalation of carbon monoxide (Table 34-1) and other noxious combustion gases. Death from smoke inhalation usually occurs before thermal injuries occur or become fatal. The presence of soot in the airway of an outwardly burned body is a sign that the victim was alive and breathing at the time of the fire. The level of carbon monoxide in the blood is also a measure of smoke inhalation (Table 34-1).

When bodies are extensively damaged by fire, the tissues contract and the body assumes a "pugilistic" or defensive posture, drawing inward. This is not a conscious defensive pose but a postmortem artifact. Fire also sterilizes the body, resulting in reduced or absent postmortem decomposition and preservation of the remaining, albeit burned, tissues of the body.

ACCIDENT VERSUS HOMICIDE VERSUS SUICIDE

The rate of suicide is generally double the rate of homicides. Suicides occur by self-inflicted GSWs, asphyxiation by hanging (or rarely by drowning), intentional drug overdoses and a variety of other more rare means.

Cutting

Fatal exsanguination by cutting across the wrists is unusual despite many attempts, more commonly in females than in males. If cuts are made across the wrists, multiple strong tendons prevent the incision from reaching the larger blood vessels, and peripheral vasospasm and clotting minimize the blood loss. To be effective, as with the ancient Romans, consuming alcohol to dilate the peripheral blood vessels, cutting longitudinally and deeply between the tendons and being immersed in a warm bath to slow blood clotting are more successful in this regard. Incisions across the neck or throat are also effective for many of the same the reasons described in the earlier discussion of strangulation (Fig. 34-8). Fatal neck incisions are often part of homicidal assaults; however, in a determined victim, they may also be suicidal.

Motor Vehicles

Vehicular suicide can occur when a driver intentionally precipitates a motor vehicle accident, such as by driving into a tree or telephone pole. Vehicular homicide can also occur when a victim is purposely assaulted, using a motor vehicle with intent to kill. Deaths in vehicles may also be natural deaths rather than accidents. As an example, a driver may suffer a fatal heart attack behind the wheel, which then precipitates a motor vehicle accident.

Gunshot Wounds

Among white males, a self-inflicted GSW to the head is the preferred method of suicide. Suicidal GSWs to other parts of the body are rare, although suicide by GSW in women is rare in general. Females generally prefer suicide by intentional drug overdose. Black and Hispanic males are less likely than white males to commit suicide.

Drug Overdose

With intentional overdose, the presence or absence of pill bottle(s) at the scene of death is not determinative. Victims often transfer the medication to another vessel before taking the fatal overdose. The presence or absence of pills in the stomach is also not necessarily determinative, depending upon the dosage, form and metabolism of the fatal drug(s).

Hanging

With respect to manual asphyxia, suicidal hanging can happen from rafters, fixtures, doorways or even the horizontal poles for hanging clothes in closets. It is not necessary for the feet to be unable to touch the ground for hangings to occur. A once-confusing circumstance of sexual asphyxia has now been understood. Males (and infrequently females) can

FIGURE 34-8. Multiple linear, parallel, superficial cutting wounds (hesitation wounds) in the right side of the face and neck of this 20-year-old man who died of self-inflicted sharp force injuries. Additional stab and cutting wounds were present in the chest, abdomen and wrists.

TABLE 34-2
ACUTE FATAL CHEMICAL POISONINGS

Chemical	Exposures	Toxicity
Benzene	Occupational-industrial, chemical manufacturing, solvent use, gasoline (3%)	Acute CNS and respiratory failure
Chloroform and carbon tetrachloride	Cleaning solvents	Depressant effects on CNS and heart Hepatic necrosis, fatty liver, liver failure
Cyanide/prussic acid (HCN)	Trace amounts in nuts and fruit seeds as natural pesticides (e.g., bitter almond [*Prunus amygdalus*])	Acute global anoxia; binds to mitochondrial cytochrome oxidase, arrests cellular respiration
Ethylene glycol	Antifreeze (ethanol substitute)	CNS depression and metabolic acidosis Oxalate urinary crystals and renal failure
Gasoline and kerosene	Accidental ingestion Inhalation of combustion products	Gastrointestinal Asphyxiation, carbon monoxide poisoning (see Table 34-1)
Methanol	Ethanol substitute	Metabolism to formaldehyde, then formic acid; blindness, seizures, coma
Trichlorethylene	Industrial solvent	CNS depression; minimal liver toxicity

devise various means for temporarily restricting blood supply to the brain to heighten autoerotic experience—the ensuing anoxia apparently leads to increased sexual sensation. On occasion, if the apparatus used involves being suspended in a kind of hanging, the victim may lose consciousness while masturbating and then imperceptibly proceed to suffer further strangulation and fatal asphyxia.

Poisonings

There are many natural and manufactured substances that may cause poisoning, fatal or nonfatal (Table 34-2). Poisonings can be caused by chemicals, drugs, plants or other biotoxins. In forensic medicine, it is important to determine whether fatal overdoses of drugs are accidental, homicidal or suicidal.

Both illicit and prescription drugs can be abused through intravenous injection. Heroin (synthetic acetyl morphine) is an opioid that does not occur in nature and is the prototype for intravenous drug abuse. Cocaine and amphetamines are also injected. These substances cause constriction of blood vessels, especially in the cerebral circulation, leading to anoxic brain injury. Fatal brain abscess may result from the introduction of infectious contaminants.

Talc is a noninfectious contaminant frequently introduced through illicit intravenous drugs. It is a nonactive filler used to "cut" (effectively diluting) the drug itself. Talc granulomas in the lungs present a characteristic appearance (see Chapter 8).

Plant poisonings are common as irritants to the skin or respiratory system. Rarely, ingestion of poisonous plants may be fatal in sufficient dose, especially with babies or children who may be unaware of the danger and for whom a smaller dose may be fatal. Biotoxins created by bacteria and fungi are responsible for gastrointestinal poisonings, causing fatal dehydration in circumstances where advanced medical care is not available (e.g., cholera). Other toxins cause hepatocellular necrosis acutely, and liver cancer chronically, as with aflatoxins from Asia and Africa (see Chapter 14). So-called mycotoxins are in fashion as pseudoscience for causing any number of illnesses, from sick building syndrome to fatal fungal infections of the CNS. The science behind such claims is often not accepted by the courts as credible.

Chemical poisonings are the most common form of acute fatal poisonings and are summarized in Table 34-2.

Electrical Injury and Lightning Strikes

Exposure to household voltage, or high voltage, often in an occupational setting or during storms that cause downed electrical lines, may be fatal but leave barely perceptible evidence. Electrical currents can create cardiac arrhythmias and sudden death. Where the current exits the body, there may be a trace of thermal injury on the surface of the skin, which has a dry, leathery appearance (as observed in postmortem wounds, see below). Any overlying clothing may also show subtle tears and burns.

Usually, a fatal electrical shock is instantaneous, as the victim will let go or fall away from the source. When voltages are very high and contact is prolonged, there tends to be more extensive injury owing to the heat generated by resistance to the current in the body. Lightning strikes are a dramatic type of fatal electrical shock.

TIMING OF DEATH

Since the forensic pathologist invariably arrives after the time of death, he attempts to establish the interval between death and examination of the body. Over a period of hours, the medical examiner relies on *algor mortis* (body temperature), *livor mortis* (postmortem lividity) and *rigor mortis* (postmortem rigidity), all of which are influenced by environmental temperature and other factors.

Body Temperature

After death, normal body temperature falls at a predictable rate, if one takes into account the size of the body and the external temperature. The ability to retain heat by the body generally varies directly with increasing size, as the surface area of the body, through which heat is lost, is proportional to the square of the height. The mass or weight of the body, in which heat is retained, varies as the cube of the height. Factors that increase body temperature at the time of death require recalibration in estimating the time since death, for example, in people dying with a fever or from acute cocaine intoxication.

Lividity

Postmortem lividity results from passive pooling of blood into dependent areas owing to the effects of gravity. It presents as a distinctive red-purplish discoloration, unlike anything seen in life. The pattern of lividity indicates the position of the dead body and, depending on the presence of shifting patterns, whether a body was moved at certain intervals after death. Up to a period of 1–2 hours, lividity can be displaced with manual pressure (unfixed lividity), and the skin will blanche to a pale white color. After 3–4 hours, lividity becomes fixed and cannot be displaced by manual pressure.

Rigor

Postmortem rigidity (rigor mortis) is the result of a chemical reaction whereby muscle tissues irreversibly go through a process of contraction, causing the body and appendages to become stiff. Over the initial few hours, rigidity develops. Over several more hours, rigidity begins to pass away again and the body becomes lax. Once rigor passes, it does not return. Since it is a chemical process, it is accelerated by higher temperatures and retarded by lower ones. Rigor mortis starts from the top down—that is, it extends from the head and neck down to the arms and then the legs.

Decomposition

Postmortem decomposition is essentially a competition between decay from the outside-in and putrefaction from the inside-out. The process involves activity of aerobic decay organisms, such as bacteria and fungi, as well as insects. Putrefaction results from the activity of internal bacteria in the gastrointestinal tract that grow anaerobically after death. If the external environment is very hot, perceptible decay may ensue from the outside. But generally, in light of retained body temperature at the time of death, putrefaction predominates, causing decomposition from the inside to predominate.

Decomposition itself also presents a competition over time between desiccation and decay/putrefaction. In a very hot, arid environment, such as the sands of Egypt, a body may actually dry out before internal bacteria can bring about decomposition. Once a body is desiccated, it does not provide a fertile medium for bacterial growth, and the body becomes preserved, potentially for long periods of time. The ancient "secret" of Egyptian mummification lay in the removal of internal organs that harbored bacteria, together with exposing the body to desiccation.

As decomposition ensues, postmortem blood presents a fertile medium for bacterial growth. Wherever tissues are injured, bacterial decomposition is accelerated by the presence of blood in the wounds. Initially, below the skin, discoloration occurs along the distributions of blood vessels, as bacteria metabolize respiratory pigments to variously colored chemicals, appearing blue-green, yellow and purple-black. Another product of postmortem bacterial metabolism is the generation of decomposition gases, which accumulate under the skin. These expand areas of subdermal connective tissues, especially in the areolar looser tissues around the eyes, face and torso. These gases may also expel decomposition fluids (which may appear "bloody") from body orifices.

Disarticulation

As soft tissues decompose, after a period of weeks or months (depending upon seasonality, environmental temperatures and exposures) the skeleton becomes exposed to decay. Although the skeletal elements are usually preserved (and eventually over time the mineralized matrix becomes fossilized), there is a pattern by which skeletal elements become disarticulated from one another after soft tissues have disintegrated.

The first bone to disarticulate from the skeleton is the mandible. In addition to being highly recognizable as a human bone, it often carries specific information as to the identity of the deceased through dental work. Although the dense cortical bone and the teeth are very durable, they may not be found with the skeleton. The next articulation to be lost from the skeleton is the skull from the spinal column (which is otherwise held in place by the ribs). Separation of the skull from the skeleton can also prevent problems for the identification of the skeletal remains. Then, various bones of the arms and legs, hands and feet become disarticulated in a predictable sequence.

  confluent hepatic necrosis and, 851–852, 851f
  hepatitis A virus, 844, 844f
  hepatitis B virus, 845–848, 845f
  hepatitis C virus, 848–850
  hepatitis D virus, 848
  hepatitis E virus, 850
  hepatitis F virus, 851
  hepatitis G virus, 851
  infectious agents of, 844t
  major features of, 850t
  mild chronic, 852f
  pathology of, 851–852
  severe chronic, 853f
Viral infections, 371, 1254
  DNA viruses and
    adenovirus, 377, 377f
    cytomegalovirus (CMV), 382–384, 384f
    Epstein-Barr virus, 382, 383f
    herpesviruses, 379–382
    human papillomavirus (HPVs), 384
    human parvovirus (erythrovirus) B19, 377–378
    monkeypox, 378–379
    smallpox (variola), 378
  latent, 371
  RNA viruses and, 371
    intestinal virus infections, 375
    mumps, 374–375
    respiratory viruses, 371–373
    viral exanthems, 373–374
    viral hemorrhagic fevers, 375–377, 376t
Viral myocarditis, 660–661, 661f
Viral orchitis, 982f
Viral otitis media, 1301
Viral pneumonia, 696
Viral rhinitis, 1285
Viral set point, 164f
Virchow-Robin spaces, 455, 1437
Virchow, Rudolf, 3
Viremia, 470t
Virulence, 369–370
Viruses, and human cancer, 232–234
Visceral–abdominal obesity, 518
Visceral larva migrans (toxocariasis), 462–463
Visceral leishmaniasis, 452, 453f, 871
Visceral organs, congenital syphilis on, effect of, 250
Vitamin A, 359–360
  deficiency of, 359, 359f
  functions of, 359
  for night vision, 359
  toxicity, 359–360
Vitamin B_{12} (cyanocobalamin), 1089
  absorption of, 1090f
  relationship of folic acid to, 1089f
Vitamin B complex, 360–363, 360t
  biotin (B_7), 363
  cyanocobalamin (B_{12}), 363
  folic acid (B_9), 363
  niacin (B_3), 361–362, 362f
  pantothenic acid (B_5), 362
  pyridoxine (B_6), 362–363
  riboflavin (B_2), 361, 361f
  thiamine (B_1), 360–361, 360f
Vitamin B_{12} deficiency, 1459
  hypersegmented granulocytes in, 1091f

Vitamin C, 9, 95, 364–365, 364f
  deficiency of, 364–365, 364f. *See also* Scurvy
Vitamin D, 365
  deficiency of, 365
  excess, 365
  intestinal malabsorption, 1333
Vitamin D–dependent rickets, 1334
Vitamin D dietary deficiency, and rickets, 1333
Vitamin deficiencies
  intoxication, 1459–1461
  subacute combined degeneration
    vitamin B_{12} deficiency, 1459
  Wernicke syndrome
    vitamin B_1 deficiency, 1459
Vitamin D metabolism
  acquired alterations in, 1334
  and bone mineralization, 1333
  disorders of, 1333–1334
  renal disorders of phosphate metabolism, 1334–1335
Vitamin D receptor (VDR), 1330
Vitamin D–resistant rickets. *See* X-linked hypophosphatemia
Vitamin E, 9, 365
Vitamin K, 365–366
Vitamin K epoxide reductase complex 1 (VKORC1), 303
Vitronectin, 99
VLBW. *See* Very low birth weight (VLBW)
